# about the author

## John W. Santrock

John Santrock received his Ph.D. from the University of Minnesota. He taught at the University of Charleston and the University of Georgia before joining the Program in Psychology at the University of Texas at Dallas, where he currently teaches a number of undergraduate courses and received the University's Effective Teaching Award. In 2010, he created the UT-Dallas Santrock undergraduate scholarship, an annual award that is given to outstanding undergraduate students majoring in developmental psychology to enable them to attend research conventions.

John Santrock (back row middle) with the 2015 recipients of the Santrock Travel Scholarship Award in developmental psychology. Created by Dr. Santrock, this annual award provides undergraduate students with the opportunity to attend a professional meeting. A number of the students shown here attended the 2015 meeting of the Society for Research in Child Development.

Courtesy of Jessica Serna

John has been a member of the editorial boards of *Child Development* and *Developmental Psychology*. His research on father custody is widely cited and used in expert witness testimony to promote flexibility and alternative considerations in custody disputes. John also has authored these exceptional McGraw-Hill texts: *Children* (14th edition), *Adolescence* (17th edition), *A Topical Approach to Life-Span Development* (9th edition), and *Educational Psychology* (6th edition).

For many years, John was involved in tennis as a player, teaching professional, and coach of professional tennis players. At the University of Miami (FL), the tennis team on which he played still holds the NCAA Division I record for most consecutive wins (137) in any sport. His wife,

Mary Jo, has a master's degree in special education

and has worked as a teacher and a Realtor. He has two daughters—Tracy, who worked for a number of years as a technology marketing specialist, and Jennifer, who has been a medical sales specialist. However, recently both have followed in their mother's footsteps and are now Realtors. He has one granddaughter, Jordan, age 26, who works for the accounting firm Ernst & Young, and two grandsons, Alex, age 13, and Luke, age 11. In the last two decades, John also has spent time painting expressionist art.

### Dedication:

**With special appreciation to my mother,  
Ruth Santrock, and my father, John Santrock.**

# expert consultants

Life-span development has become an enormous, complex field, and no single author, or even several authors, can possibly keep up with all of the rapidly changing content in the many periods and different areas of life-span development. To solve this problem, author John Santrock has sought the input of leading experts about content in a number of areas of life-span development. These experts have provided detailed evaluations and recommendations in their area(s) of expertise.

The following individuals were among those who served as expert consultants for one or more of the previous editions of this text:

**Urie Bronfenbrenner**, *Cornell University*

Following are the expert consultants for the seventeenth edition, who (like those of previous editions) literally represent a *Who's Who* in the field of life-span development.

**William J. Hoyer** Dr. Hoyer is a leading expert on cognitive aging and life-span development. He obtained his Ph.D. from West Virginia University and is currently Professor of Psychology at Syracuse University. Dr. Hoyer is also a faculty affiliate of the Aging Studies Institute at Syracuse University. His research focuses on age-related changes in memory, attention, and learning. His research appears in journals such as *Psychology of Aging*; *Aging, Neuropsychology, and Cognition*; and *Journal of Gerontology: Psychological Sciences*. He is co-author of *Adult Development and Aging*. Dr. Hoyer is a Fellow in the American Psychological Association, the Association for Psychological Science, and The Gerontological Society of America.

*"In the chapter 'Introduction,' college students generally have a key interest in this topic (why people turn out the way they do), and I think Dr. Santrock succeeds (relative to the competition) in hooking readers of this edition early on current issues, questions, topics, and methods. Coverage of theoretical underpinnings has the potential to become too dry or too irrelevant for today's student—not so, here. Dr. Santrock manages to give purpose to our understanding of the theoretical bases of the field. The practical applications and personal significance of key aspects of the study of development come across with meaning in the first chapter. . . . Dr. Santrock conveys an*

*accurate and interesting account of the middle adult years. . . . The chapter 'Cognitive Development in Late Adulthood' nicely extends the topics covered in 'Cognitive Development in Middle Adulthood' to later life. A distinctive and commendable feature of the chapter is the inclusion of new, pertinent findings and ideas into the overall framing and conceptualization of the main themes and topics (the nature of cognitive change, training, neuroscience underpinnings, education, work, and spirituality)." —William Hoyer, Syracuse University*

**Patricia Miller** Dr. Miller is a leading expert in children's cognitive development. She obtained her Ph.D. from the Institute of Child Development at the University of Minnesota and currently is Professor of Psychology at San Francisco State University, having previously been a professor at the University of Michigan, University of Georgia, and University of Florida. Her research focuses on children's executive function, memory, attention, and learning strategies. Topics of current projects include the development of executive function in preschool children, the effects of exercise on children's executive function and academic achievement, and the development and transfer of strategies. Dr. Miller is a recent president of the developmental

psychology division of the American Psychological Association and is a Fellow of that organization as well as the Association for Psychological Science. She also has been an Associate Editor of *Child Development* and has served on the editorial boards of several major developmental journals. Her book, *Theories of Developmental Psychology*, is in its fifth edition, and she is co-author or co-editor of three other volumes. Dr. Miller's work has been published in leading research journals such as *Child Development*, *Developmental Psychology*, and *Cognitive Development*.

*"... as always, the text manages to cover the most important research, including new recent studies, while still keeping classic older research. . . . The new material is presented well. For example, in the chapter 'Cognitive Development in Infancy,' Dr. Santrock describes it clearly. The updates on executive function are good. . . . The text engages students by applying research to real-world topics important to them. The Connections features are great pedagogical components. Unlike many textbook authors, Dr. Santrock presents the controversies in the field. This is an important strength, for it conveys to students which knowledge in the discipline is solid and which is a work in progress. . . . an excellent textbook!" —Patricia Miller, San Francisco State University*

**Ross Thompson** Dr. Thompson is one of the world's leading experts on children's socioemotional development. He obtained his Ph.D. in psychology from the University of Michigan, has taught at the University of Nebraska, and currently is Distinguished Professor of Psychology at the University of California-Davis, where he directs the Social and Emotional Development Lab. As a developmental psychologist, Dr. Thompson studies early parent-child relationships, the development of emotion understanding and emotion regulation, early moral development, and the growth of self-understanding in young children. He also works on the applications of developmental research to public policy concerns, including school readiness and its development, early childhood investments, and early mental health. Dr. Thompson has published five books, several best-selling textbooks, and over 200 papers related to his work. He is a founding member of the National Scientific Council on the Developing Child, has twice been Associate Editor of *Child Development*, and has received the Boyd McCandless Young Scientist Award for Early Distinguished Achievement from the American Psychological Association. Dr. Thompson also recently was given the Ann Brown Award for Excellence in Developmental Research and the University of California-Davis Distinguished Scholarly Public Service Award. He has also recently been given the Urie Bronfenbrenner Award for Lifetime Contributions to Developmental Psychology by the American Psychological Association.

*"I like this chapter ('Socioemotional Development in Early Childhood'). The writing is engaging and illuminating, the questions that lead the reader along are the right ones, and the coverage. . . . current and comprehensive. The bridges between science and practice are strong and important. . . . This chapter ('Socioemotional Development in Middle and Late Childhood') covers considerable terrain, all of it relevant to the developmental stages covered here, and nearly all somehow managing to be covered in sufficient depth during this period. Again, the connections between science and practice are strong. . . . Although I can claim significantly less expertise in adolescence than for earlier developmental stages, I was*

*charmed and engaged by this chapter's ('Socioemotional Development in Adolescence') discussion of the opportunities and challenges uniquely posed by this stage of development."* —**Ross Thompson, University of California-Davis**

### **Karen Fingerman**

Karen Fingerman is a leading expert on aging, families, and socio-emotional development. She currently holds the position of Professor, Department of Human Development and Family Sciences, at the University of Texas-Austin. Dr. Fingerman attained her Ph.D. at the University of Michigan and completed a postdoctoral fellowship at Stanford University. She has published more than 100 articles on positive and negative relationships involving mothers and daughters, grandparents and grandchildren, friends and acquaintances, and peripheral social ties. Dr. Fingerman's research has been funded by the Brookdale Foundation, as well as the MacArthur Transitions to Aging group.

*"I have such great respect for Dr. Santrock's textbook. He does an excellent job of keeping it up-to-date and covering the key issues on each topic. It's actually a pleasure to read and critique. . . . Dr. Santrock definitely hits on the key issues regarding each phase of the lifespan. . . . I like the use of learning goals. The emphasis on careers is a terrific angle to add to the textbook."* —**Karen Fingerman, University of Texas-Austin**

### **John Richards**

Dr. John Richards is a leading expert on infant attention and children's brain development. He obtained his Ph.D. from UCLA and is currently the Carolina Distinguished Professor at the University of South Carolina. Dr. Richards is a Fellow of the American Psychological Association, American Psychological Society, and American Association for the Advancement of Science. He has been an associate editor for *Infant Behavior and Development*. Dr. Richards' research has been published in numerous developmental and neuroscience journals, including *Child Development*, *Developmental Psychology*, *Developmental Neuroscience*, *Cognitive Neuroscience*, *Neuroimaging*, and *Journal of Neuroscience*.

*"These ('Physical Development in Infancy' and 'Cognitive Development in Infancy') are two very good chapters. There are a lot of recent citations and sufficient coverage of historical information. The fact that this is a revision from several editions means that many of the chapters have good material from prior editions that is supplemented by new information."* —**John Richards, University of South Carolina**

### **Karen Rodrigue**

Dr. Karen Rodrigue is a leading expert on cognition, neuroscience, and aging. She is a professor at the Center for Vital Longevity, University of Texas at Dallas. Dr. Rodrigue obtained her Ph.D. at Wayne State University. Her research focuses on disease markers of Alzheimer disease, changes in the aging brain, and the role of hypertension in brain development and cognitive health. Dr. Rodrigue recently was given the "Rising Star" Award by the American Psychological Society.

*"The narrative (and perspective) very much reflect the latest and most important research in the field. . . . The chapters do a great job covering the diversity of key theories and findings in the area of physical and cognitive development in later adulthood. Each concept is presented in an engaging and clear manner and cumulatively, the chapters will provide students with a firm foundation of the key concepts and current research in this field. . . . Many new, updated references also is a strength."* —**Karen Rodrigue**, *University of Texas-Dallas*

Courtesy of Karen Rodrigue

**Sheung-Tak Cheng** Dr. Cheng is a leading expert on aging and socioemotional development. He currently is Chair Professor of Psychology and Gerontology at The Education University of Hong Kong. Dr. Cheng has published

more than 100 articles in psychology and gerontology, with a main interest in dementia and family caregiving. He developed the benefit-finding intervention for Alzheimer's family caregivers. Dr. Cheng is currently serving as Associate Editor of *Psychology and Aging* and is a Fellow in the American Psychological Association, the Association for Psychological Science, and the Gerontological Association of America. He also has been given the Outstanding International Psychologist Award by the American Psychological Association.

*"The Socioemotional Selectivity and the Family/Social Relationships sections are quite well done and comprehensive. I'm also glad issues of ethnic minorities are not forgotten."* —**Sheung-Tak Cheng**, *The Education University of Hong Kong*

# Connecting research and results

As a master teacher, John Santrock connects current research and real-world applications. Through an integrated, personalized digital learning program, students gain the insight they need to study smarter and improve performance.

McGraw-Hill Education Connect is a digital assignment and assessment platform that strengthens the link between faculty, students, and course work, helping everyone accomplish more in less time. Connect Life-Span includes assignable and assessable videos, quizzes, exercises, and interactivities, all associated with learning objectives. Interactive assignments and videos allow students to experience and apply their understanding of psychology to the world with fun and stimulating activities.

connect®

## Real People, Real World, Real Life

At the higher end of Bloom's taxonomy (analyze, evaluate, create), the McGraw-Hill Education Milestones video series is an observational tool that allows students to experience life as it unfolds, from infancy to late adulthood. This ground-breaking, longitudinal video series tracks the development of real children as they progress through the early stages of physical, social, and emotional development in their first few weeks, months, and years of life. Assignable and assessable within Connect Life-Span, Milestones also includes interviews with adolescents and adults to reflect development throughout the entire life span.

## Inform and Engage on Psychological Concepts

At the lower end of Bloom's taxonomy, students are introduced to Concept Clips—the dynamic, colorful graphics and stimulating animations that break down some of psychology's most difficult concepts in a step-by-step manner, engaging students and aiding in retention. They are assignable and assessable in Connect or can be used as a jumping-off point in class. Accompanied by audio narration, Concept Clips cover topics such as object permanence and conservation, as well as theories and theorists like Bandura's social cognitive theory, Vygotsky's sociocultural theory, Buss's evolutionary theory, and Kuhl's language development theory.

## Power of Process for **PSYCHOLOGY**

## Prepare Students for Higher-Level Thinking

Also at the higher end of Bloom's taxonomy, **Power of Process for Psychology** helps students improve critical thinking skills and allows instructors to assess these skills efficiently and effectively in an online environment. Available through Connect, pre-loaded journal articles are available for instructors to assign. Using a scaffolded framework such as understanding, synthesizing, and analyzing, Power of Process moves students toward higher-level thinking and analysis.

Students helped inform the revision strategy of *Life-Span Development*. McGraw-Hill Education's Smartbook is the first and only adaptive reading and learning experience! SmartBook helps students distinguish the concepts they know from the concepts they don't, while pinpointing the concepts they are about to forget. SmartBook continuously adapts to create a truly personalized learning path and offers students learning resources such as videos, Concept Clips, and slides to further reinforce difficult concepts. SmartBook's real-time reports help both students and instructors identify the concepts that require more attention, making study sessions and class time more efficient.

### Informed by Students

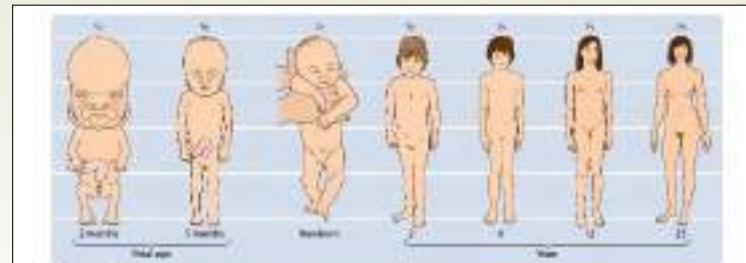

Content revisions are informed by data collected anonymously through McGraw-Hill Education's SmartBook.

**STEP 1.** Over the course of three years, data points showing concepts that caused students the most difficulty were anonymously collected from Connect for Life-Span Development's SmartBook®.

**STEP 2.** The data from LearnSmart was provided to the author in the form of a *Heat Map*, which graphically illustrates "hot spots" in the text that affect student learning (see image at right).

**STEP 3.** The author used the *Heat Map* data to refine the content and reinforce student comprehension in the new edition. Additional quiz questions and assignable activities were created for use in Connect to further support student success.

**RESULT:** Because the *Heat Map* gave the author empirically based feedback at the paragraph and even sentence level, he was able to develop the new edition using precise student data that pinpointed concepts that gave students the most difficulty.

**FIGURE 3.3**  
**CHILD-TO-CHILD PROPORTIONS OF THE HUMAN BODY DURING GROWTH.** As individuals develop throughout childhood, one of the most noticeable physical changes is that the head becomes proportionately smaller to the rest of the body. The horizontal lines refer to the child's age in months at the bottom of the figure.

**Infancy** The average newborn is 20 inches long and weighs 7 pounds. At birth, the infant's head is 1/3 of his total body weight. By 2 years of age, the head is only 1/8 of total body weight, or 10 to 12 inches long and weighs between 35 and 40 pounds.

In the first several days of life, an infant loses about 1 to 2 percent of their body weight. Once infants begin to eating, swelling, and diapering, they grow rapidly, gaining an average of 1 to 2 pounds per month during their first month. Typically, they more than double their birth weight by the time of 4 months and have nearly tripled it by their first birthday. Infants grow about 1 foot per year during the first five years, increasing their height by about 10 percent per decade from birth.

Average rate of growth between 12 months and 18 months is about 2.5 inches per month. By 2 years of age, infants weigh approximately 20 to 22 pounds. Average growth is similar to birth period per month during the first year. At age 3, they have reached about one-third of their adult weight. The average 3-year-old is 32 to 35 inches tall, which is one-half the height of adult height.

**Early Childhood** As children grow older, the percentage increase in height and weight decreases, reaching a plateau around year 11 (Eaton, 2010). The rate of weight gain and height gain during these years, like birth and growth during the first year, follows a similar pattern. At roughly 10 inches and 3 inches per year, respectively, these gains become one-half the previous year's growth rate. Note that these growth rates do not continue during the prepubescent years, but there is still one-third more than double the rate of growth seen during the first year of life (Berkman, 2010).

Growth patterns vary individually (Whalen & Holloman, 2003). Think back to your preschool years. This was probably the first time you noticed that some children were taller than you, while others were shorter. In fact, taller, more active, more social, more energetic, more talkative, and more outgoing children tend to have more positive school experiences and are more successful in school than shorter, less active, less talkative, and more withdrawn children (Meece, 2008).

**Adolescence** Adolescence is a period of rapid growth. Between the ages of 10 and 18, adolescents grow an average of 2.5 inches per year. This growth is accompanied by increased energy, increased activity, and increased risk taking. During preadolescence, an adolescent's body grows at an average rate of 4% (Kane, 2010).

**Middle and Late Childhood** The period of middle and late childhood is known as slow, continuous growth. This is a period of just better for rapid growth spurts of adolescence.

## Powerful Reporting

Whether a class is face-to-face, hybrid, or entirely online, Connect for Life-Span Development provides tools and analytics to reduce the amount of time instructors need to administer their courses. Easy-to-use course management tools allow instructors to spend less time administering and more time teaching, while easy-to-use reporting features allow students to monitor their progress and optimize their study time.

- The At-Risk Student Report provides instructors with one-click access to a dashboard that identifies students who are at risk of dropping out of the course due to low engagement levels.
- The Category Analysis Report details student performance relative to specific learning objectives and goals, including APA outcomes and levels of Bloom's taxonomy.
- Connect Insight is a one-of-a-kind visual analytics dashboard—now available for both instructors and students—that provides at-a-glance information regarding student performance.
- The LearnSmart Reports allow instructors and students to easily monitor progress and pinpoint areas of weakness, giving each student a personalized study plan to achieve success.

## Online Instructor Resources

The resources listed here accompany *Life-Span Development*, Seventeenth Edition. Please contact your McGraw-Hill representative for details concerning the availability of these and other valuable materials that can help you design and enhance your course.

**Instructor's Manual** Broken down by chapter, this resource provides chapter outlines, suggested lecture topics, classroom activities and demonstrations, suggested student research projects, essay questions, and critical thinking questions.

**Test Bank and Computerized Test Bank** This comprehensive Test Bank includes more than 1,500 multiple-choice and approximately 75 essay questions. Organized by chapter, the questions are designed to test factual, applied, and conceptual understanding. All test questions are available within TestGen™ software.

**PowerPoint Slides** The PowerPoint presentations, now WCAG compliant, highlight the key points of the chapter and include supporting visuals. All of the slides can be modified to meet individual needs.

## Making Connections . . . From My Classroom to *Life-Span Development* to You

Having taught life-span development every semester for more than three decades, I'm always looking for ways to improve my course and *Life-Span Development*. Just as McGraw-Hill looks to those who teach the life-span development course for input, each year I ask the almost 200 students in my life-span development course to tell me what they like about the course and the text, and what they think could be improved. What have my students told me lately about my course and text? Students say that highlighting connections among the different aspects of life-span development helps them to better understand the concepts. They confirm that a *connections* theme provides a systematic, integrative approach to the course material. Thus, I have continued to use this theme to shape my current goals for my life-span development course, which, in turn, are incorporated into *Life-Span Development*:

1. **Connecting with today's students** To help students learn about life-span development more effectively.
2. **Connecting research to what we know about development** To provide students with the best and most recent theory and research in the world today about each of the periods of the human life span.
3. **Connecting developmental processes** To guide students in making developmental connections across different points in the human life span.
4. **Connecting development to the real world** To help students understand ways to apply content about the human life span to the real world and improve people's lives; and to motivate them to think deeply about their own personal journey through life and better understand who they were, are, and will be.

### Connecting with Today's Students

In *Life-Span Development*, I recognize that today's students are as different in some ways from the learners of the last generation as today's discipline of life-span development is different from the field 30 years ago. Students now learn in multiple modalities; rather than sitting down and reading traditional printed chapters in linear fashion from beginning to end, their work preferences tend to be more visual and more interactive, and their reading and study often occur in short bursts. For many students, a traditionally formatted printed textbook is no longer enough when they have instant, 24/7 access to news and information from around the globe. Two features that specifically support today's students are the adaptive ebook, Smartbook (see xvii), and the learning goals system.

### The Learning Goals System

My students often report that the life-span development course is challenging because of the amount of material covered. To help today's students focus on the key ideas, the Learning Goals System I developed for *Life-Span Development* provides extensive learning connections throughout the chapters. The learning system connects the chapter opening outline, learning

Discuss physical growth and development in infancy.

- The cephalocaudal pattern is the sequence in which growth proceeds from top to bottom. The proximodistal pattern is the sequence in which growth starts at the center of the body and moves toward the extremities.
- The average North American newborn is 20 inches long and weighs 7.6 pounds. Infants grow about 1 inch per month in the first year and nearly triple their weight by their first birthday. The rate of growth slows in the second year.
- One of the most dramatic changes in the brain in the first two years of life is dendrite spreading, which increases the connections between neurons. Myelination, which speeds the conduction of nerve impulses, continues through infancy and even into adolescence.
- The cerebral cortex has two hemispheres (left and right). Lateralization refers to specialization of function in one hemisphere or the other. Early experiences play an important role in brain development.

goals for the chapter, mini-chapter maps that open each main section of the chapter, *Review, Connect, and Reflect* questions at the end of each main section, and the chapter summary at the end of each chapter.

The learning system keeps the key ideas in front of the student from the beginning to the end of the chapter. The main headings of each chapter correspond to the learning goals that are presented in the chapter-opening spread. Mini-chapter maps that link up with the learning goals are presented at the beginning of each major section in the chapter.

Then, at the end of each main section of a chapter, the learning goal is repeated in *Review, Connect, and Reflect*, which prompts students to review the key topics in the section, connect to existing knowledge, and relate what they learned to their own personal journey through life. *Reach Your Learning Goals*, at the end of the chapter, guides students through the bulleted chapter review, connecting with the chapter outline/learning goals at the beginning of the chapter and the *Review, Connect, and Reflect* questions at the end of major chapter sections.

## connecting through research

### How Does the Quality and Quantity of Child Care Affect Children?

In 1991, the National Institute of Child Health and Human Development (NICHD) began a comprehensive, longitudinal study of child-care experiences. Data were collected on a diverse sample of almost 1,400 children and their families at 10 locations across the United States over a period of seven years. Researchers used multiple methods (trained observers, interviews, questionnaires, and testing) and measured many facets of children's development, including physical health, cognitive development, and socioemotional development. Following are some of the results of what is now referred to as the NICHD Study of Early Child Care and Youth Development or NICHD SECCYD (NICHD Early Child Care Research Network, 2001, 2002, 2003, 2004, 2005, 2006, 2010).

- **Patterns of use.** Many families placed their infants in child care very soon after the child's birth, and there was considerable instability in the child-care arrangements. By 4 months of age, nearly three-fourths of the infants had entered some form of nonmaternal child care. Almost half of the infants were cared for by a relative when they first entered care; only 12 percent were enrolled in child-care centers.

infrequent—only 12 percent of the children studied had experienced positive nonparental child care (such as positive talk, lack of detachment and flat affect, and language stimulation). Further, infants from low-income families experienced lower-quality child care than did infants from higher-income families. When quality of caregivers' care was high, children performed better on cognitive and language tasks, were more cooperative with their mothers during play, showed more positive and skilled interaction with peers, and had fewer behavior problems. Caregiver training and good child-staff ratios were linked with higher cognitive and social competence when children were 54 months of age. Using data collected as part of the NICHD early child care longitudinal study, a research analysis indicated that higher-quality early childhood care, especially at 27 months of age, was linked to children's higher vocabulary scores in the fifth grade (Belsky & others, 2007).

Higher-quality child care was also related to higher-quality mother-child interaction among the families that used nonmaternal care. Further, poor-quality care was related to higher rates of insecure attachment to the mother among infants who were 15 months of age, but only

## Connecting Research to What We Know about Development

Over the years, it has been important for me to include the most up-to-date research available. I continue that tradition in this edition by looking closely at specific areas of research, involving experts in related fields, and updating research throughout. *Connecting Through Research* describes a study or program to illustrate how research in life-span development is conducted and how it influences our understanding of the discipline. Topics range from *How Can Newborns' Perception Be Studied? to Parenting and Children's Achievement: My Child Is My Report Card, Tiger Moms, and Tiger Babies Strike Back to What Is the Relationship Between Fitness in Young Adults and Cardiovascular Health in Middle Age? to Does Engaging in Intellectually Challenging Activities Affect Quality of Life and Longevity?*

The tradition of obtaining detailed, extensive input from a number of leading experts in different areas of life-span development also continues in this edition. Biographies and photographs of the leading experts in the field of life-span development appear on pages xiii to xv, and the chapter-by-chapter highlights of new research content are listed on pages xxii to xlvi. Finally, the research discussions have been updated in every period and topic. I expended every effort to make this edition of *Life-Span Development* as contemporary and up-to-date as possible. To that end, there are more than 1,500 citations from 2017, 2018, and 2019.

## Connecting Developmental Processes

Development through the life span is a long journey, and too often we forget or fail to notice the many connections from one point in development to another. A significant number of these connections are made in the text narrative, and features are included to help students connect topics across the periods of development.

**Developmental Connections**, which appear multiple times in each chapter, point readers to where the topic is discussed in a previous or subsequent chapter. *Developmental Connections* highlight links across age periods of development and connections between biological, cognitive, and socioemotional processes. These key developmental processes are typically discussed in isolation from each other, and students often fail to see their connections. Included in the *Developmental Connection* is a brief description of the backward or forward connection. For example, consider the development of the brain. In recent editions, I have significantly expanded content on the changes in the brain through the life span, including new coverage of changes in the brain during prenatal development and an expanded discussion of the aging brain in older adults. The prenatal brain discussion appears in “Prenatal Development and Birth” and the aging brain is described in “Physical Development in Late Adulthood.” An important brain topic that we discuss in these two chapters is neurogenesis, the production of new neurons. Connections between these topics in these two chapters are highlighted through *Developmental Connections*.

**Topical Connections: Looking Back and Looking Forward** begin and conclude each chapter by placing the chapter’s coverage in the larger context of development. These sections remind the reader of what happened developmentally in previous periods of development and make connections to topics that will be discussed in more detail.

Finally, a *Connect* question appears in the section self-reviews—*Review, Connect, and Reflect*—so students can practice making connections between topics. For example, in “Physical and Cognitive Development in Middle and Late Childhood,” students are asked to connect what they learned about attention in “Cognitive Development in Infancy” and “Cognitive Development in Early Childhood” with what they have just read about attention deficit hyperactivity disorder in the middle and late childhood chapter.

## Connecting Development to the Real World

In addition to helping students make research and developmental connections, *Life-Span Development* shows the important connections between the concepts discussed and the real world. In recent years, students in my life-span development course have increasingly told me that they want more of this type of information. In this edition, real-life connections are explicitly made through the chapter opening vignette, *Connecting Development to Life*, the *Milestones* program that helps students watch life as it unfolds, and *Connecting with Careers*.

Each chapter begins with a story designed to increase students’ interest and motivation to read the chapter. For example, “Cognitive Development in Late Adulthood” begins with a description of the remarkable Helen Small, who published her first book at age 91 and completed her undergraduate degree 70 years after she started college.

*Connecting Development to Life* describes the influence of development in a real-world context on topics including *From Waterbirth to Music Therapy*, *Increasing Children’s Self-Esteem*, and *Health Care Providers and Older Adults*.

The *Milestones* program, described on page xvi, shows students what developmental concepts look like by letting them watch actual humans develop. Starting from infancy, students track several individuals, seeing them achieve major developmental milestones, both physically and cognitively. Clips continue through adolescence and adulthood, capturing attitudes toward issues such as family, sexuality, and death and dying.

### developmental connection

#### Personality

Erikson proposed that individuals go through eight stages in the course of human development. Connect to “Introduction.”

### topical connections looking back

We have discussed that impressive advances occur in the development of the brain during infancy. Engaging in various physical, cognitive, and socioemotional activities strengthens the baby’s neural connections. Motor and perceptual development also are key aspects of the infant’s development. An important part of this development is the coupling of perceptions and actions. The nature-nurture issue continues to be debated with regard to the infant’s perceptual development. In this chapter, you will expand your understanding of the infant’s brain, motor, and perceptual development by further examining how infants develop their competencies, focusing on how advances in their cognitive development help them adapt to their world, and how the nature-nurture issue is a key aspect of the infant’s cognitive and language development.

### connecting development to life

#### Strategies for Parents and Their Young Adult Children

When adult children ask to return home to live, parents and their adult children should agree beforehand on the conditions and expectations. For example, they might discuss and agree on whether young adults will pay rent, wash their own clothes, cook their own meals, do any household chores, pay their phone bills, come and go as they please, be sexually active or drink alcohol at home, and so on. If these conditions aren’t negotiated at the beginning, conflict often results because the expectations of parents and young adult children will likely be violated.

Parents need to treat young adult children more like adults than children and to let go of much of their parenting role. Parents should interact with young adult children not as dependent children who need to be closely monitored and protected but rather as adults who are capable of responsible, mature behavior. Adult children have the right to choose how much they sleep and eat, how they dress, whom they choose as friends and lovers, what career they pursue, and how they spend their money. However, if the young adult children act in ways that interfere

adult life (Paul, 2003). Although well intentioned, this intrusiveness by parents can slow the process by which their children become responsible adults.

What are some strategies that can help parents and their young adult children get along better?

When they move back home, young adult children need to think about how they will need to change their behavior to make the living arrangement work. Elina Furman (2005) provides some good recommendations in *Boomerang Nation: How to Survive Living with Your Parents . . . the Second Time Around*. She recommends that when young adult children move back home they expect to make adjustments. And as recommended earlier, she urges young adults to sit down with their parents and negotiate the ground rules for living at home before they actually move back. Furman also

recommends that young adults set a deadline for how long they will live at home and then stay focused on their goals (whether they want to save enough money to pay off their debts, save enough to start a business or buy their own home, finish graduate school, and so on).

## connecting with careers

### Ahou Vaziri, Teach for America Instructor

Ahou Vaziri was a top student in author John Santrock's educational psychology course at the University of Texas at Dallas, where she majored in Psychology and Child Development. The following year she served as a teaching intern for the educational psychology course, then submitted an application to join Teach for America and was accepted. Ahou was assigned to work in a low-income area of Tulsa, Oklahoma, where she taught English to seventh- and eighth-graders. In her words, "The years I spent in the classroom for Teach for America were among the most rewarding experiences I have had thus far in my career. I was able to go home every night after work knowing that I truly made a difference in the lives of my students."

Upon completion of her two-year teaching experience with Teach for America, Ahou continued working for the organization by recruiting college students to serve as Teach for America instructors. Subsequently, she moved into a role that involved developing curricula for Teach for America. Recently she earned a graduate degree in counseling from Southern Methodist University, and she has continued working to improve children's lives.

*Connecting with Careers* profiles careers ranging from an educational psychologist to a toy designer to a marriage and family therapist to a research scientist at an educational center to a geriatric nurse—each of which requires knowledge about human development.

A number of new *Connecting with Careers* profiles appear in the new edition. These include Gustavo Medrano, a clinical psychologist who works at the Family Institute at Northwestern University and provides therapy especially for Latino children; Dr. Faize Mustaf-Infante, a pediatrician who is passionate about preventing obesity in children; Dr. Melissa Jackson, a child and adolescent psychiatrist who provides therapy for children with a number of psychological disorders, including ADHD, anxiety, depression, and post-traumatic stress disorder; and Ahou Vaziri, a Teach for America Instructor and curriculum designer.

The careers highlighted extend from the Careers Appendix that provides a comprehensive overview of careers in life-span development to show students where knowledge of human development could lead them.

Part of applying development to the real world is understanding its impact on oneself. An important goal I have established for my life-span development course and this text is to motivate students to think deeply about their own journey of life. To further encourage students to make personal connections to content in the text, *Reflect: Your Own Personal Journey of Life* appears in the end-of-section review in each chapter. This feature involves a question that asks students to reflect on some aspect of the discussion in the section they have just read and connect it to their own life. For example, students are asked:

*Do you think there is, was/will be a best age for you to be? If so, what is it? Why?*

I always include this question in the first content lecture I give in life-span development, and it generates thoughtful and interesting class discussion. Early in the “Introduction” chapter is a research discussion on whether there is a best age to be, which includes recent research on the topic and a self-assessment that lets students evaluate their own life satisfaction. In addition, students are asked a number of personal connections questions in the photograph captions.

# Content Revisions

A significant reason why *Life-Span Development* has been successfully used by instructors for the previous sixteen editions is the painstaking effort and review that goes into making sure the text provides the latest research on all topic areas discussed in the classroom. This new edition is no exception, with more than 1,500 citations from 2017, 2018, and 2019.

Also, a number of content revisions were based on feedback obtained by McGraw-Hill using a Heat Map system that highlights aspects of the content on which students are performing well and not well on tests. In this new edition, I especially focused on clarifying content in "Physical and Cognitive Development in Infancy," "Physical and Cognitive Development in Early Childhood," and "Physical and Cognitive Development in Middle and Late Childhood." Along with many new *Connecting with Careers* profiles that highlight professionals in practice, new research and content that has especially been updated and expanded include: diversity and culture; genetics and epigenetics; neuroscience and the brain; identity issues, especially gender and transgender; health; technology; and successful aging.

Following is a sample of the many chapter-by-chapter changes that were made in this new edition of *Life-Span Development*.

## Chapter 1: Introduction

- Update on life expectancy in the United States (U.S. Census Bureau, 2017)
- New projections on the significant increase in older adults in the world, with estimates of a doubling of the population of individuals 60 and over and a tripling or quadrupling of those 80 and over by 2050 (United Nations, 2015)
- New *Connecting with Careers* profile on Gustavo Medrano, a clinical psychologist who provides therapy especially for Latino children
- Updated data on the percentage of U.S. children and adolescents under 18 years of age living in poverty, including data reported separately for African American and Latino families (Jiang, Granja, & Koball, 2017)
- In the discussion of gender, new content on transgender (Budge & Orovecz, 2018; Savin-Williams, 2017)
- In the section on contemporary topics, a new discussion of technology has been added, including an emphasis on how pervasive technology has become in people's lives and how it might influence their development
- New coverage of a recent study of 26 countries indicating that individuals in Chile had the highest life satisfaction; those in Bulgaria and Spain the lowest (Jang & others, 2017)
- New description of the positive outcomes when individuals have pride in their ethnic group, including recent research (Umana-Taylor & others, 2018)
- In the section on biological processes, new emphasis on the significant increase in studies of actual genes on development and epigenetic studies (Clukay & others, 2018; Manzi & others, 2018) as well as the brain's role in development (Park & Festini, 2018; Sullivan & Wilson, 2018) because of technological advances
- New description of emerging adulthood and the dramatic increase in studies on this transitional period between adolescence and adulthood (Arnett, 2016a, b; Jensen, 2018)
- Inclusion of a study involving 17-year survival rates of 20- to 93-year-old Korean adults indicating that when biological age became greater than chronological age, individuals were less likely to have died (Yoo & others, 2017)
- New content involving how the information processing approach often uses a computer analogy to help explain the connection between cognition and the brain, and how humans process information

- New discussion of artificial intelligence and the new emerging field of developmental robotics that examines various developmental topics and issues using robots, including a new photograph of a "human-like" baby robot (Cangelosi & Schlesinger, 2015; Morse & Cangelosi, 2017)
- Updated and expanded coverage of research methods, including the increased use of eye-tracking devices to assess infants' perception (Boardman & Fletcher-Watson, 2017); attention (Meng, Uto, & Hashiva, 2017); autism (Finke, Wilkinson, & Hickerson, 2017); and preterm birth effects on language development (Loi & others, 2017)
- In the section on physiological methods, expanded discussion of recent advances in assessing genes to include specific genes linked to childhood obesity (Xing & others, 2018)

## Chapter 2: Biological Beginnings

- Updating of chapter based on comments by leading expert Kirby Deater-Deckard
- Deletion of section on shared and non-shared environmental experiences as it is now being given less attention as a result of the increased emphasis on gene × environment interaction
- Updated and expanded research on how exercise, nutrition, and respiration can modify the expression of genes (Kader & others, 2018; Poulsen & others, 2018)
- Updated and expanded coverage of the process of methylation, in which tiny atoms attach themselves to the outside of a gene. Researchers have found that exercise, diet, and tobacco use can change whether a gene is expressed or not through the methylation process (Castellano-Castillo & others, 2018; Martin & Fry, 2018).
- Updated and expanded discussion of genome-wide association studies, including research on suicide (Sokolowski, Wasserman, & Wasserman, 2016), autism (Ramaswami & Geschwind, 2018), and glaucoma (Springelkamp & others, 2017)
- Updated and expanded research on gene-gene interaction, including studies of obesity (Bordoni & others, 2017), type 2 diabetes (Saxena, Srivastava, & Banerjee, 2017), cancer (Sucheston-Campbell & others, 2018), and cardiovascular disease (Olsen & others, 2018)
- Inclusion of recent research in which a higher-level maternal responsivity to children with fragile X syndrome's adaptive behavior improved the children's communication skills (Warren & others, 2017)

- New content on the number of children born worldwide with sickle-cell anemia and how stem cell transplantation is being explored in the treatment of infants with sickle-cell anemia (Azar & Wong, 2017)
- Updated description of how research now supports the use of hydroxyurea therapy for infants with sickle-cell anemia beginning at 9 months of age (Nevitt, Jones, & Howard, 2017)
- New *Connecting with Careers* profile on genetic counselor Jennifer Leonhard
- Inclusion of information from a recent research review that concluded fetal MRI does not provide good results in the first trimester of pregnancy because of small fetal structures and movement artifacts (Wataganara & others, 2016). In this review, it also was argued that fetal MRI can especially be beneficial in assessing central nervous system abnormalities in the third trimester of pregnancy.
- New commentary that maternal blood screening can be used to detect congenital heart disease risk in the fetus (Sun & others, 2016)
- New content on fertility drugs being more likely to produce multiple births than in vitro fertilization (March of Dimes, 2018)
- New coverage of a recent national study in which low birth weight and preterm birth were significantly higher in infants conceived through assisted reproduction technology (Sunderam & others, 2017)
- Discussion of a recent study of 3- to 5-year-old children in which parents' secure attachment increased their adopted children's secure attachment, with mothers' secure attachment making a stronger contribution to their children's secure attachment than fathers' secure attachment (Barone, Lionetti, & Green, 2017)
- Coverage of a recent research review of internationally adopted adolescents in which although a majority were well adjusted, adoptees had a higher level of mental health problems than their non-adopted counterparts (Askeland & others, 2017)
- Inclusion of recent research that revealed no differences in the adjustment of school-aged children adopted in infancy by gay, lesbian, and heterosexual parents (Farr, 2017)
- Description of a recent study of lesbian and gay adoptive families which indicated that 98 percent of the parents reported their children had adjusted well to school (Farr, Oakley, & Ollen, 2016)
- Discussion of recent research indicating that isotretinoin (used to treat acne) is commonly prescribed for adolescent girls seeking contraceptive advice but often is not accompanied by adequate information about its harmful effects on offspring if the girls become pregnant (Eltonsy & others, 2016; Stancil & others, 2017)
- Coverage of recent research on negative outcomes for fetal alcohol spectrum disorders (FASD) that include lower executive function (Kingdon, Cardoso, & McGrath, 2016), as well as externalized and internalized behavior problems (Tsang & others, 2016), and a significantly lower life expectancy (Thanh & Jonsson, 2016)
- New content about a recent large-scale U.S. study in which 11.5 percent of adolescent and 8.7 percent of adult pregnant women reported using alcohol in the previous month (Oh & others, 2017)
- New description of the French Alcohol Society's (2016) recommendation that women should not consume any alcohol during pregnancy
- Discussion of a recent meta-analysis of 15 studies that concluded smoking during pregnancy increases the risk of children having ADHD and that the risk is greater if their mother is a heavy smoker (Huang & others, 2018)
- Inclusion of recent research indicating that maternal cigarette smoking during pregnancy was linked to increased risk of cigarette smoking in offspring at 16 years of age (De Genna & others, 2016)
- Description of recent research in which daughters whose mothers smoked during their pregnancy were more likely to subsequently smoke during their own pregnancy (Ncube & Mueller, 2017)
- Coverage of a recent study that found despite the plethora of negative outcomes for maternal smoking during pregnancy, 23 percent of pregnant adolescent and 15 percent of adult pregnant women reported using tobacco in the previous month (Oh & others, 2017)
- Inclusion of recent research in which cocaine use during pregnancy was associated with impaired connectivity of the thalamus and prefrontal cortex in newborns (Salzwedel & others, 2017)
- Discussion of recent research indicating that cocaine use by pregnant women is linked to attention deficit hyperactivity disorder, oppositional defiant disorder, and posttraumatic stress disorder (PTSD) in offspring (Richardson & others, 2016), as well as self-regulation problems at age 12 (Minnes & others, 2016)
- Coverage of a recent meta-analysis that found marijuana use during pregnancy was associated with the following outcomes in offspring: low birth weight and an increased likelihood of being placed in a neonatal intensive care unit (Gunn & others, 2016)
- New research indicating that pregnant women have increased their use of marijuana in recent years (Brown & others, 2016)
- Description of recent research that found cardiac defects, pulmonary problems, and microcephaly were among the most common fetal and neonatal outcomes when pregnant women have rubella (Yazigi & others, 2017)

## Chapter 3: Prenatal Development and Birth

- Revisions based on feedback from leading expert consultant Janet DiPietro
- Added commentary about the special concern that drugs can be transferred from the mother to the fetus through the placenta (Koren & Ornoy, 2018)
- Updated data on the average length and weight of the fetus at different points in prenatal development, including revisions involving these data in Figure 3 in "Biological Beginnings"
- New commentary about neurogenesis being largely complete by about the end of the fifth month of prenatal development (Keunen, Counsell, & Benders, 2017)

- Inclusion of a recent study that concluded maternal obesity during pregnancy is associated with an increased likelihood of offspring becoming obese in childhood and adulthood (Pinto Pereira & others, 2016)
- Revised content on fish consumption by pregnant women, who are now being advised to increase their fish consumption, especially eating more low-mercury-content fish such as salmon, shrimp, tilapia, and cod (American Pregnancy Association, 2018)
- Inclusion of recent research that revealed maternal prenatal stress and anxiety were linked to lower levels of infants' self-regulation (Korja & others, 2017)
- Description of a recent study in which taking antidepressants early in pregnancy was linked to increased risk of miscarriage (Almeida & others, 2016)
- Discussion of a recent study that found when fetuses were exposed to serotonin-based antidepressants, they were more likely to be born preterm (Podrebarac & others, 2017)
- Coverage of a recent study that revealed taking antidepressants in the second or third trimester was associated with increased risk of autism in children (Boukhris & others 2016)
- Description of a recent research review that concluded tobacco smoking is linked to impaired male fertility and increases in DNA damage, aneuploidy (abnormal number of chromosomes in a cell), and mutations in sperm (Beal, Yauk, & Marchetti, 2017)
- Discussion of a recent study that revealed regular exercise by pregnant women was linked to more advanced development in the neonatal brain (Laborte-Lemoine, Currier, & Ellenberg, 2017)
- Inclusion of recent research in which two weekly 70-minute yoga sessions reduced pregnant women's stress and enhanced their immune system functioning (Chen & others, 2017)
- Discussion of a recent research review in which participation in CenteringPregnancy increased initiation of breast feeding by 53 percent overall and by 71 percent in African American women (Robinson, Garnier-Villarreal, & Hanson, 2018)
- Coverage of a recent Swedish study that found women who gave birth in water had fewer vaginal tears, shorter labor, needed fewer drugs for pain relief and interventions by medical personnel, and rated their birth experience more positively than women who had conventional spontaneous vaginal births (Ulfsdottir, Saltvedt, & Georgsson, 2018)
- Inclusion of recent studies in which massage reduced women's pain during labor (Gallo & others, 2018; Shahoei & others, 2018; Unalmis Erdogan, Yanikkerem, & Goker, 2017)
- Update on the percentage of U.S. births that take place in hospitals, at home, and in birthing centers and the percentage of babies born through cesarean delivery (Martin & others, 2017)
- New description of global cesarean delivery rates, with the Dominican Republic and Brazil having the highest rates (56 percent) and New Zealand and the Czech Republic the lowest (26 percent) (McCullough, 2016). The World Health Organization recommends a cesarean rate of 10 percent or less
- Revised and updated content on cesarean delivery to include two specific reasons it is carried out: failure to progress through labor and fetal distress
- Coverage of recent studies that have found low Apgar scores are linked to long-term needs for additional educational support and reduced educational attainment (Tweed & others, 2016), risk of developmental vulnerability at 5 years of age (Razaz & others, 2016), and risk for developing ADHD (Hanc & others, 2016)
- Updated data on the percentage of births in the United States that are preterm, low birth weight, and cesarean section (Martin & others, 2017)
- Description of recent research indicating that extremely preterm and low birth weight infants have lower executive function, especially in working memory and planning (Burnett & others, 2018)
- Inclusion of recent research that revealed kangaroo care was effective in reducing neonatal pain (Johnston & others, 2017; Mooney-Leber & Brummelte, 2017)
- Discussion of a longitudinal study in which the nurturing positive effects of kangaroo care with preterm and low birth weight infants at one year of age were still present 20 years later in a number of positive developmental outcomes (Charpak & others, 2017)
- Coverage of a recent study that revealed worsening or minimal improvement in sleep problems from 6 weeks to 7 months postpartum was associated with increased depressive symptoms (Lewis & others, 2018)
- Description of recent research that found women who had a history of depression were 20 times more likely to develop postpartum depression than women who had no history of depression (Silverman & others, 2017)
- Inclusion of recent research in which mothers' postpartum depression, but not generalized anxiety, was linked to their children's emotional negativity and behavior problems at 2 years of age (Prenoveau & others, 2017)
- Coverage of a recent meta-analysis that concluded that physical exercise during the postpartum period is a safe strategy for reducing postpartum depressive symptoms (Poyatos-Leon & others, 2017)
- Discussion of a recent study that found depressive symptoms in mothers and fathers were linked to impaired bonding with their infant in the postpartum period (Kerstis & others, 2016)

## Chapter 4: Physical Development in Infancy

- Changes based on feedback from leading children's nutrition expert, Maureen Black, and leading children's motor development expert, Karen Adolph
- New discussion of how infant growth is often not smooth and continuous but rather is episodic, occurring in spurts (Adolph & Berger, 2015; Lampl & Schoen, 2017)
- Coverage of a recent study that found higher-quality mother-infant interaction predicted a higher level of frontal lobe functioning when assessed by EEG later in infancy (Bernier, Calkins, & Bell, 2016)
- Description of a recent study in which sleep sessions lasted approximately 3.5 hours during the first few months and increased to about 10.5 hours from 3 to 7 months (Mindell & others, 2016)

- Discussion of recent research indicating that later bedtime sleep and less sleep across a 24-hour period were linked to infants having more separation distress, greater inhibition, and higher anxiety and depression levels (Mindell & others, 2017)
- Other recent research indicating that a higher level of maternal emotional availability at bedtime was associated with a lower level of infant distress at bedtime and longer infant sleep duration (Philbrook & Teti, 2016)
- New indication that approximately 15 to 25 percent of infants have sleep problems
- New commentary about how many mothers today are providing their babies with “tummy time” to prevent a decline in prone skills that can occur because of the “back to sleep movement” to prevent SIDS
- Discussion of a recent research review that revealed a positive link between infant sleeping and cognitive functioning, including memory, language, and executive function (Tham, Schneider, & Broekman, 2017)
- Coverage of a recent study that found sleep difficulties in infancy were linked to developmental problems in attention (Geva, Yaron, & Kuint, 2016)
- Description of recent research in which introduction of vegetables at 4 to 5 months of age was linked with a lower level of infant fussy eating at 4 years of age than when vegetables were introduced after 6 months (de Barse & others, 2017)
- Updated data on the continuing increase in breast feeding by U.S. mothers (Centers for Disease Control and Prevention, 2016)
- Updated support for the role of breast feeding in reducing a number of disease risks for children and their mothers (Bartick & others, 2018)
- Inclusion of a recent research review indicating that breast feeding is not associated with a reduced risk of allergies in young children (Heinrich, 2017)
- Description of recent research indicating a reduction in hospitalization for breast-fed infants and breast-feeding mothers for a number of conditions (Bartick & others, 2018)
- Discussion of a recent study that found a small increase in intelligence for children who had been breast-fed (Bernard & others, 2017)
- New Connecting with Careers profile on Dr. Faize Mustafa-Infante, pediatrician
- New coverage of a recent study of infants' organization of exploratory behaviors in planning locomotion in challenging contexts (Kretch & Adolph, 2018)
- Discussion of a recent study that examined a number of predictors of motor milestones in the first year (Flensborg-Madsen & Mortensen, 2017)
- Inclusion of recent research in which 3-month-old infants were provided with reaching experiences and subsequently engaged in increased object exploration and attention focusing at 5.5 months of age compared with infants of the same age who had not received this intervention (Libertus, Joh, & Needham, 2016)
- New coverage of a recent study that revealed 3-month-old infants who participated in active motor training using sticky

mittens that allowed them to pick up toys engaged in more sophisticated object exploration at 15 months (Wiesen, Watkins, & Needham, 2016)

- Inclusion of recent research in which kangaroo care was effective in reducing neonatal pain (Seo, Lee, & Ahn, 2016)
- Revision of the nature/nurture section in the content on perceptual development to better reflect the Gibsons' view

## **Chapter 5: Cognitive Development in Infancy**

- Changes based on feedback from leading experts Patricia Miller and John Richards
- New coverage of a recent study of 5-month-olds that found their better performance on an A-not-B task was linked to how well they focused their attention on a different task, indicating that infants' attention may be involved in performance variations on the A-not-B task (Marcovitch & others, 2016)
- Expanded and updated criticism of the innate view of the emergence of infant morality with an emphasis on the importance of infants' early interaction with others and later transformation through language and reflective thought (Carpendale & Hammond, 2016)
- Revised writing for improved clarity of the section “Evaluation of the Sensorimotor Stage”
- Inclusion of a recent study that found sustained attention at 10 months of age was linked to better self-regulation at 18 months of age, even when infants had insensitive mothers (Frick & others, 2018)
- Revised discussion of habituation for improved student understanding
- Coverage of a recent study in which hand-eye coordination involving connection of gaze with manual action on objects rather than gaze following alone predicted joint attention (Yu & Smith, 2017)
- New description of Andrew Meltzoff's (2017) view that infants' imitation informs us about their processing of social events and contributes to rapid social learning
- Revisions and updates based on feedback from leading experts Roberta Golinkoff and Virginia Marchman
- Deletion of section on infant intelligence tests as there is less interest in these tests than in the past
- New opening commentary about the nature of language learning and how it involves comprehending a sound system (or sign system for individuals who are deaf), the world of objects, actions, and events, and how units such as words and grammar connect sound and world (Hoffman, 2018; Nathan, 2018)
- Revised definition of infinite generativity to include comprehension as well as production
- Expanded description of how statistical regularity of information is involved in infant word learning (Pace & others, 2016)
- New commentary on how infants' babbling influences the behavior of their caregivers, creating social interaction that facilitates their own communicative development (Albert, Schwade, & Goldstein, 2018)
- New research that indicates age at babbling onset predicts when infants will say their first words (McGillion & others, 2017a)

- New commentary describing why gestures such as pointing promote further advances in language development
- New commentary about the vocabulary spurt and how it involves an increase in the pace at which words are learned
- Expanded discussion of statistical learning, including how infants soak up statistical regularities around them merely through exposure to them (Aslin, 2017)
- Expanded descriptions of the functions that child-directed speech serves, including providing infants with information about their native language and heightening differences with speech directed to adults (Golinkoff & others, 2015)
- Coverage of recent research in which child-directed speech in a one-to-one social context for 11- to 14-month-olds was related to productive vocabulary at 2 years of age for Spanish-English bilingual infants for both languages and each language independently (Ramirez-Esparza, Garcia-Sierra, & Kuhl, 2017)
- New discussion of recent research in several North American urban areas and the small island of Tanna in the South Pacific Ocean that found fathers in both contexts engaged in child-directed speech with their infants (Broesch & Bryant, 2018)
- New emphasis on the importance of social cues in infant language learning (Akun & others, 2018; McGillion & others, 2017b)
- Coverage of a recent study in which both full-term and pre-term infants who heard more caregiver talk (based on all-day recordings) at 16 months of age had better language skills at 18 months of age (Adams & others, 2018)
- Revised definitions of recasting, expanding, and labeling
- New content on the recent position statement issued by the American Association of Pediatrics (2016) on co-viewing of videos indicating that infants can benefit when parents watch videos with them and communicate with them about the videos
- Expanded coverage of how parents can facilitate infants' and toddlers' language development

## Chapter 6: Socioemotional Development in Infancy

- Revisions based on feedback from leading expert Joan Grusec
- New introductory comments about the important role that cognitive processes, in addition to biological and experiential influences, play in children's emotional development, both in the moment and across childhood (Bell, Diaz, & Liu, 2018; Jiang & others, 2017)
- Discussion of a recent study in which maternal sensitivity was linked to lower levels of infant fear (Gartstein, Hancock, & Iverson, 2018)
- Description of a recent study that revealed excessive crying in 3-month-olds doubled the risk of behavioral, hyperactive, and mood problems at 5 to 6 years of age (Smarius & others, 2017)
- Coverage of a recent study that found depressed mothers rocked and touched their crying infants less than non-depressed mothers did (Esposito & others, 2017a)
- New description of a study in which young infants with a negative temperament used fewer attention regulation strategies, and maternal sensitivity was linked to more adaptive emotion regulation in infants (Thomas & others, 2017)
- New research that found positive affectivity, surgency, and self-regulation capacity assessed at 4 months of age was linked to school readiness at 4 years of age (Gartstein, Putnam, & Kliewer, 2016)
- Two new research studies in which a lower level of effortful control at 3 years of age was linked with ADHD symptoms in the first grade (Willoughby, Gottfredson, & Stifter, 2017) and at 13 years of age (Einziger & others, 2018)
- Description of a recent study that revealed if parents had a childhood history of behavioral inhibition, their children who also had a high level of behavioral inhibition were at risk for developing anxiety disorders (Stumper & others, 2017)
- New coverage of recent research in which children who had a difficult temperament at 5 and 14 years were more likely to have mental health problems at 21 years of age (Kingsbury & others, 2017)
- Expanded and updated content on the increasing belief that babies are socially smarter than used to be thought, including information about research by Amanda Woodward and her colleagues (Kroug-Jespersen & Woodward, 2016; Liberman, Woodward, & Kinzler, 2018; Shneidman & Woodward, 2016; Sodian & others, 2016) indicating how quickly infants understand and respond to others' meaningful intentions
- Discussion of a recent study in which maternal sensitivity and a better home environment in infancy predicted higher self-regulation at 4 years of age (Birmingham, Bub, & Vaughn, 2017)
- Description of recent research that revealed providing parents who engage in inadequate or problematic caregiving with practice and feedback focused on interacting sensitively with their infants enhances parent-infant attachment security (Dozier & Bernard, 2017; Dozier, Bernard, & Roben, 2017; Woodhouse & others, 2017)
- Inclusion of recent research in Zambia, where siblings were substantially involved in caregiving activities, that revealed infants showed strong attachments to both their mothers and their sibling caregivers, with secure attachment being the most frequent attachment classification for both mother-infant and sibling-infant relationships (Mooya, Sichimba, & Bakermans-Kranenburg, 2016)
- Description of a recent study that did not find support for the view that genes influence mother-infant attachment (Leerkes & others, 2017b)
- Updated and expanded coverage of the neuroscience of attachment to include the role of the brain's neurotransmitter dopamine circuits that provide pleasure and reward when mothers care for their infant and are exposed to their infants' cues. These experiences and brain changes likely promote mother-infant attachment and sensitive parenting (Feldman, 2017; Kim, Strathearn, & Swain, 2016; Sullivan & Wilson, 2018).
- Discussion of a recent study that found when adults used scaffolding, infants were twice as likely to engage in helping behavior (Dahl & others, 2017)
- Coverage of a recent study of disadvantaged families in which an intervention that involved improving early maternal

- scaffolding was linked to improved cognitive skills when the children were 4 years old (Obradovic & others, 2016)
- Coverage of a recent study in which both paternal and maternal sensitivity assessed when the infant was 10 to 12 months old were linked to the child's cognitive development at 18 months of age and the child's language development at 36 months (Malmburg & others, 2016)
- New content about mothers playing 3 times more often with children than fathers do (Cabrera & Roggman, 2017)
- Inclusion of recent research with low-income families indicating that fathers' playfulness when children were 2 years of age was associated with more advanced vocabulary skills at 4 years of age, while mothers' playfulness when children were 2 years of age was linked to a higher level of emotion regulation at 4 years of age (Cabrera & others, 2017)
- Discussion of a recent study that found negative outcomes on cognitive development in infancy when fathers were more withdrawn and depressed and positive outcomes on cognitive development when fathers were more engaged and sensitive, as well as less controlling with their infants (Sethna & others, 2017)

## **Chapter 7: Physical and Cognitive Development in Early Childhood**

- Inclusion of recent research on how poverty is linked to maturational lags in children's frontal and temporal lobes, and these lags are associated with low school readiness skills (Hair & others, 2015)
- Coverage of a recent study in which young children's higher cognitive ability was linked to increased myelination by 3 years of age (Deoni & others, 2016)
- Discussion of a recent study of 4-year-old girls that found a nine-week motor skill intervention improved the girls' ball skills (Veldman & others, 2017)
- Description of recent research indicating that higher motor skill proficiency in preschool was linked to engaging in a higher level of physical activity in adolescence (Venetsanou & Kambas, 2017)
- Inclusion of recent research that found children with a low level of motor competence had a lower motivation for sports participation and lower global self-worth than their counterparts who had a high level of motor competence (Bardid & others, 2018)
- Discussion of a recent study that revealed 2½-year-old children's liking for fruits and vegetables was related to their eating more fruits and vegetables at 7 years of age (Fletcher & others, 2018)
- Updated data on the percentage of U.S. 2- to 5-year-old children who are obese (Ogden & others, 2016)
- Update on the leading causes of death in young children in the United States (Centers for Disease Control and Prevention, 2017)
- New description of the recently devised 5-2-1-0 obesity prevention guidelines for young children: 5 or more servings of fruits and vegetables, no more than 2 hours of screen

- time, minimum of 1 hour of physical activity, and 0 sugar-sweetened beverages daily (Khalsa & others, 2017)
- New discussion of a longitudinal study that revealed when young children were exposed to environmental tobacco smoke they were more likely to engage in antisocial behavior at 12 years of age (Pagani & others, 2017)
- Revisions based on feedback from leading expert Megan McClelland
- Inclusion of recent research showing the effectiveness of the Tools of the Mind approach in improving a number of cognitive processes and academic skills in young children (Blair & Raver, 2014)
- New research indicating that parental engagement in mind-mindedness advanced preschool children's theory of mind (Hughes, Devine, & Wang, 2017)
- Inclusion of a recent study of 3- to 5-year-old children that revealed earlier development of executive function predicted theory of mind performance, especially for false-belief tasks (Doenyas, Yavuz, & Selcuk, 2017)
- Updated and expanded theory of mind content involving various aspects of social interaction, including the influence of secure attachment and mental state talk, parental engagement, and living in a higher-socioeconomic-status family (Devine & Hughes, 2018a, b)
- Coverage of a recent study in which theory of mind predicted the severity of autism in children (Hoogenhout & Malcolm-Smith, 2017)
- Revisions in the discussion of young children's language development based on feedback from leading experts Roberta Golinkoff and Virginia Marchman
- Expanded discussion of young children's literacy and the key aspects involved
- Coverage of a recent multigenerational study that found when both children and their mothers participated in Head Start, positive cognitive and socioemotional outcomes occurred for the children (Chor, 2018)
- Update on the increase in publicly funded preschool programs that now exist in 42 states plus the District of Columbia (National Institute for Early Education Research, 2016)
- Description of two recent studies that confirmed the importance of improved parenting engagement and skills in the success of Head Start programs (Ansari & Gershoff, 2016; Roggman & others, 2016)

## **Chapter 8: Socioemotional Development in Early Childhood**

- New emphasis on the degree to which young children learn by observing the behavior of others, including a recent study in which young children who observed a peer being rewarded for confessing to cheating were more likely to be honest in the future (Ma & others, 2018)
- Inclusion of recent research indicating that a broad capacity for self-evaluative emotion was present in the preschool years and was linked to young children's empathetic concern (Ross, 2017)

- Description of a recent study in which young children with higher emotion regulation were more popular with their peers (Nakamichi, 2018)
- New commentary about connections between different emotions and how they may influence development, including a recent study in which participants' guilt proneness combined with their empathy to predict an increase in prosocial behavior (Tostevelt, Sutterlin, & Lugo, 2016)
- New discussion of how recent research has documented the role of guilt in young children's cooperation (Vaish, 2018; Vaish, Carpenter, & Tomasello, 2016)
- Coverage of a recent study in Great Britain in which gender non-conforming boys were most at risk for peer rejection (Braun & Davidson, 2017)
- Inclusion of a recent research review of a large number of studies that found authoritarian parenting was associated with a higher level of externalizing problems (Pinquart, 2017)
- Coverage of a recent study in which an authoritarian style, as well as pressure to eat, were associated with a higher risk for being overweight or obese in young children (Melis Yavuz & Selcuk, 2018)
- Discussion of a recent study that revealed children of authoritative parents engaged in more prosocial behavior than their counterparts whose parents used the other parenting styles discussed in the section (Carlo & others, 2018)
- Description of a recent research review in which authoritative parenting was the most effective parenting style in predicting which children and adolescents would be less likely to be overweight or obese later in their development (Sokol, Qin, & Puti, 2017)
- Inclusion of a recent research review of risk factors for engaging in child neglect which concluded that most risks involved parental factors, including a history of antisocial behavior/criminal offending, having mental/physical problems, and experiencing abuse in their own childhood (Mulder & others, 2018)
- New commentary about how in many traditional cultures, fathers use an authoritarian style; in such cultures, children benefit more when mothers use an authoritative parenting style
- Coverage of a recent research review that concluded there is widespread approval of corporal punishment by U.S. parents (Chiocca, 2017)
- Discussion of a longitudinal study that found harsh physical punishment in childhood was linked to a higher incidence of intimate partner violence in adulthood (Afifi & others, 2017b)
- Description of a recent Japanese study in which occasional spanking at 3 years of age was associated with a higher level of behavioral problems at 5 years of age (Okunzo & others, 2017)
- Discussion of a recent meta-analysis that found when physical punishment was not abusive, physical punishment still was linked to detrimental child outcomes (Gershoff & Grogan-Kaylor, 2016)
- Coverage of a recent study that found physical abuse was linked to lower levels of cognitive performance and school engagement in children (Font & Cage, 2018)
- Inclusion of a recent study that revealed exposure to either physical or sexual abuse in childhood and adolescence was linked to an increase in 13- to 18-year-olds' suicidal ideation, plans, and attempts (Gomez & others, 2017)
- Description of a longitudinal study in which experiencing abuse and neglect in the first five years of life was linked to having more interpersonal problems and lower academic achievement from childhood through the thirties (Raby & others, 2018)
- Coverage of a recent study that indicated a bidirectional association between a child's behavior (conduct problems, for example) and quality of sibling relationships (Pike & Oliver, 2017)
- Discussion of a recent study in which experiencing maltreatment and parental divorce during childhood was linked to midlife suicidal ideation (Stansfield & others, 2017)
- Coverage of a recent study that found interparental hostility was a stronger predictor of children's insecurity and externalizing problems than interparental disagreement and low levels of interparental cooperation (Davies & others, 2016)
- Description of recent research on non-residential fathers in divorced families that linked high father-child involvement and low interparental conflict to positive child outcomes (Flam & others, 2016)
- Discussion of a recent study that found co-parenting following divorce was positively associated with better mental health and higher self-esteem and academic achievement (Lamela & Figueiredo, 2016)
- Updated data on the percentage of gay and lesbian parents who are raising children
- Inclusion of recent research that revealed no differences in the adjustment of school-aged children adopted in infancy by gay, lesbian, and heterosexual parents (Farr, 2017)
- Description of a recent study of lesbian and gay adoptive families in which 98 percent of the parents reported their children had adjusted well to school (Farr, Oakley, & Ollen, 2017)
- Coverage of a longitudinal study that found a multi-component (school-based educational enrichment and comprehensive family services) preschool-to-third-grade intervention with low-income minority children in Chicago was effective in increasing their likelihood of graduating from high school and succeeding in college (Reynolds, Qu, & Temple, 2018)
- Update on the most recent national survey of screen time indicating a dramatic shift to greater use of mobile devices in young children (Common Sense Media, 2013)
- Inclusion of recent research with 2- to 6-year-olds that indicated increased TV viewing on weekends was associated with a higher risk of being overweight or obese (Kondolot & others, 2017)
- Description of a recent meta-analysis that found children's exposure to prosocial media is linked to higher levels of prosocial behavior and empathetic concern (Coyne & others, 2018)

## Chapter 9: Physical and Cognitive Development in Middle and Late Childhood

- New coverage of the increase in brain connectivity as children develop (Faghiri & others, 2018), including a longitudinal study that found greater connectivity between the prefrontal and parietal regions in childhood was linked to

- better reasoning ability later in development (Wendelken & others, 2017)
- Discussion of a recent study of elementary school children that revealed 55 minutes or more of daily moderate-to-vigorous physical activity was associated with a lower incidence of obesity (Nemet, 2016)
- New inclusion of processing speed as one of the cognitive processes positively influenced by children's exercise (Chu & others, 2017)
- Description of a recent meta-analysis that found participation in a sustained program of physical activity improved children's attention, executive function, and academic achievement (de Greeff & others, 2018)
- Coverage of a recent study with 7- to 13-year-olds in which a 6-week high-intensity exercise program resulted in improved cognitive control and working memory (Moreau, Kirk, & Waldie, 2018)
- Inclusion of recent research with 8- to 12-year-olds indicating that screen time was associated with lower connectivity between brain regions, as well as lower language skills and cognitive control, while time spent reading was linked to higher levels in these areas (Horowitz-Kraus & Hutton, 2018)
- Updated data on the percentage of 6- to 11-year-old U.S. children who are obese (Ogden & others, 2016)
- Inclusion of a recent Japanese study that revealed the family pattern that was linked to the highest rates of overweight/obesity in children was a combination of irregular mealtimes and the most screen time for both parents (Watanabe & others, 2016)
- Discussion of a recent study in which children were less likely to be obese or overweight when they attended schools in states that had a strong policy emphasis on serving healthy foods and beverages (Datar & Nicosia, 2017)
- Coverage of a longitudinal study in which elevated levels of body fat and blood pressure beginning in childhood were linked to premature death from coronary heart disease in adulthood (Berenson & others, 2016)
- Inclusion of research indicating that children with high blood pressure are likely to continue having it, as well as other heart abnormalities, as adults (Fan & others, 2018)
- Updated statistics on the percentage of U.S. children who have different types of disabilities and an updated version of Figure 4 (National Center for Education Statistics, 2016)
- Updated statistics on the percentage of U.S. children who have ever been diagnosed with ADHD (Centers for Disease Control and Prevention, 2016)
- Description of a recent research review that found girls with ADHD had more problematic peer relations than typically developing girls in a number of areas (Kok & others, 2016)
- Coverage of a recent research review that concluded ADHD in childhood is linked to a number of long-term outcomes (Erksine & others, 2016)
- Discussion of a recent study that found childhood ADHD was associated with long-term underachievement in math and reading (Voigt & others, 2017)
- Description of a recent study in which individuals with ADHD were more likely to become parents at 12 to 16 years of age (Ostergaard & others, 2017)
- Coverage of a recent research review that concluded stimulation medications are effective in treating children with ADHD in the short term, but long-term benefits of such medications are not clear (Rajeh & others, 2017)
- Inclusion of a recent meta-analysis that concluded physical exercise is effective in reducing cognitive symptoms of ADHD in individuals 3 to 25 years of age (Tan, Pooley, & Speelman, 2016)
- Coverage of a recent meta-analysis in which exercise was associated with better executive function in children with ADHD (Vysniauske & others, 2018)
- Description of a recent study in which an 8-week yoga program improved the sustained attention of children with ADHD (Chou & Huang, 2017)
- Inclusion of recent commentary concluding that despite positive research findings using neurofeedback, mindfulness training, and exercise to improve the attention of children with ADHD, it remains to be determined if these interventions are as effective as stimulant drugs and/or whether they benefit children as add-ons to stimulant drugs (Den Heijer & others, 2017)
- Updated data on the increasing percentage of children who are diagnosed with autism spectrum disorders (Christensen & others, 2016)
- Inclusion of a recent study that revealed a lower level of working memory was the executive function most strongly associated with autism spectrum disorders (Ziermans & others, 2017)
- New coverage of two recent surveys in which only a minority of parents reported that their child's autism spectrum disorder was identified prior to 3 years of age and that one-third to one-half of the cases were identified after 6 years of age (Sheldrick, Maye, & Carter, 2017)
- Discussion of a recent study in which children's verbal working memory was linked to these aspects of both first and second language learners: morphology, syntax, and grammar (Verhagen & Leseman, 2016)
- Inclusion of recent research that found mindfulness-based intervention improved children's attention self-regulation (Felver & others, 2017)
- Description of the most recent revision of the Wechsler Intelligence Scale for Children-V and its increased number of subtests and composite scores (Canivez, Watkins, & Dombrowski, 2017)
- Coverage of recent research that found a significant link between children's general intelligence and their self-control (Meldrum & others, 2017)
- Discussion of a recent two-year intervention with families living in poverty in which maternal scaffolding and positive home stimulation improve young children's intellectual functioning (Obradovic & others, 2016)
- New content on stereotype threat in the section on cultural bias in intelligence tests (Grand, 2017; Lyons & others, 2018; Williams & others, 2018)

- Update on the percentage of U.S. students who are classified as gifted (National Association for Gifted Children, 2017)
- New commentary that vocabulary development plays an important role in reading comprehension (Vacca & others, 2018)
- New description of the importance of encouraging students to monitor their writing progress (Graham & Harris, 2017; Harris & Graham, 2017)
- Coverage of a recent study of 6- to 10-year-old children that found early bilingual exposure was a key factor in bilingual children outperforming monolingual children on tests of phonological awareness and word learning (Jasinska & Petitto, 2018)
- Discussion of research that found bilingual children were better at theory of mind tasks than monolingual children were (Rubio-Fernandez, 2017)

## Chapter 10: Socioemotional Development in Middle and Late Childhood

- New description of recent research studies indicating that children and adolescents who do not have good perspective-taking skills are more likely to have difficulty in peer relations and engage in more aggressive and oppositional behavior (Morosan & others, 2017; Nilsen & Basco, 2017; O’Kearney & others, 2017)
- Inclusion of a longitudinal study that revealed the quality of children’s home environment (which involved assessment of parenting quality, cognitive stimulation, and the physical home environment) was linked to self-esteem in early adulthood (Orth, 2017)
- New discussion of a recent book, *Challenging the Cult of Self-Esteem in Education* (Bergeron, 2018), that criticizes education for promising high self-esteem for students, especially those who are impoverished or marginalized
- Coverage of a longitudinal study that found a higher level of self-control in childhood was linked to a slower pace of aging at 26, 32, and 38 years of age (Belsky & others, 2017)
- New description of an app that is effective in improving children’s self-control: [www.selfregulationstation.com/sr-ipad-app/](http://www.selfregulationstation.com/sr-ipad-app/)
- New discussion of a longitudinal study in which a higher level of emotion regulation in early childhood was linked to a higher level of externalizing problems in adolescence (Perry & others, 2017)
- New section, “Social-Emotional Education Programs,” that describes two increasingly implemented programs: (1) Second Step (Committee for Children, 2018) and (2) Collaborative for Academic, Social, and Emotional Learning (CASEL, 2018)
- Substantial revision of the discussion of Kohlberg’s theory of moral development to make it more concise and clear
- Expanded and updated discussion of Darcia Narváez’s emphasis on the need to make better progress in dealing with an increasing array of temptations and possible wrongdoings in a human social world that is becoming more complex over time (Christen, Narváez, & Gutzwiller, 2018)
- Inclusion of a recent study of individuals from adolescence through middle adulthood that revealed as they got older their external moral identity motivation decreased while their

- internal moral identity motivation increased (Krettenauer & Victor, 2017)
- Discussion of a recent study with eighth-grade students in 36 countries that revealed girls had more egalitarian attitudes about gender roles than boys did (Dotti Sani & Quaranta, 2015)
- Inclusion of recent research indicating that when children have a better parent-child affective relationship with their stepparent, the children have fewer internalizing and externalizing problems (Jensen & others, 2018)
- Coverage of a recent study of young adolescents in which peer rejection predicted increases in aggressive and rule-breaking behavior (Janssens & others, 2017)
- Substantial expansion and updating of information on bullying and cyberbullying (Hall, 2017; Muijs, 2017; Zarate-Garza & others, 2017)
- Description of a longitudinal study that revealed children who were bullied at 6 years of age were more likely to have excess weight gain at age 12 to 13 (Sutin & others, 2016)
- Inclusion of a longitudinal study that revealed being a victim of bullying in childhood was linked to increased use of mental health services five decades later (Evans-Lacko & others, 2017)
- Description of recent longitudinal studies that indicated victims bullied in childhood and adolescence have higher rates of agoraphobia, depression, anxiety, panic disorder, and suicidality in their early to mid-twenties (Arseneault, 2017; Copeland & others, 2013)
- Coverage of recent research in which adolescents who were bullied both directly and through cyberbullying had more behavioral problems and lower self-esteem than their counterparts who were only bullied in one of the two ways (Wolke, Lee, & Guy, 2017)
- Inclusion of a 2018 update on the Every Student Succeeds Act (ESSA), indicating that the Trump administration was going forward with ESSA but giving states much more flexibility in its implementation (Klein, 2018a, b)
- Discussion of a recent intervention (City Connects program) with first-generation immigrant children attending high-poverty schools that was successful in improving the children’s reading and math skills (Dearing & others, 2016)
- New coverage of a recent research review that concluded increases in family income for children in poverty were linked to increased achievement in middle school, as well as higher educational attainment in adolescence and emerging adulthood (Duncan, Magnuson, & Votruba-Drzal, 2017)
- New content on Teach for America (2018) and its efforts to place college graduates in teaching positions in schools located in low-income areas and inclusion of a new *Connecting with Careers* feature on Teach for America instructor Ahou Vaziri
- Coverage of recent research indicating that many parents and teachers with growth mindsets don’t have children and adolescents with growth mindsets (Haimovitz & Dweck, 2017)
- New research that indicates that parents and teachers can create growth mindsets in children and adolescents by doing the following things: teach for understanding, provide feedback that improves understanding, give students opportunities

to revise their work, communicate how effort and struggle are involved in learning, and function as partners with children and adolescents in the learning process (Hooper & others, 2016; Sun, 2015)

- Inclusion of recent research that found students from lower-income families were less likely to have a growth mindset than were students from wealthier families but the achievement of students from lower-income families was more likely to be protected if they had a growth mindset (Claro, Paunesku, & Dweck, 2016)
- Updated data on U.S. students' math and science achievement in comparison with their counterparts in other countries (Desilver, 2017; PISA, 2015; TIMSS, 2015)
- Discussion of a recent study in China that found young adolescents with authoritative parents showed better adjustment than their counterparts with authoritarian parents (Zhang & others, 2017)

## Chapter 11: Physical and Cognitive Development in Adolescence

- Coverage of a recent study of non-Latino White and African American 12- to 20-year-olds in the United States that found they were characterized much more by positive than problematic development (Gutman & others, 2017). Their engagement in healthy behaviors, supportive relationships with parents and friends, and positive self-conceptions were much stronger than their angry and depressed feelings.
- New discussion of three recent studies in Korea and Japan (Cole & Mori, 2018), China (Song & others, 2017), and Saudi Arabia (Al Alwan & others, 2017), all of which found secular trends of earlier pubertal onset in recent years
- Inclusion of research in which onset of menarche before 11 years of age was linked to a higher incidence of distress disorders, fear disorders, and externalizing disorders in females (Platt & others, 2017)
- Description of a recent study that linked childhood sexual abuse to earlier pubertal onset (Noll & others, 2017)
- Coverage of a recent study that found early-maturing girls had higher than average rates of depression and antisocial age as middle-aged adults mainly because their difficulties began in adolescence and did not lessen over time (Mendle & others, 2018)
- New research indicating that early-maturing girls are at increased risk for physical and verbal abuse in dating (Chen, Rothman, & Jaffee, 2018)
- New summary of the influence of early and late maturation on adolescent development
- New content on the role of social media and the Internet in influencing adolescents' body images, including one study of U.S. 12- to 14-year-olds that found heavier social media use was associated with body dissatisfaction (Burnette, Kwitowski, & Mazzeo, 2017)
- Inclusion of a recent study of U.S. college women that found more time on Facebook was related to more frequent body and weight concern related to comparison with other women, more attention to the physical appearance of others, and

more negative feelings about their own bodies (Eckler, Kalyango, & Paasch, 2017)

- New research that revealed young adolescent boys had a more positive body image than their female counterparts (Morin & others, 2017)
- Description of recent research in which reduced connectivity between the brain's frontal lobes and amygdala during adolescence was linked to increased depression (Scheur & others, 2017)
- Coverage of a longitudinal study that found 11- to 18-year-olds who lived in poverty conditions had diminished brain functioning at 25 years of age (Brody & others, 2017). However, those adolescents whose families participated in a supportive parenting intervention did not show this diminished brain functioning.
- New discussion of two recent studies of sexting, one indicating the frequency of sexting by high school students (Strassberg, Cann, & Velarde, 2017), the other documenting that for Latino adolescents, sexting is associated with engaging in oral, vaginal, and anal sex (Romo & others, 2017)
- Updated data on the occurrence of various sexual activities by adolescents according to age, gender, and ethnicity, including updates for Figure 5 (Kann & others, 2016a)
- New commentary that while the majority of sexual minority adolescents have competent and successful developmental paths through adolescence, a recent large-scale study revealed that sexual minority youth have a higher prevalence of health-risk factors than non-sexual-minority youth (Kann & others, 2016b)
- Updated data on the percentage of adolescent males and females who engage in oral sex (Child Trends, 2015)
- Description of a recent study that found that early sexual debut was associated with a number of problems, including sexual risk taking, substance use, violent victimization, and suicidal thoughts and attempts in both sexual minority and heterosexual adolescents (Lowry & others, 2017)
- Discussion of a recent study of Korean girls in which early menarche was associated with earlier initiation of sexual intercourse (Kim & others, 2017)
- Inclusion of recent research in which adolescents who in the eighth grade reported greater parental knowledge and more rules about dating were less likely to initiate sex between the eighth and tenth grade (Ethier & others, 2016)
- Description of a recent study of African American girls that revealed those for whom religion was very or extremely important were much more likely to have a later sexual debut (George Dalmida & others, 2018)
- Updated data on the percentage of adolescents who use contraceptives when they have sexual intercourse (Kann & others, 2016a)
- Updated data on the continued decline in adolescent pregnancy to a historic low in 2015 (Martin & others, 2017)
- Important new section on the increasing number of medical organizations and experts who have recently recommended that adolescents use long-acting reversible contraception (LARC), which consists of intrauterine devices (IUDs) and

- contraceptive implants (Allen & others, 2017; Diedrich, Klein, & Peipert, 2017; Society for Adolescent Medicine, 2017)
- New research on factors that are linked to repeated adolescent pregnancy (Dee & others, 2017; Maravilla & others, 2017)
- Inclusion of recent studies and research views that find comprehensive sex education programs and policies are far more effective in pregnancy prevention, reduction of sexually transmitted infections, and delay of sexual intercourse than are abstinence-only programs and policies (Denford & others, 2017; Jaramillo & others, 2017; Santelli & others, 2017)
- New content on the recent increase in abstinence-only-until-marriage (AOUM) policies and programs in the United States that don't seem to recognize that a large majority of adolescents and emerging adults will initiate sexual intercourse, especially given the recent increase in the age at which U.S. males and females get married (Society of Adolescent Health and Medicine, 2017)
- Updated data on the percentage of U.S. adolescents who are obese (Centers for Disease Control and Prevention, 2016)
- Updated national data on adolescents' exercise patterns, including gender and ethnic variations (Kann & others, 2016a)
- Updated data on the significant gender differences in exercise in adolescence, with females exercising far less than males (YRBSS, 2016)
- Coverage of recent research indicating that a combination of regular exercise and a diet plan results in weight loss and enhanced executive function in adolescents (Xie & others, 2017)
- Description of a recent research review concluding that among a number of cognitive factors, memory was the factor that was most often improved by exercise in adolescence (Li & others, 2017)
- Update on the low percentage of adolescents who get 8 hours of sleep or more per night (Kann & others, 2016a)
- Discussion of a recent experimental study in which adolescents' sleep was restricted to five hours for five nights, then restored to ten hours for two nights, which negatively affected their sustained attention, especially in the early morning (Agostini & others, 2017)
- Inclusion of a recent national study of more than 10,000 13-to 18-year-olds that revealed that a number of factors involving sleep timing and duration were associated with increased rates of anxiety, mood disorders, substance abuse, and behavioral disorders (Zhang & others, 2017)
- Description of a recent study of college students that revealed consistently low sleep duration was associated with less effective attention the next day (Whiting & Murdock, 2016)
- Discussion of a recent study of college students that found a higher level of text messaging activity during the day and at night was related to a lower level of sleep quality (Murdock, Horissian, & Crichtlow-Ball, 2017)
- Inclusion of new content indicating increasing concern about the rising number of adolescents who mix alcohol and energy drinks, a practice that is linked to higher rates of risky driving (Wilson & others, 2018)
- Updated coverage of the Monitoring the Future study's assessment of drug use by secondary school students, with 2017 data on U.S. eighth-, tenth-, and twelfth-graders (Johnston & others, 2018). Included in the update is an important discussion of how the increase in adolescent use of illicit drugs in the last decade is due to the increased use of marijuana by adolescents.
- Updated coverage of the Monitoring the Future study's assessment of adolescents' frequency of vaping nicotine, which now is occurring more frequently than adolescents' cigarette smoking (Johnston & others, 2018)
- Description of a recent meta-analysis of longitudinal studies that found when adolescents use e-cigarettes they are at increased risk for subsequent cigarette smoking (Soneji & others, 2018)
- Inclusion of recent research in which parental monitoring was linked to a lower level of polysubstance use by adolescents (Chan & others, 2017)
- Description of a recent intervention study that revealed Latino parents who had participated in a program that emphasized the importance of parental monitoring had adolescents who engaged in lower levels of drug use than a control group of adolescents whose parents had not participated in the program (Estrada & others, 2017)
- Discussion of a recent large-scale national study in which friends' alcohol use was a stronger influence on adolescents' alcohol use than parental use (Deutsch, Wood, & Slutske, 2018)
- New research indicating that having an increase in Facebook friends across two years in adolescence was linked to an enhanced motivation to be thin (Tiggemann & Slater, 2017)
- Coverage of a recent study in which greater use of social networking sites was linked to increased narcissism (Gnambs & Appel, 2018)
- Inclusion of new information from the Bill and Melinda Gates Foundation (2017, 2018) indicating that many adolescents graduate from high school without obtaining the necessary academic skills to succeed in college or to meet the demands of the modern workplace
- Updated data on school dropouts, including the dramatic decrease in dropout rates for Latino adolescents in recent years (National Center for Education Statistics, 2017)
- Inclusion of new information on the Bill and Melinda Gates Foundation's (2011, 2016) funding of a new generation of digital courseware to improve students' learning
- Updates on expansion of "I Have a Dream" programs to encompass 28 states plus Washington, DC, and New Zealand ("I Have a Dream Foundation," 2017)

## Chapter 12: Socioemotional Development in Adolescence

- Coverage of research indicating that low self-esteem in early adolescence predicted depressive symptoms in late adolescence and emerging adulthood (Messelink, Van Roekel, & Oldehinkel, 2018)
- New discussion of recent longitudinal studies that revealed the ethnic identity of adolescents is influenced by positive and diverse friendships (Rivas-Drake & others, 2017; Santos & others, 2017)

- Description of a recent study that revealed high school students who reported turning to spiritual beliefs when they were experiencing problems were less likely to engage in substance use (Debnam & others, 2018)
- Discussion of a recent study across three countries (England, Scotland, and Canada) in which adolescents who reported having a higher level of spirituality were more likely to have positive health outcomes (Brooks & others, 2018)
- Description of a recent study of Chinese American families that found parent-adolescent conflict increased in early adolescence, peaked at about 16 years of age, and then declined through late adolescence and emerging adulthood (Juang & others, 2018)
- Inclusion of recent research with fifth- to eighth-graders in which a higher level of parental monitoring was associated with students' having higher grades (Top, Liew, & Luo, 2017)
- Coverage of a study that found adolescents with high levels of depressed mood were likely to engage in drinking when their parents engaged in parental monitoring (Kelly, Becker, & Spirito, 2017). However, in this study, parents with a high level of depressed mood were less likely to monitor their adolescents effectively than their counterparts who were less depressed.
- Inclusion of a recent study that revealed from 16 to 20 years of age, adolescents perceived that they had increasing independence and a better relationship with their parents (Hadiwijaya & others, 2017)
- Discussion of a recent study of Latino families that revealed a higher level of secure attachment with mothers during adolescence was linked to a lower level of heavy drug use (Gattamorta & others, 2017)
- Coverage of a recent longitudinal study that found a secure base of attachment knowledge in adolescence and emerging adulthood was predicted by observations of maternal sensitivity across childhood and adolescence (Waters, Ruiz, & Roisman, 2017)
- Discussion of a recent study that found boys were more likely to be influenced by peer pressure involving sexual behavior than were girls (Widman & others, 2016)
- Description of recent research in which adolescents adapted their smoking and drinking behavior to that of their best friends (Wang & others, 2016)
- Inclusion of recent research on adolescent girls that found friends' dieting predicted whether adolescent girls would engage in dieting or extreme dieting (Balantekin, Birch, & Savage, 2018)
- Discussion of a recent study indicating that friendship quality was linked to the quality of romantic relationships in adolescence (Kochendorfer & Kerns, 2017)
- Inclusion of recent research in which having a supportive romantic relationship in adolescence was linked with positive outcomes for adolescents who had a negative relationship with their mothers (Szwebo, Hessel, & Allen, 2017)
- Discussion of recent research that revealed mother-daughter conflict in Mexican American families was linked to an increase in daughters' romantic involvement (Tyrell & others, 2016)
- New main section on "Socioeconomic Status and Poverty"
- Inclusion of a recent study that found of 13 risk factors, low SES was the most likely to be associated with smoking initiation in fifth graders (Wellman & others, 2017)
- Discussion of a recent Chinese study in which adolescents in low-SES families were more likely to have depressive symptoms (Zhou, Fan, & Yin, 2017)
- Coverage of a U.S. longitudinal study that revealed low SES in adolescence was linked to having a higher level of depressive symptoms at age 54 for females (Pino & others, 2018). In this study, low-SES females who had completed college were less likely to have depressive symptoms than low-SES females who had not completed college.
- Inclusion of a U.S. longitudinal study that found low SES in adolescence was a risk factor for cardiovascular disease 30 years later (Doom & others, 2017)
- Coverage of a recent study of 12- to 19-year-olds that found their perceived well-being was lowest when they had lived in poverty from 0 to 2 years of age (compared with 3 to 5, 6 to 8, and 9 to 11 years of age) and also indicating that each additional year lived in poverty was associated with lower perceived well-being in adolescence (Gariepy & others, 2017)
- Description of a recent study that found these four psychological and social factors predicted higher achievement by adolescents living in poverty: (1) academic commitment, (2) emotional control, (3) family involvement, and (4) school climate (Li, Allen, & Casillas, 2017)
- Description of a recent study comparing Asian, Latino, and non-Latino immigrant adolescents in which immigrant Asian adolescents had the highest level of depression, lowest self-esteem, and experienced the most discrimination (Lo & others, 2017)
- New discussion of various ways that stress can negatively influence the development of ethnic minority families and adolescents (Davis & others, 2018)
- Inclusion of a recent study of Mexican-origin youth that revealed when adolescents reported a higher level of familism, they engaged in lower levels of risk taking (Wheeler & others, 2017)
- Description of a recent study in which night-time mobile phone use and poor sleep behavior increased from 13 to 16 years of age (Vernon, Modecki, & Barber, 2018)
- Discussion of a recent study in which heavy media multitaskers were less likely to delay gratification and more likely to endorse intuitive, but wrong, answers on a cognitive reflection task (Schutten, Stokes, & Arnell, 2017)
- Coverage of recent research that found less screen time was linked to adolescents' better health-related quality of life (Wang & others, 2018) and that a higher level of social media use was associated with a higher level of heavy drinking by adolescents (Brunborg, Andreas, & Kvaavik, 2017)
- Updated data on the percentage of adolescents who use social networking sites and engage in text messaging daily (Lenhart, 2015; Lenhart & others, 2015)
- Updated statistics on the decline in U.S. juvenile delinquency cases (Hockenberry & Puzzanchera, 2017)
- Inclusion of a recent study of more than 10,000 children and adolescence which found that living in a family environment characterized by poverty and child maltreatment was linked

- to increased risk of entering the juvenile justice system in adolescence (Vidal & others, 2017)
- Description of a recent study of middle school adolescents that found peer pressure for fighting and friends' delinquent behavior were linked to adolescents' aggression and delinquent behavior (Farrell, Thompson, & Mehari, 2017)
- Inclusion of recent research in which adolescent males with callous-unemotional traits were at increased risk of engaging in delinquency (Ray & others, 2017)
- New content indicating that at 12 years of age, 5.2 percent of females and 2 percent of males had experienced first-onset depression (Breslau & others, 2017). Also in this study, the cumulative incidence of depression from 12 to 17 years of age was 36 percent for females and 14 percent for boys.
- Recent research that found co-rumination with friends was linked to greater peer stress for adolescent girls (Rose & others, 2017)
- Discussion of recent research indicating that family therapy can be effective in reducing adolescent depression (Poole & others, 2018)
- Inclusion of a recent study that revealed adolescents who were isolated from their peers and whose caregivers emotionally neglected them were at significant risk for developing depression (Christ, Kwak, & Lu, 2017)
- Description of a recent meta-analysis in which adolescent females who were obese were more likely to have depression (Quirk & others, 2017)
- Inclusion of recent research indicating that adolescents who were being treated in a suicide clinic experienced lower family cohesion than nonclinical adolescents and adolescents going to a general psychiatric clinic (Jakobsen, Larsen, & Horwood, 2017)
- Updated data on the percentage of U.S. adolescents who seriously consider suicide each year (Kann & others, 2016a)
- Discussion of recent research indicating that the most significant factor in a first suicide attempt during adolescence was major depressive episode, while for children it was child maltreatment (Peyre & others, 2017)
- Description of two recent studies that revealed maltreatment during the childhood years was linked with suicide attempts in adulthood (Park, 2017; Turner & others, 2017)
- Inclusion of a recent study that found a sense of hopelessness predicted an increase in suicidal ideation in depressed adolescents (Wolfe & others, 2018)
- New coverage of the most recent research on Fast Track in which one-third of its reduction in later crime outcomes in emerging adulthood were accounted for by improvements in social and self-regulation skills at 6 to 11 years of age (Sorensen, Dodge, and the Conduct Problems Prevention Research Group, 2016)
- New section, "The Changing Landscape of Emerging and Early Adulthood," that describes how today's emerging and young adults have very different profiles and experiences in education, work, and lifestyles compared with their counterparts from earlier generations (Vespa, 2017)
- Inclusion of recent research indicating that recent cohorts of emerging adults seem more reluctant to mature than earlier cohorts (Smith & others, 2018)
- Description of a national longitudinal study of emerging adult health lifestyles in which three clusters involved whether individuals smoked or not, engaged in binge drinking or not, were obese or not, and exercised regularly or were sedentary: (1) consistently healthy lifestyle, (2) consistently unhealthy lifestyle, and (3) shifting lifestyle over time (Daw, Margolis, & Wright, 2017)
- Inclusion of a recent study with U.S. community college students that found they believe they will be an adult when they are able to care for themselves and others (Katsiaficas, 2017)
- New coverage of recent trends in first-year college students' increasing motivation to be well-off financially, as well as their increased reports of feeling overwhelmed with what they have to do, depressed, and anxious (Eagan & others, 2017)
- Discussion of a recent study in which a higher level of energy drink consumption was linked to more sleep problems in college students (Faris & others, 2017)
- Updated data on the incidence of obesity in U.S. adults (Flegal & others, 2016)
- Discussion of recent international comparisons of 33 countries in which the United States had the highest percentage of obese adults (38.2 percent) and Japan the lowest percentage (3.7); the average of the countries was 23.2 percent of the population being obese (OECD, 2017)
- New section on binge-eating disorder (Browley & others, 2017; Stice & others, 2017; Wilfley, Fitzsimmons-Craft, & Eichen, 2017)
- Inclusion of a recent study in which individuals with BED were more likely to come from families with ineffective functioning, especially in the area of emotional involvement (Tetzlaff & others, 2017)
- Description of cognitive behavior therapy and interpersonal therapy as the most strongly supported therapies for treating binge eating disorder (Grilo, 2017)
- Inclusion of a research review that concluded studies in which individuals are randomly assigned to engage in exercise have shown exercise and pharmacological treatments are equally effective in treating depression (Netz, 2017)
- Coverage of a recent meta-analysis in which moderate and vigorous aerobic exercise resulted in a lower incidence of major depressive disorder (Schuch & others, 2016b)
- Discussion of a national survey that revealed individuals with higher levels of physical activity and cardiovascular fitness were less likely to have depressive symptoms (Loprinzi & others, 2017)
- Description of a recent study that found higher screen time by parents was linked to both parents' and children's higher waist-to-height ratio (Dong & others, 2017)

## Chapter 13: Physical and Cognitive Development in Early Adulthood

- New coverage of Seth Schwartz's (2016) view that emerging adulthood is a two-sided coin in which an individual can experience and pursue positive improvements in their life and well-being or experience downward turns in their life and well-being

- Inclusion of recent research that revealed a mortality risk reduction for individuals who replaced screen time with an increase in daily activity levels (Wijndaele & others, 2017)
- Updated data on binge drinking in college and through early adulthood, including new Figure 3 (Schulenberg & others, 2017)
- Updated data on extreme binge drinking in college students, including data on not only 10 or more drinks at one time in the last two weeks, but also 15 or more in the same time frame (Schulenberg & others, 2017)
- Inclusion of a longitudinal study that revealed frequent binge drinking and marijuana use in the freshman year of college predicted delayed college graduation (White & others, 2018)
- Coverage of a recent study in which pregaming occurred more frequently in college women when they drank alcohol mixed with energy drinks (Linden-Carmichael & Lau-Barraco, 2017)
- Description of a recent U.S. national study of more than 43,000 adults that found between 2001–2002 and 2012–2013, high-risk drinking and alcohol use disorder increased more in women, older adults, ethnic minorities, and individuals from low socioeconomic groups (Grant & others, 2017)
- Updated data on the continuing decline in smoking by U.S. adults, including new data indicating 480,000 individuals in the U.S. die each year because of smoking, a figure that includes 41,000 individuals who die each year as a result of secondhand smoke (Centers for Disease Control and Prevention, 2018a)
- Updated data on the percentage of individuals in emerging adulthood and early adulthood who are using electronic vaporizers (which include e-cigarettes) (Schulenberg & others, 2017)
- Inclusion of recent research in which sexual activity in adults on day 1 was linked to greater well-being the next day (Kashdan & others, 2018). In this study, higher reported sexual pleasure and intimacy predicted more positive affect and less negative affect the next day.
- Coverage of a recent research review that concluded a sexual double standard continues to exist, with stricter social norms for female sexuality (Boislard, van de Bongardt, & Blais, 2016)
- New research indicating that suicidal ideation was associated with entrance into a friends-with-benefits (FWB) relationship as well as continuation of the FWB relationship (Dube & others, 2017)
- Updated data based on a national survey that found 3.8 percent of U.S. adults reported that they were gay, lesbian, bisexual, or transsexual (Gallup, 2015)
- New commentary that whether an individual is heterosexual, gay, lesbian, or bisexual, the person cannot be talked out of his or her sexual orientation (King, 2017)
- Updated statistics on HIV/AIDS in the United States (Centers for Disease Control and Prevention, 2018) and around the world (UNAIDS, 2017)
- New description of a recent study of 1,423 four-year universities in which those with higher tuition, more liquor violations, and greater numbers of fraternity men and athletes were more likely to report rape on their campuses (Wiersma-Mosley, Jozkowski, & Martinez, 2017)
- New coverage of the “Me Too” movement and sexual harassment
- New discussion of a study that found the search for and presence of meaning was linked to wisdom in emerging adults (Webster & others, 2018)
- Updated data on the percentage of full-time and part-time college students who work, which has decreased slightly in recent years (Condition of Education, 2017)
- Updated data on the average number of hours U.S. adults work per week (Saad, 2014)
- Updated data from a recent survey in which employers said that 2017 was the best year since 2007 for recent college graduates to enter the job market (CareerBuilder, 2017)
- Inclusion of recent research in which an increase in job strain increased workers’ insomnia while a decrease in job strain reduced their insomnia (Halonen & others, 2018)
- Description of a recent study that found depression following job loss predicted increased risk of continued unemployment (Stolove, Galatzer-Levy, & Bonanno, 2017)
- Coverage of a study that revealed heavy drinking from age 16 to 30 was linked to higher unemployment in middle age (Berg & others, 2018)

## Chapter 14: Socioemotional Development in Early Adulthood

- Description of a longitudinal study in which disinhibition in childhood predicted self-efficacy in adulthood (Blatny & others, 2015)
- Coverage of a longitudinal study that tracked participants from 8 to 35 years of age and found relative to a low-stable trajectory, an increasing trajectory of shyness was linked to social anxiety, mood, and substance use disorders in adulthood (Tang & others, 2017)
- New content based on a longitudinal study that revealed emotional dysregulation in the fifth grade was linked to engaging in violent crimes at 22 to 23 years of age (Kalvin & Bierman, 2017)
- Inclusion of a longitudinal study of participants from 13 to 72 years of age in which avoidant attachment declined across the lifespan and being in a relationship predicted lower levels of anxious and avoidant attachment across adulthood (Chopik, Edelstein, & Grimm, 2018)
- Description of a study in which attachment-anxious individuals had higher levels of health anxiety (Maunder & others, 2017)
- Coverage of a recent research review that concluded insecure attachment in adulthood was linked to a higher level of social anxiety (Manning & others, 2017)
- Updated data on the number of Americans who have tried Internet matchmaking, and gender differences in the categories males and females lie about in Internet matchmaking forums (statisticbrain.com, 2017)
- Description of recent research on how romantic relationships change in emerging adulthood, including different characteristics of adolescent and emerging adult romantic relationships (Lantagne, Furman, & Novak, 2017)
- New section, “Relationship Education for Adolescents and Emerging Adults,” that examines the increasing number of

- relationship education programs for adolescents and emerging adults, describes their main components, and evaluates their effectiveness (Hawkins, 2018; Simpson, Leonhardt, & Hawkins, 2018)
- Inclusion of data from the recent Match.com Singles in America 2017 national poll that describes Millennials' interest in having sex before a first date, interest in marrying but taking considerable time to get to know someone before committing to a serious relationship, and males' interest in having females initiate the first kiss and ask a guy for his phone number (Match.com, 2017)
  - Updated data on the percentage of U.S. adults who are single (U.S. Census Bureau, 2017)
  - Updated data on the percentage of U.S. adults who are cohabiting, which increased to 18 million people in 2016, an increase of 29 percent since 2007 (Stepler, 2017; U.S. Census Bureau, 2016)
  - Inclusion of recent research indicating that women who cohabited within the first year of a sexual relationship were less likely to get married than women who waited more than one year before cohabiting (Sassler, Michelmore, & Qian, 2018)
  - Coverage of a recent study in which cohabitating individuals were not as mentally healthy as their counterparts in committed marital relationships (Braithwaite & Holt-Lunstad, 2017)
  - Description of a recent study of long-term cohabitation (more than 3 years) in emerging adulthood that found emotional distress was higher in long-term cohabitation than in time spent single, with men especially driving the effect (Memitz, 2018). However, heavy drinking was more common in time spent single than in long-term cohabitation.
  - Updated data on the percentage of U.S. adults who are married (Parker & Stepler, 2017)
  - Updated data on the continued trend to wait longer before getting married in the United States, with the age at first marriage now at 29.5 years for men and 27.4 years for women (Livingston, 2017)
  - Movement of section on gender and friendships from the section on love to the new section on "Gender Relationships"
  - New section, "Cross-Cultural Differences in Romantic Relationships," that includes comparisons of collectivist and individualist cultures (Gao, 2016) as well as intriguing comparisons of romantic relationships in Japan, Brazil, France, and Qatar (Ansari, 2015)
  - Inclusion of a large-scale study that revealed experiencing a romantic breakup lowered individuals' self-esteem but that the effect disappeared one year after the breakup (Luciano & Orth, 2017)
  - New discussion of the marriage paradox including research showing that emerging adults may not be abandoning marriage because they don't like marriage or are disinterested in it, but are delaying marriage because they want to position themselves in the best possible way for developing a healthy marital relationship (Willoughby, Hall, & Goff, 2015; Willoughby & James, 2017)
  - Coverage of a recent study of married, divorced, widowed, and single adults that revealed married individuals had the best cardiovascular profile; single men the worst (Manfredini & others, 2017)
  - Inclusion of a recent study in Great Britain that found no differences in the causes of breakdowns in marriage and cohabitation (Gravning & others, 2017). In this study, "grew apart," "arguments," "unfaithfulness/adultery," "lack of respect, appreciation," and "domestic violence" were the most frequent reasons given for such breakdowns.
  - Description of a study of individuals one to 16 years into their marriage that found an increasing trajectory of tension over the course of the marriage was consistently linked to an eventual divorce (Birditt & others, 2017)
  - Updated statistics on divorce rates around the world, with Russia continuing to have the highest rate (OECD, 2016)
  - Coverage of a study that found individuals who were divorced had a higher risk of having alcohol use disorder (Kendler & others, 2017)
  - Inclusion of recent data indicating that the remarriage rate for men is almost twice as high as it is for women (Livingston, 2017)
  - Updated data on the average age at which U.S. women first give birth, which occurred more frequently in their thirties than in their twenties in 2016 for the first time ever, with an average age of 27 for first-time mothers in 2016 (Centers for Disease Control and Prevention, 2017)
  - New research that found the frequency of sexual intercourse in the second to fourteenth years of a marriage was important to marital satisfaction, but that a satisfying sex life and a warm interpersonal relationship were more important (Schoenfeld & others, 2017)
  - New main section, "Gender Communication, Relationships, and Classification"
  - Extensive new content on transgender (Budge & Orovecz, 2017; Budge & others, 2018a, b; Katz-Wise & others, 2018)
  - Discussion of a variety of terms used to describe transgender individuals
  - New content indicating that it is much more common to have a transgender identity of being born male but identifying with being a female than the reverse (Zucker, Lawrence, & Kreukels, 2016)
  - Discussion of a recent research review that concluded transgender youth have higher rates of depression, suicide attempts, and eating disorders than their non-transgender peers (Connolly & others, 2016)

## **Chapter 15: Physical and Cognitive Development in Middle Adulthood**

- Inclusion of a recent research review that found positive subjective time perceptions were linked to better health and well-being while negative subjective time perceptions were associated with lower levels of health and well-being (Gabrian, Dutt, & Wahl, 2017)
- Description of a recent study in which undergraduate students were shown a computer-generated graph of a person identified as a younger adult, middle-aged adult, or older adult (Kelley, Soboroff & Lovaglia, 2017). When asked

- which person they would choose for a work-related task, they selected the middle-aged adult most often.
- New commentary about how neurobiological functioning slowly declines in middle age, but competence at work and completing life's everyday tasks usually show little or no decline. Also, because of a sense of urgency, many adults may do their best work in middle age.
  - Update on the percentage of adults 40 to 59 years of age classified as obese (40.2 percent) (Centers for Disease Control and Prevention, 2016)
  - Coverage of recent research in which an increase in weight gain from early to middle adulthood was linked to an increased risk of major chronic diseases and unhealthy aging (Zheng & others, 2017)
  - Inclusion of recent research that revealed greater intake of fruits and vegetables was linked to increased bone density in middle-aged and older adults (Qui & others, 2017)
  - Discussion of a Chinese study that found men and women who gained an average of 22 pounds or more from 20 to 45–60 years of age had an increased risk of hypertension and cholesterol, as well as elevated triglyceride levels in middle age (Zhou & others, 2018)
  - Description of a recent study that revealed a healthy diet in adolescence was linked to a lower risk of cardiovascular disease in middle-aged women (Dahm & others, 2018)
  - Inclusion of a 32-year study that found individuals who continued to have a lower socioeconomic status through the years of the study had a lower level of cardiovascular health than their counterparts whose SES improved across the study years (Savelieva & others, 2017)
  - New coverage of the American Heart Association's Life's Simple 7—the seven factors that people need to optimize to improve their cardiovascular health
  - Description of a study in which optimal Life's Simple 7 at middle age was linked to better cardiovascular health recovery following a heart attack later in life (Mok & others, 2018)
  - Inclusion of a longitudinal study in which increased respiratory fitness from early adulthood to middle adulthood was linked to less decline in lung health over time (Benck & others, 2017)
  - New research indicating that perceiving oneself as feeling older predicted an increase in sleep difficulties in middle age over time (Stephan & others, 2017)
  - Discussion of a recent study of young and middle-aged adults that found females had more sleep problems than males (Rossler & others, 2017). However, the good news in this study is that a majority of individuals (72 percent) reported that they did not have any sleep disturbances.
  - New content on the important role of cortisol in stress and health (Leonard, 2018; Wichmann & others, 2017)
  - Coverage of a recent study of men and women from 21 to 55 years of age in which married individuals had lower cortisol levels than their never-married or previously married counterparts (Chin & others, 2017)
  - Inclusion of recent research indicating a bidirectional link between perceived control and health (Infurna & others, 2013; Robinson & Lachman, 2017)
  - Discussion of a recent study that found the more frequently middle-aged and older adults had sex, the better their overall cognitive functioning was, and especially so in working memory and executive function (Wright, Jenks, & Demeyere, 2018)
  - Coverage of a recent cross-cultural study in China that found Mosuo women had fewer negative menopausal symptoms and higher self-esteem than Han Chinese women (Zhang & others, 2016)
  - Discussion of a recent study that revealed the more minutes per week women exercised during the menopausal transition, the lower their stress level was (Guerin & others, 2018)
  - Description of the increased use of acupuncture to reduce negative symptoms of menopause (Lund & others, 2018)
  - Inclusion of the recent position statement of the North American Menopause Society (2017) regarding the current status of research on various aspects of hormone replacement therapy (HRT)
  - Inclusion of a consensus that there is a slight increase in breast cancer for women taking hormone replacement therapy (American Cancer Society, 2017; [www.breastcancer.org](http://www.breastcancer.org), 2017)
  - Discussion of recent studies and research reviews that indicate testosterone replacement therapy (TRT) does not increase the risk of prostate cancer (Debruyne & others, 2017; Yassin & others, 2017)
  - Description of a recent study in which TRT-related benefits in quality of life and sexual function were maintained for 36 months after initial treatment (Rosen & others, 2017)
  - Inclusion of recent research on 24- to 93-year-olds that found everyday problem solving performance increased from early to middle adulthood but began to show a decline at about 50 years of age (Chen, Hertzog, & Park, 2017). In this study, fluid intelligence predicted everyday problem-solving performance in young adults but, with increasing age, crystallized intelligence became a better predictor.
  - Coverage of a Danish study across 33 years of individuals 20 to 93 years of age which found that those who engaged in a light level of leisure-time physical activity lived 2.8 years longer, those who engaged in a moderate level of leisure-time physical activity lived 4.5 years longer, and those who engaged in a high level of leisure-time physical activity lived 5.5 years longer (Schnohr & others, 2017)
  - Updated data on the modest decline in the percentage of Americans who believe in God and think religion is very important in their lives (Pew Research Center, 2015)
  - Inclusion of recent data on the percentage of women (60 percent) and men (47 percent) who say religion is very important in their lives (Pew Research Center, 2016)
  - Discussion of a recent study that found spiritual well-being predicted which heart failure patients would still be alive five years later (Park & others, 2016)
  - New research that indicated adults who volunteered had lower resting pulse rates and their resting pulse rate improved when they were deeply committed to religion (Krause, Ironson, & Hill, 2017)
  - Coverage of a recent study of veterans with combat exposure in which those who engaged in negative religious coping were

more likely to have posttraumatic stress disorder (PTSD) symptoms while those who engaged in positive religious coping were more likely to have perceived posttraumatic growth (PPTG) symptoms (Park & others, 2017)

## Chapter 16: Socioemotional Development in Middle Adulthood

- Discussion of a recent study in which participating in an intergenerational civic engagement program enhanced older adults' self-perceptions of generativity (Gruenewald & others, 2016)
- Inclusion of recent research that found a higher level of generativity in middle age was linked to greater wisdom in late adulthood (Ardelt, Gerlach, & Vaillant, 2018)
- Coverage of a recent study of gender differences in coping with stress that revealed women were more likely than men to seek psychotherapy, talk to friends about the stress, read a self-help book, take prescription medication, and engage in comfort eating (Liddon, Kingerlee, & Barry, 2017). In this study, when coping with stress, men were more likely than women to attend a support group meeting, have sex or use pornography, try to fix problems themselves, and not admit to having problems.
- Discussion of recent research indicating that individuals high in conscientiousness, agreeableness, and extraversion live longer while those high in neuroticism die earlier (Graham & others, 2017)
- Description of recent research that found individuals high in openness to experience have superior cognitive functioning across the life span, have better health and well-being (Strickhouser, Zell, & Krizan, 2017), and are more likely to eat fruits and vegetables (Conner & others, 2017)
- Inclusion of recent research that found conscientiousness was linked to better health and well-being (Strickhouser, Zell, & Krizan, 2017), increased academic success in medical school (Sobowale & others, 2018), decreased addiction to Instagram (Kircaburun & Griffiths, 2018), lower risk for alcohol addiction (Raketic & others, 2017), and lower risk of dementia (Terracciano & others, 2017)
- Discussion of recent research indicating that people high in agreeableness have a lower risk of dementia (Terracciano & others, 2017)
- Description of recent research in which individuals who were higher in neuroticism had a higher risk of dementia (Terracciano & others, 2017)
- Inclusion of a recent research review in which the personality trait that changed the most as a result of psychotherapy was emotional stability, followed by extraversion (Roberts & others, 2017). In this study, the personality traits of individuals with anxiety disorders changed the most, those with substance use disorders the least.
- Inclusion of recent research in which more pessimistic college students had more anxious mood and stress symptoms (Lau & others, 2017)
- Discussion of a recent study of married couples that revealed the worst health outcomes occurred when both spouses decreased their optimism across a four-year period (Chopik, Kim, & Smith, 2018)
- Description of a recent study in which lonely individuals who were optimistic had a lower suicide risk (Chang & others, 2018)
- Inclusion of recent research with middle-aged adults that indicated positive marital quality was linked to better health for both spouses (Choi, Yorgason, & Johnson, 2016)
- New discussion of the increasing divorce rate in middle-aged adults and the reasons for the increase (Stepler, 2017), as well as the recent labeling of divorce in adults age 50 and older as "gray divorce" (Crowley, 2018)
- Coverage of a recent study of divorced adults 50+ years old that found divorce was more likely to occur if couples had been married fewer years, had a marriage of lower quality, did not own a home, and had financial problems (Lin & others, 2018)
- Description of a recent Swiss study of middle-aged adults in which single divorcees were more lonely and less resilient than their married and remarried counterparts (Knopfli & others, 2016). Also in this study, single divorcees had the lowest self-reported health.
- New commentary that grandparents play especially important roles in grandchildren's lives when family crises such as divorce, death, illness, abandonment, or poverty occur (Dolbin-McNab & Yancura, 2017)
- New content on how grandparents in many countries facilitate women's participation in the labor force
- Coverage of a recent study of adult grandchildren in which grandparents provided more frequent emotional support to the grandchildren when parents were having life problems and more frequent financial support when parents were unemployed (Huo & others, 2018)
- Description of the increasing percentage of grandparents who are raising grandchildren (U.S. Census Bureau, 2015)
- Discussion of a recent study that revealed parent and offspring marital disruptions were linked, with each parental disruption associated with a 16 percent increase in the number of offspring marital disruptions (Amato & Patterson, 2017). In this study, marital conflict also was related to more marital disruptions in offspring.
- Coverage of research indicating that when a grown child suffers problems, it decreases their parents' well-being (Suitor & others, 2017). When more than one grown child have problems, parental well-being decreases further.
- Inclusion of recent research in which older adult fathers had elevated depressive symptoms when they reported having more negative relationships with their middle-aged children (Polenick & others, 2018). Also in this study, the association was stronger for older adult fathers and their middle-aged daughters, and the fathers had better health when they had better relationships with their daughters.
- Description of an intergenerational study of African Americans that found grown children who had a better relationship with their biological father (but not their social father) were more involved as fathers with their own children (Brown, Kogan, & Kim, 2018)
- Coverage of a recent Chinese intergenerational study in which sons were more likely to receive financial and helping/caring support from elderly parents (Chen & Jordan, 2018).

Also in this study, sons were more likely to give financial support and daughters to give helping and caring support to elderly parents.

## Chapter 17: Physical Development in Late Adulthood

- Updated life expectancy rates for a number of developed countries (Central Intelligence Agency, 2015)
- Discussion of recent projections for life expectancy in 2030 in 35 developed countries, with the United States increasing in life expectancy but having one of the lowest projected increases of all countries in the study (Kontis & others, 2017). In this study, South Korea is expected to have the highest life expectancy of the 35 countries in 2030, with South Korean women the first group to break the 90-year barrier with a projected life expectancy of 90.8 in 2030.
- Life expectancy updates in the United States with gender and ethnic comparisons (U.S. Department of Health and Human Services, 2017)
- Coverage of a recent study of U.S. and Japanese centenarians that found in both countries, health resources (better cognitive function, fewer hearing problems, and positive daily living activities) were linked to a higher level of well-being (Nakagawa & others, 2018)
- New description of a study using the Chinese Longitudinal Healthy Longevity Survey that found severe loneliness at prior assessment points predicted poorer cognitive function at subsequent assessment points (Zhong & others, 2017)
- Update on the oldest living person in the world and in the United States in 2017
- Update on gender differences in the oldest people alive in the world today, with no men among the oldest 25 individuals
- Updated and expanded coverage of the diseases that are linked to mitochondrial dysfunction to include diabetic kidney disease (Forbes & Thorburn, 2018)
- Inclusion of recent research in which older adults lost significant excess weight and improved their mobility considerably by participating in a community-based weight reduction program (Rejeski & others, 2017)
- Updated information about diseases that women are more likely to die from than men are (Ostan & others, 2016)
- Discussion of a recent study that revealed long sleep duration predicted all-cause mortality in individuals 65 years and older (Beydoun & others, 2017)
- Coverage of a recent Korean study in which sleeping 9 hours a day or longer was linked to a higher incidence of sarcopenia (Kwon & others, 2017)
- Description of a recent Chinese study in which older adults who engaged in a higher level of overall physical activity, leisure-time exercise, and household activity were less likely to have sleep problems (Li & others, 2018)
- Inclusion of a recent study of older adults that revealed walking a dog regularly was associated with better physical health (Curl, Bibbo, & Johnson, 2017)
- Description of a recent study that found a 10-week exercise program improved the physical (aerobic endurance, agility,

and mobility) and cognitive (selective attention and planning) functioning of elderly nursing home residents (Pereira & others, 2017)

- Expanded discussion of falls in elderly adults, including information that falls are the leading cause of fatal injuries among individuals who are 65 years and older (National Center for Health Statistics, 2018)
- Coverage of a recent study in which individuals who had relative to low physical fitness and increased to intermediate or high fitness were at a lower risk for all-cause mortality (Brawner & others, 2017)
- Description of a recent study of frail elderly adults in which a high-intensity walking intervention reduced their frailty, increased their walking speed, and improved their mobility (Danilovich, Conroy, & Hornby, 2018)
- Inclusion of a recent research review that concluded exercise reduces depressive symptoms in older adults (Seo & Chao, 2018)
- Coverage of recent research on older adults that found poorer visual function was associated with cognitive decline (Monge & Madden, 2016; Roberts & Allen, 2016), and with having fewer social contacts and engaging in less challenging social/leisure activities (Cimarolli & others, 2017)
- New coverage of the recent increased interest in using stem-cell-based therapy to treat macular degeneration (Bakondi & others, 2017)
- New discussion of a recent Japanese study of older adults (mean age: 76 years) in which undergoing cataract surgery reduced the risk of developing mild cognitive impairment (Miyata & others, 2018)
- Coverage of a recent study of 80- to 106-year-olds that found a substantial increase in hearing loss in the ninth and tenth decades of life (Wattamwar & others, 2017). In this study, although hearing loss was universal in the 80- to 106-year-olds, only 59 percent wore hearing aids.
- In a recent study, older adults with a hearing problem who used a hearing aid were less likely to be lonely than their counterparts with a hearing problem who did not use a hearing aid (Weinstein, Sirow, & Moser, 2016)
- New discussion of a recent study of 65- to 85-year-olds that found dual sensory loss in vision and hearing was linked to reduced social participation and less social support, as well as increased loneliness (Mick & others, 2018)
- Coverage of a recent study of elderly adults in which those who had a dual sensory impairment involving vision and hearing had functional limitations, experienced cognitive decline, were lonely, and had communication problems (Davidson & Gutherie, 2018)
- Discussion of another recent study in which older adults with a dual sensory impairment involving vision and hearing had more depressive symptoms (Han & others, 2018)
- Coverage of a recent research review that concluded older adults have a lower pain sensitivity but only for lower pain intensities (Lautenbacher & others, 2017)
- Inclusion of a recent study in which a Mediterranean diet lowered the risk of cardiovascular problems in adults age 65 and older (Nowson & others, 2018)

- Update on the leading causes of death in older adults, with recent data indicating that beginning in the 65- to 74-year-old age range, cancer has replaced cardiovascular disease as the leading cause of death in the United States (Centers for Disease Control and Prevention, 2018)
- Inclusion of a recent study that revealed moderate drinkers were more likely to be alive and not have a cognitive impairment at 85 years of age (Richards & others, 2018)
- Inclusion of recent research on older adults in which resistance training improved their physical functioning, psychological well-being, and quality of life (Pedersen & others, 2017)
- Update on the percentage of older adults who are overweight or obese (Flegal & others, 2016)
- Coverage of four recent studies that found overweight and obese older adults are less healthy and experience an earlier death than their normal-weight counterparts (Batsis & others, 2018; Bowman & others, 2017; Khan & others, 2018; Stenholm & others, 2017)

## Chapter 18: Cognitive Development in Late Adulthood

- Updated chapter opening story on Helen Small's remarkable life and longevity
- Inclusion of a recent study that found slow processing speed predicted an increase in older adults' falls one year later (Davis & others, 2017)
- Coverage of a recent study in which impaired visual processing speed predicted an increase in vehicle crashes in older adults (Huisingsh & others, 2017)
- New research that indicated cognitive speed of processing training was associated with driving frequency and prolonged driving in older adults across a five-year period (Ross & others, 2016)
- Discussion of a recent experimental study in which high-intensity aerobic training was more effective than moderate-intensity aerobic training or resistance training in improving older adults' processing speed (Coetsee & Terblanche, 2017)
- Coverage of a recent study of older adults that found slower processing speed was associated with unsafe driving (Hotta & others, 2018)
- Inclusion of a recent study of older adults that found playing games involving processing speed for five sessions a week across four weeks improved their processing speed (Nouchi & others, 2017)
- Inclusion of a recent study of older adults in which using compensation strategies was associated with higher levels of independence in everyday living in both cognitively normal and mildly cognitively impaired older adults (Tomaszewski & others, 2018)
- Discussion of a recent study of older adults which revealed that across a 10-year period women who were physically active experienced less decline in executive function than women who were not physically active (Hamer, Muniz Terrera, & Demakakos, 2018)
- Description of a recent experimental study that revealed yoga practice that included postures, breathing, and meditation

- improved the attention and information processing of older adults (Gothe, Kramer, & McAuley, 2017)
- Coverage of a recent study that found that when older adults regularly engaged in mindfulness meditation, their goal-directed attention improved (Malinowski & others, 2017)
- Inclusion of a recent study indicating that visual distraction especially impaired auditory selective attention in older adults (Van Gerven & Guerreiro, 2016)
- Description of a recent study that found a mindfulness training program improved older adults' explicit memory (Banducci & others, 2017)
- Coverage of a recent study that revealed imagery strategy training improved older adults' working memory (Borella & others, 2017)
- Inclusion of recent research in which aerobic endurance was linked to better working memory in older adults (Zettel-Watson & others, 2017)
- Discussion of recent research with young, middle-aged, and older adults that found all three age groups' working memory improved with training but that older adults improved less than young adults with the training (Rhodes & Katz, 2017)
- New section, "Metacognition," that includes information about strengths and weaknesses in metacognitive skills in older adults compared with those of younger adults (Hargis & others, 2017; McGillivray & Castel, 2017)
- Inclusion of recent research that found young adults made better decisions than older adults in unfamiliar domains, but not in familiar domains (Wayde, Black, & Gilpin, 2017)
- New section, "Mindfulness," reflecting the increased interest in mindfulness training in improving older adults' cognitive functioning (Fountain-Zaragoza & Prakash, 2017)
- Description of a recent study in which self-reflective exploratory processing of difficult life circumstances was linked to a higher level of wisdom (Westrate & Gluck, 2017)
- Discussion of a recent study of cognitive functioning in older adults in ten European countries that found improved memory between 2004 and 2013, with the changes more positive for those who had decreases in cardiovascular diseases and increases in exercise and educational achievement (Hessel & others, 2018)
- New coverage of a recent Australian study that found older adults who had retired from occupations that involved higher complexity maintained their cognitive advantage over their retired counterparts who had worked in less complex occupations (Lane & others, 2017)
- New discussion of a recent study of older adults working in low-complexity jobs that found experiencing novelty in their work (assessed through recurrent work-task changes) was linked to better processing speed and working memory (Oltmanns & others, 2017)
- Inclusion of recent research revealing that older adults with type 2 diabetes had more severe cognitive impairment than their counterparts who did not have the disease (Bai & others, 2017)
- Coverage of a recent study of the oldest-old Chinese that revealed early-stage kidney disease was associated with cognitive decline (Bai & others, 2017)

- Inclusion of a recent study that revealed older adults who continued to work in paid jobs had better physical and cognitive functioning than retirees (Tan & others, 2017)
- New discussion of a study that found those who had retired for health reasons had lower verbal memory and verbal fluency than their counterparts who had retired voluntarily or for family reasons (Denier & others, 2017)
- Coverage of a recent study that found the following were among the most important motives and preconditions to continue working beyond retirement age: financial, health, knowledge, and purpose in life (Sewdas & others, 2017)
- New content on links between nutrition and cognitive aging, including a recent research review that concluded multinutrient approaches using the Mediterranean diet are linked to a lower risk of cognitive impairment (Abbatecola, Russo, & Barbieri, 2018)
- Discussion of a recent study that revealed time to death during terminal decline was a good predictor of cognitive decline over time (Bendayan & others, 2017)
- Description of a recent research review in which engaging in low or moderate exercise was linked to improved cognitive functioning in older adults with chronic diseases (Cai & others, 2017)
- Description of recent research in which participating in physical activity in late adulthood was linked to less cognitive decline (Gow, Pattie, & Geary, 2017)
- Coverage of a recent study that found fish oil supplementation improved the working memory of older adults (Boespflug & others, 2016)
- New description of a study that revealed cognitive training using virtual-reality-based games with stroke patients improved their attention and memory (Gamito & others, 2017)
- Inclusion of a recent study that revealed individuals with Alzheimer disease were less likely to use syntactic components in their language than those who did not have Alzheimer disease (Orimaye & others, 2017)
- Description of a recent study in which the lower working memory capacity of older adults compared with younger adults impaired their comprehension of sentences (Sung & others, 2017)
- New content on Ellen Bialystok and her colleagues' (2016) conclusion that being bilingual may be one of the best ways to delay the onset of Alzheimer disease by as many as four or five years
- Inclusion of recent research in which bilingual Alzheimer patients had better neural network functioning, especially in the neural network involving executive function, than did monolingual Alzheimer patients (Perani & others, 2017)
- Updated statistics on the percentage of U.S. older adults in different age groups in the work force, including 2017 data (Mislinski, 2018)
- Updates on the OECD's surveys on average age of retirement in leading economic countries with France now having the lowest average age and Korea the highest (OECD, 2017)
- Updated data on the average age of retirement that includes 2017 data (Anspach, 2017)
- Inclusion of a recent study that revealed baby boomers expect to work longer than their predecessors from prior generations (Dong & others, 2017)
- Description of a recent research review in which workplace organizational policies, financial security, and poor physical and mental health were antecedents of early retirement (Topa, Depolo, & Alcover, 2018)
- Updated data (2017) on the percentage of American workers who are very confident that they will have a comfortable retirement (Greenwald, Copeland, & VanDerhei, 2017)
- Coverage of a recent research review that concluded in the last two decades depression is not more common in older adults than in younger adults and not more likely to be caused by psychological factors (Haigh & others, 2018). In this review, it also was found that depression in older adults is more likely to be chronic (that is, has a higher rate of relapse) than in younger adults, which is likely linked to higher medical problems in older adults.
- Inclusion of a recent study of community-dwelling older adults in which light physical exercise, taking lessons, using a computer, and participating in community activities predicted a lower level of depressive symptoms (Uemura & others, 2018)
- New discussion of a recent research review that concluded depressed older adults respond to psychological treatments as effectively as their younger adult counterparts do (Haigh & others, 2018). However, also in this review, it was concluded that antidepressants are less effective with older adults than younger adults.
- Researchers have recently found that electroconvulsive treatment (ECT) is more effective than antidepressants in treating older adults' depression (Dols & others, 2017; Rhebergen & others, 2015; Spaans & others, 2015)
- Description of a recent Taiwanese study that found consistent moderate exercise of 15 minutes or more per session three times a week was associated with a lower risk of developing depressive symptoms (Chang & others, 2017)
- Inclusion of recent studies supporting the effectiveness of reminiscence therapy in reducing depressive symptoms in older adults (Wu & others, 2018; Yen & Lin, 2018)
- Coverage of recent national statistics indicating that the suicide rate is highest in the 45-to-64 age group, followed by individuals 85 and over, while the 65–84 age group has a lower rate of suicide than these groups, a rate similar to that of 20- to 34-year-olds (Centers for Disease Control and Prevention, 2015)
- Discussion of a recent study that revealed older adults who had moderate to severe depression were 48 times more likely to engage in suicidal ideation than their counterparts who had minimal to mild depressive symptoms (Rossom & others, 2018)
- Inclusion of recent research on suicide in older adults with content on triggers for suicidal ideation, psychological factors in suicide, and protective factors (Huang & others, 2017)
- Coverage of a recent study in which a decline in socioeconomic status was linked to increased suicide attempts in older adults (Dombrovski & others, 2018)

- Updated data on the percentage of older adults with Alzheimer disease and updates on the significant increase in Alzheimer disease in individuals 85 and older (Alzheimer's Association, 2017)
- New content on women being more likely to have the APOE4 gene than men and commentary about the APOE4 gene being the strongest genetic predictor of late-onset (65 years and older) Alzheimer disease (Dubal & Rogine, 2017)
- New content on APP, PSEN1, and PSEN2 gene mutations being linked to the early onset of Alzheimer disease (Carmona, Hardy, & Guerreiro, 2018)
- New discussion of the epigenetics of Alzheimer disease, including the role of DNA methylation (Kader & others, 2018; Marioni & others, 2018; Zaghlool & others, 2018)
- Update on the five drugs that have been approved by the U.S. Food and Drug Administration to treat Alzheimer disease (Almeida, 2018)
- Inclusion of recent research indicating that older adults who attended religious services regularly lived longer than their counterparts who did not attend these services (Idler & others, 2017)
- Coverage of a recent study in which older adult women had higher levels of spirituality than did older men (Bailly & others, 2018)
- New description of a recent study of older adults in which secure attachment to God was linked to an increase in optimism and self-esteem in the future (Kent, Bradshaw, & Uecker, 2018)
- New discussion of a recent study of older adults in which religious service attendance was associated with higher levels of resilience and lower levels of depression (Manning & Miles, 2018)
- Coverage of a recent study that revealed higher levels of spiritual/religious coping were linked to lower levels of depressive symptoms (Lee & others, 2017)
- Inclusion of a recent study of Latinos that found lack of religiosity was associated with elevated anxiety and depressive symptoms in older adults but not in young and middle-aged adults (Leman & others, 2018)
- Inclusion of a recent meta-analysis that concluded emotional experiences in older adults are more positive than for younger adults (Laureiro-Martinez, Trujillo, & Unda, 2017). Also, in this review, it was concluded that older adults focus less on negative events in the past than younger adults do.
- New commentary by Laura Carstensen (2016) noting that when older adults focus on emotionally meaningful goals they are more satisfied with their lives, feel better, and experience fewer negative emotions
- New recommendations on ways that older adults can become more socially engaged (Sightlines Project, 2016)
- Coverage of a recent study in which emotionally unstable adults' self-esteem declined the most in the second half of life (von Soest & others, 2018). In this study, not having a cohabiting partner, being unemployed and having a disability were associated with having a lower level of self-esteem and a steeper decline in self-esteem over a five-year period.
- New description of a study that found older adults with a higher level of conscientiousness experienced less cognitive decline as they aged (Luchetti & others, 2016)
- New discussion of a study of older adults in which higher levels of neuroticism predicted higher frailty and lower levels of openness to experience and agreeableness predicted lower frailty (Stephan & others, 2017)
- Coverage of a study indicating that in older adults, a higher level of agreeableness was linked to a lower risk of developing dementia while a higher level of neuroticism was associated with a higher risk of developing dementia (Terracciano & others, 2017)
- Discussion or research revealing that older adults with higher levels of openness and lower levels of agreeableness engaged in more frequent sexual activity and had lower levels of sexual dysfunction (Allen & Desille, 2017). Also in this study, higher levels of conscientiousness were related to more conservative attitudes about sex and lower levels of sexual dysfunction.
- Inclusion of recent research indicating that higher levels of conscientiousness, openness to experience, agreeableness, and extraversion were linked to positive emotions in older adults, while neuroticism was associated with negative emotions (Kalbaugh & Huffman, 2017)
- New content indicating that individuals who are extraverted and low in neuroticism are likely to live longer (Graham & others, 2017)
- Discussion of a recent study of 15- to 105-year-old individuals in 29 European countries that revealed younger individuals engaged in age discrimination more than did older individuals (Bratt & others, 2018)
- Updated research indicating that low-SES older adults are at greater risk for an earlier death than higher-SES older adults (Domenech-Abella & others, 2018)
- Updated data on significant increases in use of the Internet, smartphones, and social networking by U.S. older adults (Anderson, 2017)
- Updated data on the percentage of older adults who are married and who are widowed (U.S. Census Bureau, 2017)

## Chapter 19: Socioemotional Development in Late Adulthood

- Description of a recent study that supports the activity theory of aging by indicating that an activity-based lifestyle was associated with lower levels of depression in older adults (Juang & others, 2018)
- Coverage of a study that found an instrumental reminiscence intervention improved the coping skills of older adults (Satorres & others, 2018)
- Inclusion of a recent study of individuals 22 to 94 years of age that revealed on days when middle-aged and older adults, as well as individuals who were less healthy, used more selective optimization with compensation strategies, they reported having a higher level of happiness (Teshale & Lachman, 2016)
- Discussion of a recent study in which older adults reacted with less anger about a personal memory than younger adults did (Kunzmann & others, 2017)

- Coverage of a recent study that found, among older men, those who were married were more likely to endorse stereotypically masculine traits but also to have higher androgyny scores than unmarried older men (Lemaster, Delany, & Strough, 2017)
- Description of a recent study that explored centenarians' marital history and living arrangements with outcomes that were quite different for men and women (Poulain & Herm, 2016)
- Inclusion of a recent study indicating lower rates of divorce among older adults who had been married for a longer time, had better marital quality, owned a home, and were wealthier (Lin & others, 2018)
- Discussion of a recent study in which partnered older adults were more likely to receive Social Security, enjoy relatively higher Social Security benefits, and less likely to live in poverty (Lin, Brown, & Hammersmith, 2017)
- Updated data on the dramatic increase in older adults who are now cohabiting (Stepler, 2017)
- New discussion of recent research on the health and well-being of older LGBT individuals with a focus on comparisons of those who are married, unmarried and partnered, and single (Goldsen & others, 2017)
- Updated data on the percentage of men and women 65 years and older who are divorced, which increased dramatically from 1980 to 2015 (U.S. Census Bureau, 2016b)
- Coverage of a recent national study of older adults in which men who are in cohabiting relationships have psychological well-being that is similar to married men and better than daters and the unpartnered (Wright & Brown, 2017). In contrast, there were few differences in psychological well-being of women based on their partnership status.
- New discussion of research indicating that middle-aged adults feel more positive about providing support for their children than for their aging parents (Birditt & others, 2018)
- Inclusion of recent research that found older adults who volunteered regularly had a lower risk of cognitive impairment (Infurna, Okun, & Grimm, 2016)
- Description of a recent study that revealed older adults reported fewer problems with friends, fewer negative friendship qualities, less frequent contact with friends, and more positive friendship qualities with a specific friend than younger adults did (Schlosnagle & Strough, 2017)
- Inclusion of a recent study in which 18 percent of older adults stated that they were often or frequently lonely (Due, Sandholt, & Waldorff, 2018)
- Expanded discussion of socioemotional selectivity theory to include the role of a decreasing amount of time to live as an explanation for prioritizing meaningful relationships in late adulthood (Moss & Wilson, 2017; Segerstrom & others, 2016)
- Description of a recent Hong Kong study in which older adults 75 and older who used smartphones and the Internet to connect with family, friends, and neighbors had a higher level of psychological well-being than those who did not (Fang & others, 2018)
- Coverage of a recent 2016 Nielsen survey that found older adults watch a staggering amount of television—51 hours, 32 minutes per week—far more than any other age group (Recode, 2016)
- Description of a longitudinal study of individuals from 13 to 72 years of age in which attachment anxiety declined in middle-aged and older adults (Chopik, Edelstein, & Grimm, 2018). Also in this study, attachment avoidance decreased in a linear fashion across the life span. Being in a relationship was linked with lower rates of attachment anxiety and attachment avoidance, and men were higher in attachment avoidance throughout the life span.
- Updated data on the percentage of older adults who engage in volunteering (U.S. Bureau of Labor Statistics, 2016)
- Inclusion of recent research on links between volunteering by older adults and improved health (Burr & others, 2018; Carr, Kail, & Rowe, 2018), better cognitive functioning (Proulx, Curl, & Ermer, 2018), and less loneliness (Carr & others, 2018)
- Expanded and updated discussion of why volunteering has positive outcomes for older adults (Carr, 2018)
- Updated data on the increasing number of older adults living in poverty (U.S. Census Bureau, 2016a)
- Inclusion of recent research indicating that the life satisfaction of Latino older adults was higher than for African American and non-Latino older adults (Zhang, Braun, & Wu, 2017)
- Coverage of recent research in which older adult immigrants had higher levels of life satisfaction than native-born older adult U.S. residents (Calvo, Carr, & Matz-Costa, 2017). In this study, Latino immigrants had the highest life satisfaction of all groups studied. These findings have been labeled the “happiness paradox.”
- Description of a recent study in which four factors emerged as best characterizing successful aging: proactive engagement, wellness resources, positive spirit, and valued relationships (Lee, Kahana, & Kahana, 2017)

## Chapter 20: Death, Dying, and Grieving

- Inclusion of a recent study in which completion of advance directives was associated with a lower probability of receiving life-sustaining treatment (Yen & others, 2018)
- Updated information on countries that allow euthanasia (Belgium, Columbia, Luxembourg, and the Netherlands) and assisted suicide (Belgium, Canada, Finland, Luxembourg, the Netherlands, and Switzerland)
- Update on the increasing number of states that allow assisted suicide—California, Colorado, Montana, Oregon, Vermont, and Washington, as well as Washington, DC
- New definition of assisted suicide as a key term and clearer distinctions made between euthanasia, in which the patient self-administers the lethal medication and is allowed to decide when and where to do this, and euthanasia, in which the physician or a third party administers the lethal medication
- Inclusion of a recent Gallup poll in which 69 percent of U.S. adults said that euthanasia should be legal, 51 percent said that they would consider ending their own lives if faced with a terminal illness, and 50 percent reported that physician-assisted suicide is morally acceptable (Swift, 2016)
- New content on recent criticisms of the “good death” concept that suggest moving away from focusing on a single

- event to improving people's last years and decades of life (Pollock & Seymour, 2018; Smith & Periyakoli, 2018)
- Significantly revised content in the section on children's conceptions of death to include recent research indicating that young children have a better understanding of death than was previously thought as well as developmental changes that occur (Panagiotaki & others, 2018; Rosengren, Gutierrez, & Schein, 2014a, b)
- Discussion of recent research indicating that children know more about death than their parents think they do and that there is considerable variability in their conceptions of death (Panagiotaki & others, 2018)
- Coverage of a recent research review that concluded relatively brief interventions with bereaved children after the death of a parent can prevent children from developing severe problems such as traumatic grief and mental disorders (Bergman, Axberg, & Hanson, 2017)
- Description of recent experimental studies that found the Family Bereavement Program, a 12-session program designed to promote effective parenting and teach coping skills following the death of a parent or caregiver, was effective in preventing children and adolescents from developing severe problems such as traumatic grief and mental disorders; reducing the risk of depression, prolonged grief disorder, and alcohol problems; and improving their coping skills up to 6 years after the program ended (Sandler & others, 2016, 2017)
- New research on the percentage of adult bereavement cases that involve prolonged grief disorder and ages at which this disorder is more likely to occur (Lundorff & others, 2017)
- Inclusion of a 7-year longitudinal study of older adults in which those experiencing prolonged grief had greater cognitive decline than those with normal grief (Perez & others, 2018)
- Discussion of a recent study that found individuals with complicated grief had higher levels of neuroticism (Goetter & others, 2018)
- Coverage of a study that found cognitive behavior therapy reduced prolonged grief symptoms (Bartl & others, 2018)
- Updated content about a recent extension of the dual-process model of bereavement, which mainly focused on an individual's bereavement, toward an integrative intrapersonal/interpersonal model that includes bereaved immediate family members and relatives who also have experienced the loss (Stroebe & others, 2017a, b; Stroebe & Schut, 2015, 2017)
- Updated statistics on the percentage of widows in the United States (Administration on Aging, 2015)
- Description of a recent cross-cultural study indicating that depression peaked in the first year of widowhood for both men and women but continued to be present in widowed men for 6 to 10 years post bereavement (Jadhav & Weir, 2018)
- Inclusion of a recent study in which volunteering reduced widowed older adults' loneliness (Carr & others, 2018)
- Updated data on the ongoing trend toward cremation, with 50.1 percent of deaths followed by cremation in the United States in 2016 and a projected increase to 56.3 percent in 2020 (Cremation Association of North America, 2017). In 2016 in Canada, cremation occurred following 70.2 percent of deaths, with a projected increase to 79.8 percent in 2020.

# acknowledgments

I very much appreciate the support and guidance provided to me by many people at McGraw-Hill Education. Ryan Treat, Portfolio Manager for Psychology, has provided excellent guidance, vision, and direction for this book. Vicki Malinee provided considerable expertise in coordinating many aspects of the editorial process for this text. Janet Tilden again did an outstanding job as the book's copyeditor. Mary Powers did a terrific job in coordinating the book's production. Dawn Groundwater, Lead Product Developer, did excellent work on various aspects of the book's development, technology, and learning systems. Thanks also to Ann Helgerson and A.J. Laferrera for their extensive and outstanding work in marketing *Life-Span Development*. And Jennifer Blankenship provided me with excellent choices of new photographs for this edition of the book.

I also want to thank my parents, John and Ruth Santrock, my wife, Mary Jo, our children, Tracy and Jennifer, and our grandchildren, Jordan, Alex, and Luke, for their wonderful contributions to my life and for helping me to better understand the marvels and mysteries of life-span development.

## EXPERT CONSULTANTS

As I develop a new edition of this text, I consult with leading experts in their respective areas of life-span development. Their invaluable feedback ensures that the latest research, knowledge, and perspectives are presented throughout the text. Their willingness to devote their time and expertise to this endeavor is greatly appreciated. The Expert Consultants who contributed to this edition, along with their biographies and commentary, can be found on pages xv-xvii.

## REVIEWERS

I owe a special debt of gratitude to the reviewers who have provided detailed feedback on *Life-Span Development* over the years.

## The Life-Span Perspective

This book is about human development—its universal features, its individual variations, its nature. Every life is distinct, a new biography in the world. Examining the shape of life-span development allows us to understand it better. *Life-Span Development* is about the rhythm and meaning of people's lives, about turning mystery into understanding, and about weaving a portrait of who each of us was, is, and will be. In Section 1, you will read the "Introduction."

## ① The Life-Span Perspective

- Learning Goal 1** Discuss the distinctive features of a life-span perspective on development.
- The Importance of Studying Life-Span Development
  - Characteristics of the Life-Span Perspective
  - Some Contemporary Concerns

## ② The Nature of Development

- Learning Goal 2** Identify the most important processes, periods, and issues in development.
- Biological, Cognitive, and Socioemotional Processes
  - Periods of Development
  - The Significance of Age
  - Developmental Issues

## ③ Theories of Development

- Learning Goal 3** Describe the main theories of human development.
- Psychoanalytic Theories
  - Cognitive Theories
  - Behavioral and Social Cognitive Theories
  - Ethological Theory
  - Ecological Theory
  - An Eclectic Theoretical Orientation

## ④ Research on Life-Span Development

- Learning Goal 4** Explain how research on life-span development is conducted.
- Methods for Collecting Data
  - Research Designs
  - Time Span of Research
  - Conducting Ethical Research
  - Minimizing Bias

# Ted Kaczynski sprinted through high school, not bothering with his junior year and making only passing efforts at social contact.

Off to Harvard at age 16, Kaczynski was a loner during his college years.

One of his roommates at Harvard said that he avoided people by quickly shuffling by them and slamming the door behind him. After obtaining his Ph.D. in mathematics at the University of Michigan, Kaczynski became a professor at the University of California at Berkeley. His colleagues there remember him as hiding from social contact—no friends, no allies, no networking.

After several years at Berkeley, Kaczynski resigned and moved to a rural area of Montana where he lived as a hermit in a crude shack for 25 years. Town residents described him as a bearded eccentric. Kaczynski traced his own difficulties to growing up as a genius in a kid's body and sticking out like a sore thumb in his surroundings as a child. In 1996, he was arrested and charged as the notorious Unabomber, America's most-wanted killer. Over the course of 17 years, Kaczynski had sent 16 mail bombs that left 23 people wounded or maimed and 3 people dead. In 1998, he pleaded guilty to the offenses and was sentenced to life in prison.

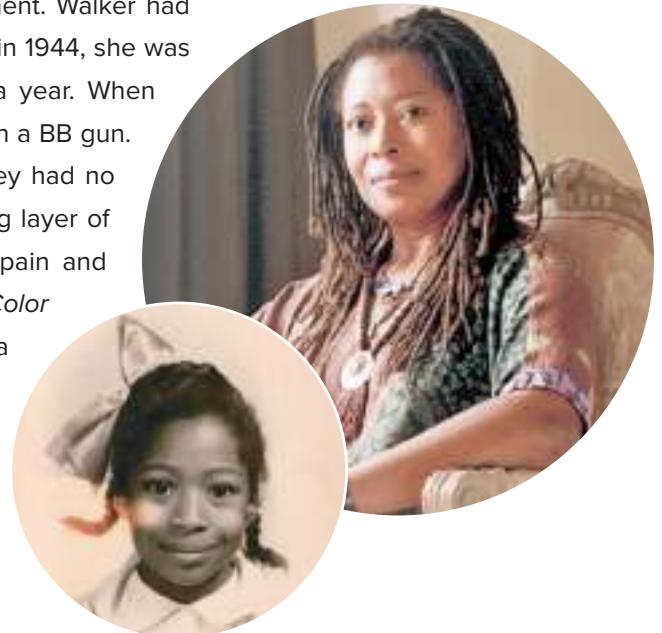

A decade before Kaczynski mailed his first bomb, Alice Walker spent her days battling racism in Mississippi. She had recently won her first writing fellowship, but rather than use the money to follow her dream of moving to Senegal, Africa, she put herself into the heart and heat of the civil rights movement. Walker had grown up knowing the brutal effects of poverty and racism. Born in 1944, she was the eighth child of Georgia sharecroppers who earned \$300 a year. When Walker was 8, her brother accidentally shot her in the left eye with a BB gun. By the time her parents got her to the hospital a week later (they had no car), she was blind in that eye, and it had developed a disfiguring layer of scar tissue. Despite the counts against her, Walker overcame pain and anger and went on to win a Pulitzer Prize for her book *The Color Purple*. She became not only a novelist but also an essayist, a poet, a short-story writer, and a social activist.

What leads one individual, so full of promise, to commit brutal acts of violence and another to turn poverty and trauma into a rich literary harvest? If you have ever wondered why people turn out the way they do, you have asked yourself the central question we will be exploring. This text traces the journey of human development—your own and that of every other member of the human species. In this chapter, we will explore what it means to take a life-span perspective on development, examine the nature of development, and outline how science helps us to understand it.

## 1 The Life-Span Perspective

The Importance of Studying Life-Span Development

LG1

Discuss the distinctive features of a life-span perspective on development.

Characteristics of the Life-Span Perspective

Some Contemporary Concerns

We reach backward to our parents and forward to our children, and through their children to a future we will never see, but about which we need to care.

—CARL JUNG

Swiss Psychiatrist, 20th Century

Each of us develops partly like all other individuals, partly like some other individuals, and partly like no other individual. Most of the time our attention is directed to each individual's uniqueness. But as humans, we have all traveled some common paths. Each of us—Leonardo da Vinci, Joan of Arc, George Washington, Martin Luther King, Jr., and you—walked at about 1 year, engaged in fantasy play as a young child, and became more independent as a youth. Each of us, if we live long enough, will experience hearing problems and the death of family members and friends. This is the general course of our **development**, the pattern of movement or change that begins at conception and continues through the human life span.

In this section, we will explore what is meant by the concept of development and why the study of life-span development is important. We will outline the main characteristics of the life-span perspective and discuss various sources of contextual influences. In addition, we will examine some contemporary concerns in life-span development.

### THE IMPORTANCE OF STUDYING LIFE-SPAN DEVELOPMENT

How might people benefit from examining life-span development? Perhaps you are, or will be, a parent or teacher. If so, responsibility for children is, or will be, a part of your everyday life. The more you learn about them, the better you can deal with them. Perhaps you hope to gain some insight about your own history—as an infant, a child, an adolescent, or a young adult. Perhaps you want to know more about what your life will be like as you grow through the adult years—as a middle-aged adult, or as an adult in old age, for example. Or perhaps you just stumbled onto this course, thinking that it sounded intriguing and that the study of the human life span might raise some provocative issues. Whatever your reasons for taking this course, you will discover that the study of life-span development is intriguing and filled with information about who we are, how we came to be this way, and where our future will take us.

Most development involves growth, but it also includes decline (as in dying). In exploring development, we will examine the life span from the point of conception until the time when life (or at least life as we know it) ends. You will see yourself as an infant, as a child, and as an adolescent, and be stimulated to think about how those years influenced the kind of individual you are today. And you will see yourself as a young adult, as a middle-aged adult, and as an adult in old age, and be motivated to think about how your experiences today will influence your development through the remainder of your adult years.

**development** The pattern of change that begins at conception and continues through the life span. Most development involves growth, although it also includes decline brought on by aging and dying.

**life-span perspective** The perspective that development is lifelong, multidimensional, multidirectional, plastic, multidisciplinary, and contextual; involves growth, maintenance, and regulation; and is constructed through biological, sociocultural, and individual factors working together.

## CHARACTERISTICS OF THE LIFE-SPAN PERSPECTIVE

Although growth and development are dramatic during the first two decades of life, development is not something that happens only to children and adolescents (Kennedy & Raz, 2015). The traditional approach to the study of development emphasizes extensive change from birth to adolescence (especially during infancy), little or no change in adulthood, and decline in old age. But a great deal of change does occur in the five or six decades after adolescence. The life-span approach emphasizes developmental change throughout adulthood as well as childhood (Park & Festini, 2018; Schaie & Willis, 2016).

**Life Expectancy** Recent increases in human life expectancy have contributed to the popularity of the life-span approach to development. The upper boundary of the human life span (based on the oldest age documented) is 122 years, as indicated in Figure 1; this maximum life span of humans has not changed since the beginning of recorded history. What has changed is life expectancy—the average number of years that a person born in a particular year can expect to live. In the twentieth century alone, life expectancy in the United States increased by 32 years, thanks to improvements in sanitation, nutrition, and medicine (see Figure 2). In 2016, the life expectancy in the United States was 79 years of age (U.S. Census Bureau, 2017). Today, for most individuals in developed countries, childhood and adolescence represent only about one-fourth of their lives.

For the first time in U.S. history, there are more people over 60 years of age than under 15 years of age. In less than a century, more years were added to human life expectancy than in all of the prior millennia.

Laura Carstensen (2015, 2016) recently described the challenges and opportunities presented by this dramatic increase in life expectancy. In her view, the remarkable increase in the number of people living to an old age has happened so quickly that science, technology, and social expectations have not kept pace. She proposes that the challenge is to change from a world constructed mainly for young people to a world that is more compatible and supportive for the increasing number of people living to age 100 and beyond.

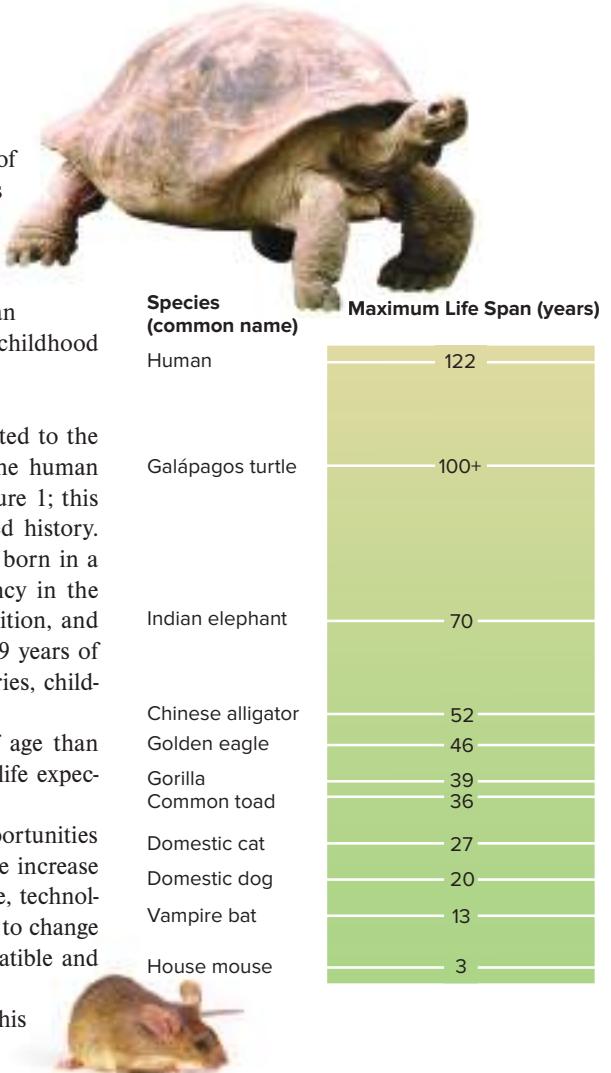

In further commentary, Carstensen (2015, p. 70) remarked that making this transformation would be no small feat:

... parks, transportation systems, staircases, and even hospitals presume that the users have both strength and stamina; suburbs across the country are built for two parents and their young children, not single people, multiple generations or elderly people who are not able to drive. Our education system serves the needs of young children and young adults and offers little more than recreation for experienced people.

Indeed, the very conception of work as a full-time endeavor ending in the early sixties is ill suited for long lives. Arguably the most troubling aspect of our view of aging is that we fret about ways the older people lack the qualities of younger people rather than exploit a growing new resource right before our eyes: citizens who have deep expertise, emotional balance, and the motivation to make a difference.

Certainly some progress has been made recently in improving the lives of older adults. In our discussion of late adulthood, you will read about progress in understanding and influencing the aging process through interventions such as modifying the activity of genes related to aging, improving brain function in the elderly, and slowing or even reversing the effects of various chronic diseases. You'll also learn about ways to help people plan for a better life when they get old, become more cognitively sharp as they age, improve their physical fitness, and feel more satisfied with their lives as older adults. But much more remains to be accomplished, as suggested earlier by Laura Carstensen, as well as others (Bergeron, Ossenkoppele, & Laforce, 2018; Shrestha & others, 2018).

**The Life-Span Perspective** The belief that development occurs throughout life is central to the life-span perspective on human development, but this perspective has other characteristics as well. According to life-span development expert Paul Baltes (1939–2006), the **life-span perspective** views development as lifelong, multidimensional, multidirectional, plastic, multidisciplinary, and contextual, and as a process that involves growth, maintenance, and regulation of loss (Baltes, 1987, 2003; Baltes, Lindenberger, & Staudinger, 2006). In Baltes'

Paul Baltes, a leading architect of the life-span perspective of development, converses with one of the long-time research participants in the Berlin Aging Study that he directs. She joined the study in the early 1990s and has participated six times in extensive physical, medical, psychological, and social assessments. In her professional life, she was a physician.

view, it is important to understand that development is constructed through biological, socio-cultural, and individual factors working together. Let's explore each of these components of the life-span perspective.

**Development Is Lifelong** In the life-span perspective, early adulthood is not the endpoint of development; rather, no age period dominates development. Researchers increasingly study the experiences and psychological orientations of adults at different points in their lives. Later in this chapter, we will describe the age periods of development and their characteristics.

**Development Is Multidimensional** No matter what your age might be, your body, mind, emotions, and relationships are changing and affecting each other. Consider the development of Ted Kaczynski, the Unabomber discussed at the beginning of this chapter. When he was 6 months old, he was hospitalized with a severe allergic reaction and his parents were rarely allowed to visit him. According to his mother, the previously happy baby was never the same after his hospitalization. He became withdrawn and unresponsive. As Ted grew up, he had periodic "shutdowns" accompanied by rage. In his mother's view, a biological event during infancy warped the development of her son's mind and emotions.

Development has biological, cognitive, and socioemotional dimensions. Even within a dimension, there are many components (Dale & others, 2018; Moss & Wilson, 2018; Zammit & others, 2018). For example, attention, memory, abstract thinking, speed of processing information, and social intelligence are just a few of the components of the cognitive dimension.

**Development Is Multidirectional** Throughout life, some dimensions or components of a dimension expand and others shrink. For example, when one language (such as English) is acquired early in development, the capacity for acquiring second and third languages (such as Spanish and Chinese) decreases later in development, especially after early childhood (Levitt, 1989). During adolescence, as individuals establish romantic relationships, their time spent with friends may decrease. During late adulthood, older adults might become wiser because they have more experience than younger adults to draw upon to guide their decision making (Rakoczy & others, 2018; Thomas & others, 2018), but they perform more poorly on tasks that require speed in processing information (Salthouse, 2017).

**Development Is Plastic** Even at 10 years old, Ted Kaczynski was extraordinarily shy. Was he destined to remain forever uncomfortable with people? Developmentalists debate how much plasticity people have in various dimensions at different points in their development (Roisman & Cicchetti, 2017; Park & Festini, 2018). Plasticity means the capacity for change. For example, can you still improve your intellectual skills when you are in your seventies or eighties? Or might these intellectual skills be fixed by the time you are in your thirties so that further improvement is impossible? Researchers have found that the cognitive skills of older adults can be improved through training and acquisition of effective strategies (Motes & others, 2018; Shah & others, 2017). However, possibly we possess less capacity for change as we grow older (Shivarama Shetty & Sajikumar, 2017). Understanding plasticity and its constraints is a key element on the contemporary agenda for developmental research (Almy & Cicchetti, 2018; Park & Festini, 2018).

**Developmental Science Is Multidisciplinary** Psychologists, sociologists, anthropologists, neuroscientists, and medical researchers all share an interest in unlocking the mysteries of development through the life span. How do your heredity and health limit your intelligence? Do intelligence and social relationships change with age in the same ways around the world? How do families and schools influence intellectual development? These are examples of research questions that cut across disciplines.

**Development Is Contextual** All development occurs within a context, or setting. Contexts include families, schools, peer groups, churches, cities, neighborhoods, university laboratories, countries, and so on. Each of these settings is influenced by historical, economic, social, and cultural factors (Lubetkin & Jia, 2017; Nair, Roche, & White, 2018).

Contexts, like individuals, change (Taylor, Widaman, & Robins, 2018). Thus, individuals are changing beings in a changing world. As a result of these changes, contexts exert three types of influences (Baltes, 2003): (1) normative age-graded influences, (2) normative history-graded

influences, and (3) nonnormative or highly individualized life events. Each type of influence can have a biological or environmental impact on development.

**Normative age-graded influences** are similar for individuals in a particular age group. These influences include biological processes such as puberty and menopause. They also include sociocultural factors and environmental processes such as beginning formal education (usually at about age 6 in most cultures) and retiring from the workforce (which takes place during the fifties and sixties in most cultures).

**Normative history-graded influences** are common to people of a particular generation because of historical circumstances (Ganguli, 2017; Heo & others, 2018). For example, during their youth American baby boomers shared the experience of the Cuban missile crisis, the assassination of John F. Kennedy, and the Beatles invasion. Other examples of normative history-graded influences include economic, political, and social upheavals such as the Great Depression in the 1930s, World War II in the 1940s, the civil rights and women's rights movements of the 1960s and 1970s, the terrorist attacks of 9/11/2001, the integration of computers and cell phones into everyday life during the 1990s, and time spent on social media in the last decade (Schaie, 2016a, b; Tsai, Shillair, & Cotton, 2017). Long-term changes in the genetic and cultural makeup of a population (due to immigration or changes in fertility rates) are also part of normative historical change.

**Nonnormative life events** are unusual occurrences that have a major impact on the lives of individual people. These events do not happen to everyone, and when they do occur they can influence people in different ways (Fredriksen-Goldsen & others, 2017; Jacobson & others, 2018; Shah & others, 2018). Examples include the death of a parent when a child is young, pregnancy in early adolescence, a fire that destroys a home, winning the lottery, or getting an unexpected career opportunity.

**Development Involves Growth, Maintenance, and Regulation of Loss** Baltes and his colleagues (2006) assert that the mastery of life often involves conflicts and competition among three goals of human development: growth, maintenance, and regulation of loss. As individuals age into middle and late adulthood, the maintenance and regulation of loss in their capacities takes center stage. Thus, a 75-year-old man might aim not to improve his memory or his golf swing but to maintain his independence and his ability to play golf at all. In the chapters on “Physical and Cognitive Development in Middle Adulthood” and “Socio-emotional Development in Middle Adulthood” we will discuss these ideas about maintenance and regulation of loss in greater depth.

**Development Is a Co-construction of Biology, Culture, and the Individual** Development is a co-construction of biological, cultural, and individual factors working together (Baltes, Reuter-Lorenz, & Rösler, 2012). For example, the brain shapes culture, but it is also shaped by culture and the experiences that individuals have or pursue. In terms of individual factors, we can go beyond what our genetic inheritance and our environment give us. We can author a unique developmental path by actively choosing from the environment the things that optimize our lives (Rathunde & Csikszentmihalyi, 2006).

## SOME CONTEMPORARY CONCERNs

Pick up a newspaper or magazine and you might see headlines like these: “Technology Shortens Toddlers’ Attention Spans,” “Political Leanings May Be Written in the Genes,” “Mother Accused of Tossing Children into Bay,” “Transgender Bathroom Laws Face Controversy,” “FDA Warns About Long-Term Effects of ADHD Drug,” “Heart Attack Deaths Higher in African American Patients,” or “Test May Predict Alzheimer Disease.” Researchers using the life-span perspective are examining these and many other topics of contemporary concern. The roles that health and well-being, parenting, education, sociocultural contexts, and technology play in life-span development, as well as how social policy is related to these issues, are a particular focus of this edition.

**Health and Well-Being** Health professionals today recognize the powerful influences of lifestyles and psychological states on health and well-being (Hales, 2018; Rolfs, Pinna, & Whitney, 2018). In every chapter of *Life-Span Development*, issues of health and well-being are integrated into our discussions.

Clinical psychologists are among the health professionals who help people improve their well-being. Read about one clinical psychologist who helps adolescents and adults improve their developmental outcomes in *Connecting with Careers*.

## Gustavo Medrano, Clinical Psychologist

Gustavo Medrano specializes in helping children, adolescents, and adults of all ages improve their lives when they have problems involving depression, anxiety, emotion regulation, chronic health conditions, and life transitions. He works individually with clients and also provides therapy for couples and families. As a native Spanish speaker, he also provides bicultural and bilingual therapy for clients.

Dr. Medrano is a faculty member at the Family Institute at Northwestern University in Evanston, Illinois. He obtained his undergraduate degree in psychology at Northwestern and then became a high school teacher through Teach for America, a program where participants spend at least two years teaching in a high-poverty area. He received his master's and doctoral degrees in clinical psychology at the University of Wisconsin–Milwaukee. As a faculty member at Northwestern, in addition to doing clinical therapy with clients, he conducts research focusing on how family experiences, especially parenting, influence children's and adolescents' ability to cope with chronic pain and other challenges.

For more information about what clinical psychologists do, see the *Careers in Life-Span Development* appendix.

**culture** The behavior patterns, beliefs, and all other products of a group that are passed on from generation to generation.

**cross-cultural studies** Comparison of one culture with one or more other cultures. These provide information about the degree to which development is similar, or universal, across cultures, and the degree to which it is culture-specific.

**ethnicity** A characteristic based on cultural heritage, nationality characteristics, race, religion, and language.

**socioeconomic status (SES)** Refers to the grouping of people with similar occupational, educational, and economic characteristics.

**gender** The characteristics of people as males or females.

**social policy** A national government's course of action designed to promote the welfare of its citizens.

**Parenting and Education** Can two gay men raise a healthy family? Are children harmed if both parents work outside the home? Are U.S. schools failing to teach children how to read and write and calculate adequately? We hear many questions like these involving pressures on the contemporary family and conditions impairing the effectiveness of U.S. schools (Trevino-Schafer, 2018; Walsh, DeFlorio, & Burnham, 2017). In later chapters, we will analyze child care, the effects of divorce, parenting styles, child maltreatment, intergenerational relationships, early childhood education, links between childhood poverty and education, bilingual education, recent efforts to improve lifelong learning, and many other issues related to parenting and education (Gewirtz & Youssef, 2017; Morrison, 2018).

**Sociocultural Contexts and Diversity** Health, parenting, and education—like development itself—are all shaped by their sociocultural context (Duncan, Magnuson, &

Votruba-Drzal, 2017; Lansford & Banati, 2018). To analyze this context, four concepts are especially useful: culture, ethnicity, socioeconomic status, and gender.

**Culture** encompasses the behavior patterns, beliefs, and all other products of a particular group of people that are passed on from generation to generation (Kim & others, 2018). Culture results from the interaction of people over many years (Huo & Kim, 2018; Inglehart, 2018). A cultural group can be as large as the United States or as small as an isolated Appalachian town. Whatever its size, the group's culture influences the behavior of its members (Erez, 2018; Matsumoto & Juang, 2017).

**Cross-cultural studies** compare aspects of two or more cultures. The comparison provides information about the degree to which development is similar (or universal) across cultures, or is instead culture-specific (Duell & others, 2018; Petersen & others, 2017; Wagner, 2018). For example, in a recent study of 26 countries, individuals in Chile had the highest life satisfaction, while those in Bulgaria and Spain had the lowest (Jang & others, 2017).

**Ethnicity** (the word *ethnic* comes from the Greek word for “nation”) is rooted in cultural heritage, nationality, race, religion, and language. African Americans, Latinos, Asian Americans, Native Americans, European Americans, and Arab Americans are a few examples of broad ethnic groups in the United States. Diversity exists within each ethnic group (Nieto & Bode, 2018; Suarez-Orozco, 2018a, b, c). A special concern is the discrimination and prejudice experienced by ethnic minority children (Brown, 2017; Motti-Stefanidi, 2018; Zeiders & others, 2018). Recent research indicates that pride in one’s ethnic identity group has positive outcomes (Umana-Taylor & Douglass, 2017; Umana-Taylor & others, 2018). For example, in a recent study, strong ethnic group affiliation and connection served a protective function in reducing risk for psychiatric problems (Anglin & others, 2018).

**Socioeconomic status (SES)** refers to a person’s position within society based on occupational, educational, and economic characteristics. Socioeconomic status implies certain inequalities (Duncan, Magnuson, & Votruba-Drzal, 2017; Loria & Caughy, 2018). Differences in the ability to control resources and to participate in society’s rewards produce unequal opportunities (Koller, Prates Santana, & Raffaelli, 2018; Singh & Mukherjee, 2018).

**Gender** refers to the characteristics of people as males and females. Few aspects of our development are more central to our identity and social relationships than gender (Dettori & Gupta, 2018; Ellemers, 2018; Liben, 2017).

Recently, considerable interest has been generated about a category of gender classification, *transgender*, a broad term that refers to individuals who adopt a gender identity that differs from the one assigned to them at birth (Budge & Orovacz, 2018; Savin-Williams, 2017). For example, individuals may have a female body but identify more strongly with being masculine than feminine, or have a male body but identify more strongly with being feminine than masculine. A transgender identity of being born male but identifying with being a female is much more common than the reverse (Zucker, Lawrence, & Kreukels, 2016). We will have much more to say about gender and transgender later in the text.

In the United States, the sociocultural context has become increasingly diverse in recent years. The U.S. population includes a greater variety of cultures and ethnic groups than ever before. This changing demographic tapestry promises not only the richness that diversity brings but also difficult challenges in extending the American dream to all individuals (Cano & others, 2017; Nieto & Bode, 2018). We will discuss sociocultural contexts and diversity in each chapter.

A special cross-cultural concern is the educational and psychological conditions of women around the world (UNICEF, 2017, 2018). Inadequate educational opportunities, violence, and mental health issues are among the problems faced by many women.

Considerable progress has been made in many parts of the world in girls’ school attendance (UNICEF, 2017). However, in some regions, girls continue to receive less education. For example, in secondary schools in West and Central Africa, only 76 girls are enrolled for every 100 boys (UNICEF, 2015).

**Social Policy** **Social policy** is a government’s course of action designed to promote the welfare of its citizens. Values, economics, and politics all shape a nation’s social policy (Lansford & Banati, 2018; Ruck, Peterson-Badali, & Freeman, 2017). Out of concern that policy makers are doing too little to protect the well-being of children and older adults, lifespan researchers are increasingly undertaking studies that they hope will lead to effective social policy (Lerner & others, 2018; McQueen, 2017).

Statistics such as infant mortality rates, mortality among children under 5, and the percentage of children who are malnourished or living in poverty provide benchmarks for evaluating how well children are doing in a particular society (UNICEF, 2017, 2018). Marian Wright Edelman, a tireless advocate for children’s rights, has pointed out that such indicators place the United States at or near the lowest rank for industrialized nations in the treatment of children.

Children who grow up in poverty represent a special concern (Duncan, Magnuson, & Votruba-Drzal, 2017; Suarez-Orozco, 2018a, b, c). In 2015, 19.7 percent of U.S. children under 18 years of age were living in families with incomes below the poverty line, with African American (36 percent) and Latino (30 percent) families with children having especially high rates of

Doly Akter, age 17, lives in a slum in Dhaka, Bangladesh, where sewers overflow, garbage rots in the streets, and children are undernourished. Nearly two-thirds of young women in Bangladesh marry before they are 18. Doly organized a club supported by UNICEF in which girls go door-to-door to monitor the hygiene habits of households in their neighborhood. The monitoring has led to improved hygiene and health in the families. Also, her group has managed to stop several child marriages by meeting with parents and convincing them that it is not in their daughter’s best interests. When talking with parents in their neighborhoods, the girls in the club emphasize the importance of staying in school and how this will improve their daughters’ future. Doly says that the girls in her UNICEF group are far more aware of their rights than their mothers ever were. (UNICEF, 2007). Courtesy of Naser Siddique/UNICEF Bangladesh

**FIGURE 3**  
**EXPOSURE TO SIX STRESSORS AMONG POOR AND MIDDLE-INCOME CHILDREN.** One study analyzed the exposure to six stressors among poor children and middle-income children (Evans & English, 2002). Poor children were much more likely to face each of these stressors.

poverty (Jiang, Granja, & Koball, 2017). In 2015, 12 percent of non-Latino White children were living in poverty. Compared with non-Latino White children, ethnic minority children are more likely to experience persistent poverty over many years and live in isolated poor neighborhoods where social supports are minimal and threats to positive development are abundant.

The overall poverty rate for U.S. children did drop from 21.2 percent in 2014 to 19.7 percent in 2015 (Proctor, Semega, & Kollar, 2016). The 19.7 percent figure represents an increase from 2001 (14.5 percent) but reflects a slight drop from a peak of 23 percent in 1993.

The U.S. figure of 19.7 percent of children living in poverty is much higher than the rates in other developed countries. For example, Canada has a child poverty rate of 9 percent and Sweden has a rate of 2 percent.

As indicated in Figure 3, one study found that a higher percentage of U.S. children in poor families than in middle-income families were exposed to family turmoil, separation from a parent, violence, crowding, excessive noise, and poor housing (Evans & English, 2002). One study also revealed that the more years children spent living in poverty, the higher were their physiological indices of stress (Evans & Kim, 2007).

Edelman says that parenting and nurturing the next generation of children is our society's most important function and that we need to take it more seriously than we have in the past. To read about efforts to improve the lives of children through social policies, see *Connecting Development to Life*.

Some children triumph over poverty or other adversities. They show *resilience* (Masten, 2015, 2017). Think back to the chapter-opening story about Alice Walker. In spite of racism, poverty, low socioeconomic status, and a disfiguring eye injury, she went on to become a successful author and champion for equality.

Are there certain characteristics that make children like Alice Walker resilient? Are there other characteristics that influence the development of children like Ted Kaczynski, who, despite his intelligence and education, became a killer? After analyzing research on this topic, Ann Masten and her colleagues (Masten, 2006, 2009, 2011, 2013, 2014, 2015, 2016, 2017; Masten, Burt, & Coatsworth, 2006; Masten & Kalstabakken, 2018) concluded that a number of individual factors, such as good intellectual functioning, influence resiliency. In addition, as Figure 4 shows, the families and extrafamilial contexts of resilient individuals tend to share certain features. For example, resilient children are likely to have a close relationship with a caring parent figure and bonds to caring adults outside the family.

At the other end of the life span, the well-being of older adults also creates policy issues (Burns, Browning, and Kendig, 2017; Jennifer, 2018; Volkwein-Caplan & Tahmaseb-McConatha, 2018). Key concerns are

## Improving Family Policy

In the United States, the actions of the national government, state governments, and city governments influence the well-being of children (Gottlieb & DeLoache, 2017; Lerner & others, 2018). When families seriously endanger a child's well-being, governments often step in to help. At the national and state levels, policy makers have debated for decades about whether helping poor parents ends up helping their children as well. Researchers are providing some answers by examining the effects of specific policies (Duncan, Magnuson, & Vrtoba-Drzal, 2017).

For example, the Minnesota Family Investment Program (MFIP) was designed in the 1990s primarily to influence the behavior of adults—specifically, to move adults off the welfare rolls and into paid employment. A key element of the program was its guarantee that adults participating in the program would receive more income if they worked than if they did not. When the adults' income rose, how did that affect their children? A study of the effects of MFIP found that increased incomes of working poor parents were linked with benefits for their children (Gennetian & Miller, 2002). The children's achievement in school improved, and their behavior problems decreased. A current MFIP study is examining the influence of providing specific services to low-income families at risk for child maltreatment and other negative outcomes for children (Minnesota Family Investment Program, 2009).

There is increasing interest in developing two-generation educational interventions to improve the academic success of children living in poverty (Gardner, Brooks-Gunn, & Chase-Lansdale, 2016; Sommer & others, 2016). For example, a recent large-scale effort to help children escape from poverty is the *Ascend* two-generation education intervention being conducted by the Aspen Institute (2013, 2018; King, Chase-Lansdale, & Small, 2015). The focus of the intervention emphasizes education (increasing postsecondary education for mothers and improving the quality of their children's early childhood education), economic support (housing, transportation, financial education, health insurance, and food assistance), and social capital (peer support including friends and neighbors; participation in community and faith-based organizations; school and work contacts).

Developmental psychologists and other researchers have examined the effects of many other government policies. They are seeking ways to help families living in poverty improve their well-being, and they have offered many suggestions for improving government policies (Lansford & Banati, 2018; McQueen, 2017; Motti-Stefanidi, 2018; Yoshikawa & others, 2017).

*Earlier, we learned that children who live in poverty experience higher levels of physiological stress. How might a child's stress level be affected by the implementation of MFIP?*

escalating health care costs and the access of older adults to adequate health care (Cunningham, Green, & Braun, 2018; Kane, Saliba, & Hollmann, 2017). One study found that the U.S. health care system fails older adults in many areas (Wenger & others, 2003). For example, older adults received the recommended care for general medical conditions such as heart disease only 52 percent of the time; they received appropriate care for undernutrition and Alzheimer disease only 31 percent of the time.

These concerns about the well-being of older adults are heightened by two facts. First, the number of older adults in the United States is growing dramatically, as Figure 5 shows. Second, many of these older Americans are likely to need society's help (Conway & others, 2018; Simon, Soni, & Cawley, 2017). Not only is the population of older adults growing in the United States, but the world's population of people 60 years and older is projected to increase from 900 million in 2015 to 2.1 billion in 2050 (United Nations, 2015). The world's population of those 80 years and older is expected to triple or quadruple in this time frame.

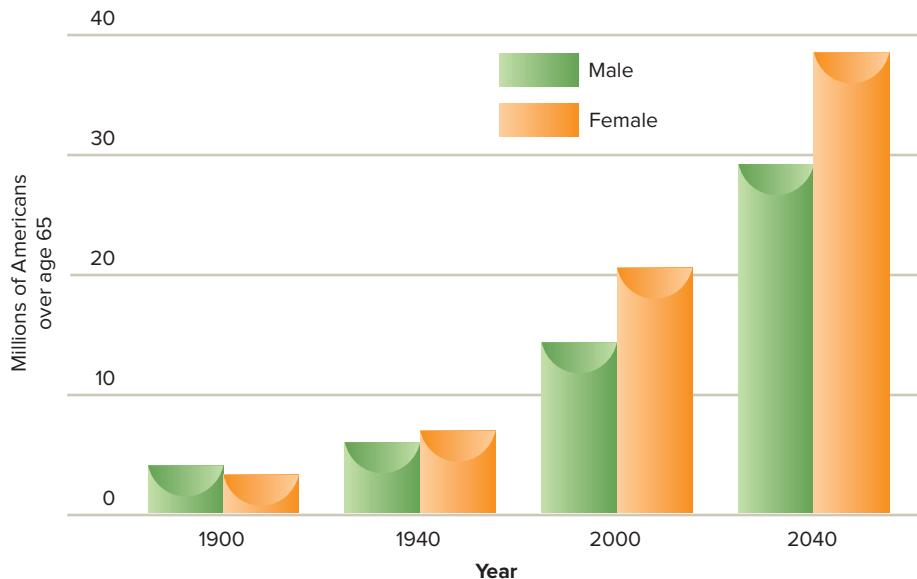

Compared with adults in earlier decades, U.S. adults today are less likely to be married, more likely to be childless, and more likely to be living alone (Poey, Burr, & Roberts, 2017). As the older population continues to expand during the twenty-first century, an increasing number of older adults will be without either a spouse or children—traditionally the main sources of support for older adults. These individuals will need social relationships, networks, and other forms of support (Andrew & Meeks, 2018; Shankar & others, 2017).

**THE AGING OF AMERICA.** The number of Americans over age 65 has grown dramatically since 1900 and is projected to increase further from the present to the year 2040. A significant increase will also occur in the number of individuals in the 85-and-over group. Centenarians—persons 100 years of age or older—are the fastest-growing age group in the United States, and their numbers are expected to swell in the coming decades.

©DaydreamsGirl/Getty Images

**Technology** A final discussion in our exploration of contemporary topics is the recent dramatic, almost overwhelming increase in the use of technology at all points in human development (Lever-Duffy & McDonald, 2018; Vernon, Modecki, & Barber, 2018). From the introduction of television in the mid '50s, to the replacement of typewriters with computers that can do far more than just print words, and later to the remarkable invention of the Internet and the proliferation of smartphones, followed by the pervasiveness of social media and the development of robots that can do some jobs better than humans can, our way of life has been changed permanently by technological advances.

We will explore many technology topics in this edition. Later in this chapter you will read about the emerging field of developmental robotics in our discussion of information processing, and you will ponder the influence of technology on generations such as the millennials. Other topics we will explore include whether

babies should watch television and videos, with special attention to potential effects of audiovisual media on language development; indications that too much screen time reduces children's participation in physical activities and increases their risk for obesity and cardiovascular disease; the effects on learning when many adolescents spend more time using various media than they do in school and the question of whether multitasking with various electronic devices is harmful or beneficial; as well as the degree to which older adults are adapting to the extensive role of technology in their lives, especially since they grew up without so much technology.

Periods of Development

The Significance of Age

Developmental Issues

In this section, we will explore what is meant by developmental processes and periods, as well as variations in the way age is conceptualized. We will examine key developmental issues and strategies we can use to evaluate them.

If you wanted to describe how and why Alice Walker or Ted Kaczynski developed during their lifetimes, how would you go about it? A chronicle of the events in any person's life can quickly become a confusing and tedious array of details. Two concepts help provide a framework for describing and understanding an individual's development: developmental processes and periods.

### BIOLOGICAL, COGNITIVE, AND SOCIOEMOTIONAL PROCESSES

At the beginning of this chapter, we defined development as the pattern of change that begins at conception and continues through the life span. The pattern is complex because it is the product of biological, cognitive, and socioemotional processes (see Figure 6).

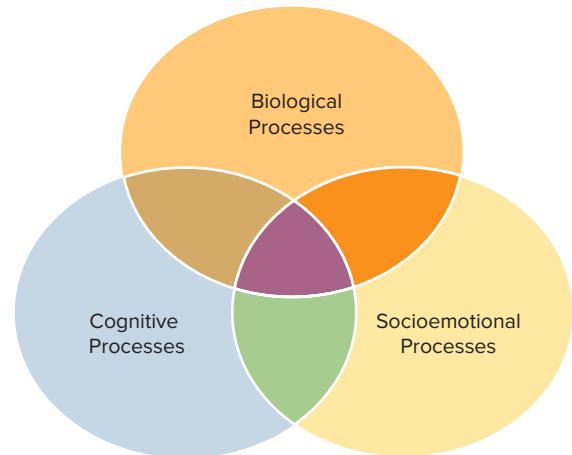

**Biological Processes** Biological processes produce changes in an individual's physical nature. Genes inherited from parents, brain development, height and weight gains, changes in motor skills, nutrition, exercise, the hormonal changes of puberty, and cardiovascular decline are all examples of biological processes that affect development. Especially in recent years with the advent of new techniques to study people's actual genetic makeup, there has been a substantial increase in studies that focus on the role of genes in development at different points in the life span (Amare & others, 2017; Bardak & others, 2018). Likewise, with the invention of brain-imaging techniques such as magnetic resonance imaging, there has been an explosion of research on how the brain influences many aspects of development at different points in the life span (Bell & others, 2018; Park & Festini, 2018).

**Cognitive Processes** Cognitive processes refer to changes in the individual's thought, intelligence, and language. Watching a colorful mobile swinging above the crib, putting together a two-word sentence, memorizing a poem, imagining what it would be like to be a movie star, and solving a crossword puzzle all involve cognitive processes.

**Socioemotional Processes** Socioemotional processes involve changes in the individual's relationships with other people, changes in emotions, and changes in personality. An infant's smile in response to a parent's touch, a toddler's aggressive attack on a playmate, a school-age child's development of assertiveness, an adolescent's joy at the senior prom, and the affection of an elderly couple all reflect the role of socioemotional processes in development.

**Connecting Biological, Cognitive, and Socioemotional Processes** Biological, cognitive, and socioemotional processes are inextricably intertwined (Diamond, 2013). Consider a baby smiling in response to a parent's touch. This response depends on biological processes (the physical nature of touch and responsiveness to it), cognitive processes (the ability to understand intentional acts), and socioemotional processes (the fact that smiling often reflects a positive emotional feeling and helps to connect us in positive ways with other human beings). Nowhere is the connection across biological, cognitive, and socioemotional processes more obvious than in two rapidly emerging fields:

- *developmental cognitive neuroscience*, which explores links between development, cognitive processes, and the brain (Bell & others, 2018; Nyberg, Pudas, & Lundquist, 2017).
- *developmental social neuroscience*, which examines connections between socioemotional processes, development, and the brain (Silvers & others, 2017; Sullivan & Wilson, 2018).

**FIGURE 6**  
**PROCESSES INVOLVED IN DEVELOPMENTAL CHANGES.** Biological, cognitive, and socioemotional processes interact as individuals develop.

#### developmental connection

##### Brain Development

Is there a link between changes in the adolescent's brain and their mood swings and increased risk taking? Connect to "Physical and Cognitive Development in Adolescence."

**biological processes** Changes in an individual's physical nature.

**cognitive processes** Changes in an individual's thought, intelligence, and language.

**socioemotional processes** Changes in an individual's interpersonal relationships, emotions, and personality.

In many instances, biological, cognitive, and socioemotional processes are bidirectional. For example, biological processes can influence cognitive processes and vice versa. Thus, although usually we will study the different processes of development (biological, cognitive, and socioemotional) separately, keep in mind that we are talking about the development of an integrated individual with a mind and body that are interdependent. In many places throughout the book, we will call attention to these connections.

## PERIODS OF DEVELOPMENT

The interplay of biological, cognitive, and socioemotional processes produces the periods of the human life span (see Figure 7). A *developmental period* refers to a time frame in a person's life that is characterized by certain features. For the purposes of organization and understanding, we commonly describe development in terms of these periods. The most widely used classification of developmental periods involves the eight-period sequence shown in Figure 7. Approximate age ranges are listed for the periods to provide a general idea of when each period begins and ends.

The *prenatal period* is the time from conception to birth. It involves tremendous growth—from a single cell to an organism complete with brain and behavioral capabilities—and takes place in approximately a 9-month period.

*Infancy* is the developmental period from birth to 18 or 24 months. Infancy is a time of extreme dependence upon adults. During this period, many psychological activities—language, symbolic thought, sensorimotor coordination, and social learning, for example—are just beginning.

The term *toddler* is often used to describe a child from about 1 ½ to 3 years of age. Toddlers are in a transitional period between infancy and the next period, *early childhood*.

*Early childhood* is the developmental period from 3 through 5 years of age. This period is sometimes called the “preschool years.” During this time, young children learn to become more self-sufficient and to care for themselves, develop school readiness skills (following instructions, identifying letters), and spend many hours playing with peers. First grade typically marks the end of early childhood.

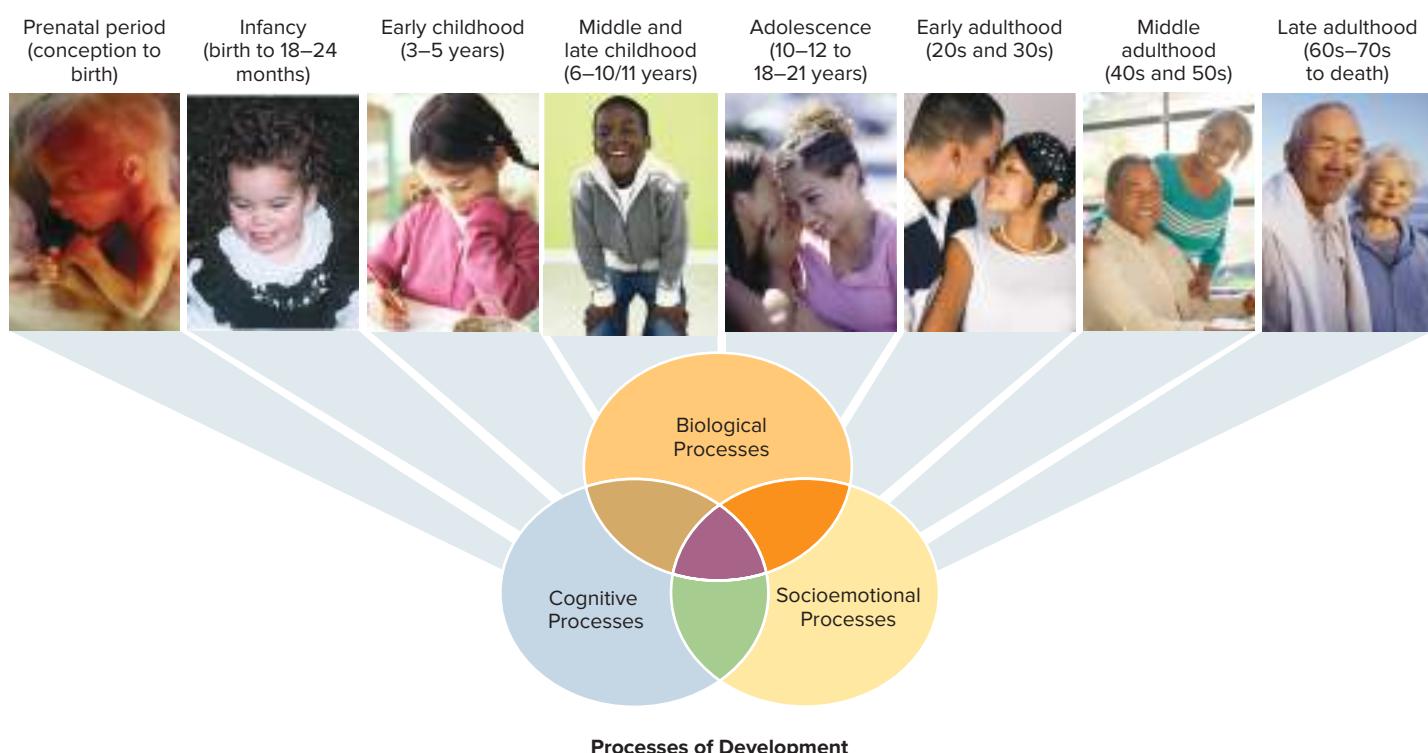

*Middle and late childhood* is the developmental period from about 6 to 10 or 11 years of age, approximately corresponding to the elementary school years. During this period, children

master the fundamental skills of reading, writing, and arithmetic, and they are formally exposed to the larger world and its culture. Achievement becomes a more central theme of the child's world, and self-control increases.

*Adolescence* is the developmental period of transition from childhood to early adulthood, entered at approximately 10 to 12 years of age and ending at 18 to 21 years of age. Adolescence begins with rapid physical changes—dramatic gains in height and weight, changes in body contour, and the development of sexual characteristics such as enlargement of the breasts, growth of pubic and facial hair, and deepening of the voice. At this point in development, the pursuit of independence and an identity are preeminent. Thought is more logical, abstract, and idealistic. More time is spent outside the family.

There has been a substantial increase in interest in the transition between adolescence and early adulthood, a transition that can be a long one as individuals develop more effective skills to become full members of society. Recently, the transition from adolescence to adulthood has been referred to as *emerging adulthood*, the period from approximately 18 to 25 years of age (Arnett, 2015, 2016a, b). Experimentation and exploration characterize the emerging adult. At this point in their development, many individuals are still exploring which career path they want to follow, what they want their identity to be, and which lifestyle they want to adopt (for example, single, cohabiting, or married) (Jensen, 2018; Padilla-Walker & Nelson, 2017).

*Early adulthood* is the developmental period that begins in the early twenties and lasts through the thirties. It is a time of establishing personal and economic independence, advancing in a career, and for many, selecting a mate, learning to live with that person in an intimate way, starting a family, and rearing children.

*Middle adulthood* is the developmental period from approximately 40 to about 60 years of age. It is a time of expanding personal and social involvement and responsibility; of assisting the next generation in becoming competent, mature individuals; and of reaching and maintaining satisfaction in a career.

*Late adulthood* is the developmental period that begins during the sixties or seventies and lasts until death. It is a time of life review, retirement, and adjustment to new social roles and diminishing strength and health.

Late adulthood has the longest span of any period of development, and as noted earlier, the number of people in this age group has been increasing dramatically. As a result, life-span developmentalists have been paying more attention to late adulthood (Bangerter & others, 2018; Frankenmolen & others, 2018; Orkaby & others, 2018). Paul Baltes and Jacqui Smith (2003) argue that a major change takes place in older adults' lives as they become the "oldest-old," on average at about 85 years of age. For example, the "young-old" (classified as 65 through 84 in this analysis) have substantial potential for physical and cognitive fitness, retain much of their cognitive capacity, and can develop strategies to cope with the gains and losses of aging. In contrast, the oldest-old (85 and older) show considerable loss in cognitive skills, experience an increase in chronic stress, and become more frail.

Thus, Baltes and Smith concluded that considerable plasticity and adaptability characterize adults from their sixties until their mid-eighties but that the oldest-old have reached the limits of their functional capacity, which makes interventions to improve their lives difficult. Nonetheless, as will be described in later chapters, considerable variation exists in the degree to which the oldest-old retain their capabilities (Mejia & others, 2017).

**Four Ages** Life-span developmentalists who focus on adult development and aging increasingly describe life-span development in terms of four "ages" (Baltes, 2006; Willis & Schaie, 2006):

*First age:* Childhood and adolescence

*Second age:* Prime adulthood, ages 20 through 59

*Third age:* Approximately 60 to 79 years of age

*Fourth age:* Approximately 80 years and older

The major emphasis in this conceptualization is on the third and fourth ages, especially the increasing evidence that individuals in the third age are healthier and can lead more active, productive lives than their predecessors in earlier generations. However, when older adults reach their eighties (fourth age), especially 85 and over, health and well-being decline for many individuals.

One's children's children's children. Look back to us as we look to you; we are related by our imaginations. If we are able to touch, it is because we have imagined each other's existence, our dreams running back and forth along a cable from age to age.

**Three Developmental Patterns of Aging** K. Warner Schaie (2016a, b) recently described three different developmental patterns that provide a portrait of how aging can encompass individual variations:

- *Normal aging* characterizes most individuals, for whom psychological functioning often peaks in early middle age, remains relatively stable until the late fifties to early sixties, and then shows a modest decline through the early eighties. However, marked decline can occur as individuals approach death.
- *Pathological aging* characterizes individuals who show greater than average decline as they age through the adult years. In early old age, they may have mild cognitive impairment, develop Alzheimer disease later on, or have a chronic disease that impairs their daily functioning.
- *Successful aging* characterizes individuals whose positive physical, cognitive, and socio-emotional development is maintained longer, declining later in old age than is the case for most people. For too long, only the declines that occur in late adulthood were highlighted, but recently there has been increased interest in the concept of successful aging (Docking & Stock, 2018).

**Connections Across Periods of Development** A final important point needs to be made about the periods of the human life span. Just as there are many connections between biological, cognitive, and socioemotional processes, so are there many connections between the periods of the human life span. A key element in the study of life-span development is how development in one period is connected to development in another period. For example, when individuals reach adolescence, many developments and experiences have already taken place in their lives. If an adolescent girl becomes depressed, might her depression be linked to development early in her life, as well as recent and current development? Throughout the text we will call attention to such connections across periods of development through *Developmental Connection* inserts that guide you to earlier or later connections with the material you are currently reading.

## THE SIGNIFICANCE OF AGE

In our description of developmental periods, we linked an approximate age range with each period. But we also have noted that there are variations in the capabilities of individuals of the same age, and we have seen how age-related changes can be exaggerated. How important is age in understanding the characteristics of an individual?

**Age and Happiness** Is there a best age to be? An increasing number of studies indicate that in the United States adults are happier as they age. Consider also a U.S. study

of approximately 28,000 individuals from 18 to 88 that revealed happiness increased with age (Yang, 2008). About 33 percent were very happy at 88 years of age compared with only about 24 percent in their late teens and early twenties. Why might older people report being happier and more satisfied with their lives than younger people? Despite facing higher incidences of physical problems and losses, older adults are more content with what they have in their lives, have better relationships with the people who matter to them, are less pressured to achieve, have more time for leisurely pursuits, and have many years of experience resulting in wisdom that may help them adapt better to their circumstances than younger adults do (Carstensen, 2015; Sims, Hogan, & Carstensen, 2015). Researchers have also found that baby boomers (those born between 1946 and 1964) tend to report being less happy than individuals born earlier—possibly because they are not lowering their aspirations and idealistic hopes as they age, as did earlier generations. Because growing older is a certain outcome of staying alive, it is good to know that we are likely to be happier as older adults than we were when we were younger.

Which of these individuals is likely to be the happiest and to report the highest level of psychological well-being?

Not all studies, though, have found an increase in life satisfaction with age (Steptoe, Deaton, & Stone, 2015). Some studies indicate that the lowest levels of life satisfaction occur in middle age, especially from 45 to 54 years of age (OECD, 2014). Other studies have found that life satisfaction varies across some countries. For example, respondents in research studies conducted in the former Soviet Union and Eastern Europe, as well as in South American countries, reported a decrease in life satisfaction with advancing age (Deaton, 2008). Further, older adults in poor health, such as those with cardiovascular disease, chronic lung disease, and depression, tend to be less satisfied with their lives than their healthier older adult counterparts (Lamont & others, 2017).

Now that you have read about age variations in life satisfaction, think about how satisfied you are with your life. To help you answer this question, complete the items in Figure 8, which presents the most widely used measure in research on life satisfaction (Diener, 2018).

**Conceptions of Age** According to some life-span experts, chronological age is not very relevant to understanding a person's psychological development (Botwinick, 1978). *Chronological age* is the number of years that have elapsed since birth. But time is a crude index of experience, and it does not cause anything. Chronological age, moreover, is not the only way to measure age (MacDonald & Stawski, 2016). Just as there are different domains of development, there are different ways of thinking about age.

Age has been conceptualized not just as chronological age but also as biological age, psychological age, and social age (Hoyer & Roodin, 2009). *Biological age* is a person's age in terms of biological health. Determining biological age involves knowing the functional capacities of a person's vital organs. One person's vital capacities may be better or worse than those of other people of comparable age (Richards & others, 2015). A recent study of 17-year survival rates in Korean adults 20 to 93 years of age found that when biological age was greater than chronological age individuals were less likely to have died (Yoo & others, 2017). The younger the person's biological age, the longer the person is expected to live, regardless of chronological age.

*Psychological age* is an individual's adaptive capacities compared with those of other individuals of the same chronological age. Thus, older adults who continue to learn, are flexible, are motivated, have positive personality traits, control their emotions, and think clearly are engaging in more adaptive behaviors than their chronological age-mates who do not continue to learn, are rigid, are unmotivated, do not control their emotions, and do not think clearly (Rakoczy & others, 2018; Thomas & others, 2018). A longitudinal study of more than 1,200 individuals across seven decades revealed that the personality trait of conscientiousness (being organized, careful, and disciplined, for example) predicted lower mortality (frequency of death) risk from childhood through late adulthood (Martin, Friedman, & Schwartz, 2007). And a recent study found that a higher level of conscientiousness was protective of cognitive functioning in older adults (Wilson & others, 2015).

*Social age* refers to connectedness with others and the social roles individuals adopt. Individuals who have better social relationships with others are happier and more likely to live longer than individuals who are lonely (Carstensen & others, 2015; Reed & Carstensen, 2015).

Life-span expert Bernice Neugarten (1988) argues that in U.S. society chronological age is becoming irrelevant. The 28-year-old mayor, the 35-year-old grandmother, the 65-year-old father of a preschooler, the 55-year-old widow who starts a business, and the 70-year-old student illustrate that old assumptions about the proper timing of life events no longer govern our lives. We still have some expectations for when certain life events—such as getting married, having children, and retiring—should occur. However, chronological age has become a less accurate predictor of these life events in our society. Moreover, issues such as how to deal with intimacy and how to cope with success and failure appear and reappear throughout the life span.

From a life-span perspective, an overall age profile of an individual involves not just chronological age but also biological age, psychological age, and social age. For example, a 70-year-old man (chronological age) might be in good physical health (biological age), be experiencing memory problems and not be coping well with the demands placed on him by his wife's recent hospitalization (psychological age), and have a number of friends with whom he regularly plays golf (social age).

## DEVELOPMENTAL ISSUES

Was Ted Kaczynski born a killer, or did his life turn him into one? Kaczynski himself thought that his childhood was the root of his troubles, saying that he grew up as a genius in a boy's body and never fit in with other children. Did his early experiences determine his later life? Is your own journey through life marked out ahead of time, or can your experiences change your path? Are the experiences you have early in your journey more important than later ones? Is your journey more like taking an elevator up a skyscraper with distinct stops along the way or more like a cruise down a river with smoother ebbs and flows? These questions point to three issues about the nature of development: the roles played by nature and nurture, stability and change, and continuity and discontinuity.

What are some key developmental issues?  
©Rubberball/PictureQuest

**nature-nurture issue** Debate about whether development is primarily influenced by nature or nurture. Nature refers to an organism's biological inheritance, nurture to its environmental experiences.

**Nature and Nurture** The **nature-nurture issue** involves the extent to which development is influenced by nature and by nurture. Nature refers to an organism's biological inheritance, nurture to its environmental experiences.

According to those who emphasize the role of nature, just as a sunflower grows in an orderly way—unless flattened by an unfriendly environment—so too the human grows in an orderly way. An evolutionary and genetic foundation produces commonalities in growth and development (Freedman, 2017; Starr, Evers, & Starr, 2018).

We walk before we talk, speak one word before two words, grow rapidly in infancy and less so in early childhood, experience a rush of sex hormones in puberty, reach the peak of our physical strength in late adolescence and early adulthood, and then physically decline. Proponents of the importance of nature acknowledge that extreme environments—those that are psychologically barren or hostile—can depress development. However, they believe that basic growth tendencies are genetically programmed into humans (Johnson, 2017).

By contrast, other psychologists emphasize the importance of nurture, or environmental experiences, in development (Almy & Cicchetti, 2018; Nicolaisen & Thorsen, 2017; Rubin & Barstead, 2018). Experiences run the gamut from the individual's biological environment

(nutrition, medical care, drugs, and physical accidents) to the social environment (family, peers, schools, community, media, and culture).

There has been a dramatic increase in the number of studies that reflect the *epigenetic view*, which states that development reflects an ongoing, bidirectional interchange between genes and the environment. These studies involve specific DNA sequences (Bakusic & others, 2017; Halldorsdottir & Binder, 2017). The epigenetic mechanisms involve the actual molecular modification of the DNA strand as a result of environmental inputs in ways that alter gene functioning (Moore, 2017; Clukay & others, 2018; Marzi & others, 2018). In “Biological Beginnings” we will explore the epigenetic approach in greater depth.

**Stability and Change** Is the shy child who hides behind the sofa when visitors arrive destined to become a wallflower at college dances, or might the child become a sociable, talkative individual? Is the fun-loving, carefree adolescent bound to have difficulty holding down a 9-to-5 job as an adult? These questions reflect the **stability-change issue**, which involves the degree to which early traits and characteristics persist through life or change.

Many developmentalists who emphasize stability in development argue that stability is the result of heredity and possibly early experiences in life. For example, many argue that if an individual is shy throughout life (as Ted Kaczynski was), this stability is due to heredity and possibly early experiences in which the infant or young child encountered considerable stress when interacting with people.

Developmentalists who emphasize change take the more optimistic view that later experiences can produce change. Recall that in the life-span perspective, plasticity, the potential for change, exists throughout the life span, although possibly to different degrees (Park & Festini, 2018; Motes & others, 2018). Experts such as Paul Baltes (2003) argue that older adults often show less capacity for learning new things than younger adults do. However, many older adults continue to be good at practicing what they have learned earlier in life.

The roles of early and later experience are an aspect of the stability-change issue that has long been hotly debated (Chen & others, 2018; Roisman & Cicchetti, 2017). Some argue that warm, nurturant caregiving during infancy and toddlerhood predicts optimal development later in life (Cassidy, 2016). The later-experience advocates see children as malleable throughout development and believe later sensitive caregiving is just as important as earlier sensitive caregiving (Joling & others, 2018; Taylor & others, 2018).

**Continuity and Discontinuity** When developmental change occurs, is it gradual or abrupt? Think about your own development for a moment. Did you gradually become the person you are today? Or did you experience sudden, distinct changes as you matured? For the most part, developmentalists who emphasize nurture describe development as a gradual, continuous process. Those who emphasize nature often describe development as a series of distinct stages.

The **continuity-discontinuity issue** focuses on the degree to which development involves either gradual, cumulative change (continuity) or distinct stages (discontinuity). In terms of continuity, as the oak grows from seedling to giant oak, it becomes more of an oak—its development is continuous (see Figure 9). Similarly, a child’s first word, though seemingly an abrupt, discontinuous event, is actually the result of weeks and months of growth and practice. Puberty might seem abrupt, but it is a gradual process that occurs over several years.

In terms of discontinuity, as an insect grows from a caterpillar to a chrysalis to a butterfly, it passes through a sequence of stages in which change is qualitatively rather than quantitatively different. Similarly, at some point a child moves from not being able to think abstractly about the world to being able to do so. This is a qualitative, discontinuous change in development rather than a quantitative, continuous change.

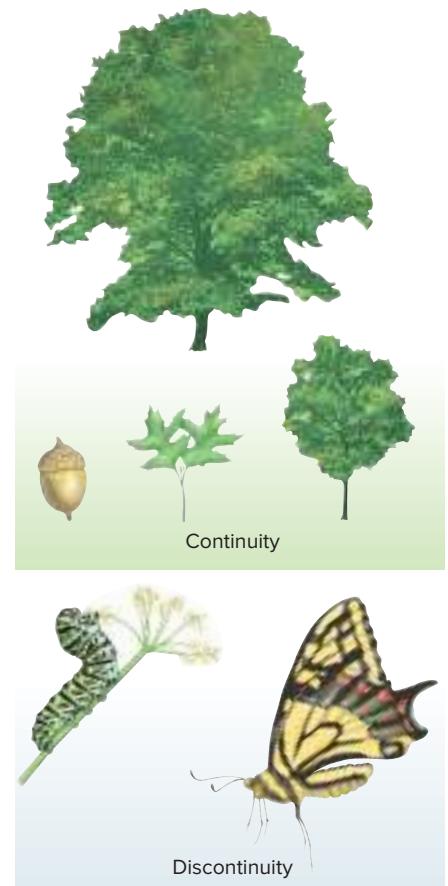

**Evaluating the Developmental Issues** Most life-span developmentalists acknowledge that development is not all nature or all nurture, not all stability or all change, and not all continuity or all discontinuity. Nature and nurture, stability and change, continuity and discontinuity characterize development throughout the human life span.

Although most developmentalists do not take extreme positions on these three important issues, there is spirited debate regarding how strongly development is influenced by each of these factors (Almy & Cicchetti, 2018; Moore, 2017).

## 3 Theories of Development

There is nothing quite so practical as a good theory.

—KURT LEWIN  
American Social Psychologist, 20th Century

**scientific method** An approach that can be used to obtain accurate information. It includes the following steps: (1) conceptualize the problem, (2) collect data, (3) draw conclusions, and (4) revise research conclusions and theory.

**theory** An interrelated, coherent set of ideas that helps to explain phenomena and facilitate predictions.

**hypotheses** Specific assumptions and predictions that can be tested to determine their accuracy.

**psychoanalytic theories** Theories that describe development as primarily unconscious and heavily colored by emotion. Behavior is merely a surface characteristic, and the symbolic workings of the mind have to be analyzed to understand behavior. Early experiences with parents are emphasized.

**Erikson's theory** Includes eight stages of human development. Each stage consists of a unique developmental task that confronts individuals with a crisis that must be resolved.

How can we answer questions about the roles of nature and nurture, stability and change, and continuity and discontinuity in development? How can we determine, for example, whether deterioration of memory in older adults can be prevented or whether special care can repair the harm inflicted by child neglect? The scientific method is the best tool we have to answer such questions (Smith & Davis, 2016).

The **scientific method** is essentially a four-step process: (1) conceptualize a process or problem to be studied, (2) collect research information (data), (3) analyze the data, and (4) draw conclusions.

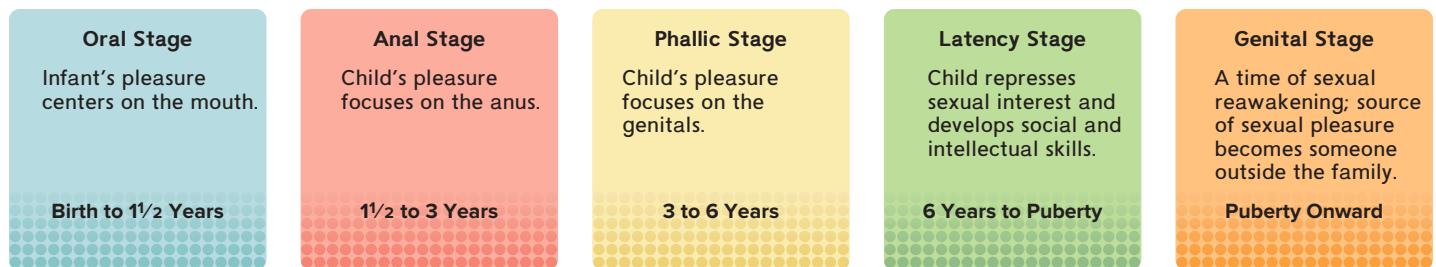

In step 1, when researchers are formulating a problem to study, they often draw on theories and develop hypotheses. A **theory** is an interrelated, coherent set of ideas that helps to explain phenomena and facilitate predictions. It may suggest **hypotheses**, which are specific assertions and predictions that can be tested. For example, a theory on mentoring might state that sustained support and guidance from an adult makes a difference in the lives of children from impoverished backgrounds because the mentor gives the children opportunities to observe and imitate the behavior and strategies of the mentor.

This section outlines key aspects of five theoretical orientations to development: psychoanalytic, cognitive, behavioral and social cognitive, ethological, and ecological. Each contributes an important piece to the life-span development puzzle. Although the theories disagree about certain aspects of development, many of their ideas are complementary rather than contradictory. Together they let us see the total landscape of life-span development in all its richness.

## PSYCHOANALYTIC THEORIES

**Psychoanalytic theories** describe development as primarily unconscious (beyond awareness) and heavily colored by emotion. Psychoanalytic theorists emphasize that behavior is merely a surface characteristic and that a true understanding of development requires analyzing the symbolic meanings of behavior and the deep inner workings of the mind. Psychoanalytic theorists also stress that early experiences with parents extensively shape development. These characteristics are highlighted in the main psychoanalytic theory, that of Sigmund Freud (1856–1939).

**Freud's Theory** As Freud listened to, probed, and analyzed his patients, he became convinced that their problems were the result of experiences early in life. He thought that as

**FIGURE 10**

**FREUDIAN STAGES.** Because Freud emphasized sexual motivation, his stages of development are known as psychosexual stages. In his view, if the need for pleasure at any stage is either undergratified or overgratified, an individual may become fixated, or locked in, at that stage of development.

children grow up, their focus of pleasure and sexual impulses shifts from the mouth to the anus and eventually to the genitals. As a result, we go through five stages of psychosexual development: oral, anal, phallic, latency, and genital (see Figure 10). Our adult personality, Freud (1917) claimed, is determined by the way we resolve conflicts between sources of pleasure at each stage and the demands of reality.

Freud's theory has been significantly revised by a number of psychoanalytic theorists. Many of today's psychoanalytic theorists maintain that Freud overemphasized sexual instincts; they argue that more emphasis should be placed on cultural experiences as determinants of an individual's development. Unconscious thought remains a central theme, but conscious thought plays a greater role than Freud envisioned. One of the most influential revisionists of Freud's ideas was Erik Erikson.

**Erikson's Psychosocial Theory** Erik Erikson (1902–1994) recognized Freud's contributions but believed that Freud misjudged some important dimensions of human development. For one thing, Erikson (1950, 1968) said we develop in psychosocial stages, rather than in psychosexual stages as Freud maintained. According to Freud, the primary motivation for human behavior is sexual in nature; according to Erikson, it is social and reflects a desire to affiliate with other people. According to Freud, our basic personality is shaped during the first five years of life; according to Erikson, developmental change occurs throughout the life span. Thus, in terms of the early-versus-later-experience issue described earlier in the chapter, Freud viewed early experience as being far more important than later experiences, whereas Erikson emphasized the importance of both early and later experiences.

In Erikson's theory, eight stages of development unfold as we go through life (see Figure 11). At each stage, a unique developmental task confronts individuals with a crisis that must be resolved. According to Erikson, this crisis is not a catastrophe but a turning point marked by both increased vulnerability and enhanced potential. The more successfully an individual resolves each crisis, the healthier development will be.

*Trust versus mistrust* is Erikson's first psychosocial stage, which is experienced in the first year of life. The development of trust during infancy sets the stage for a lifelong expectation that the world will be a good and pleasant place to live.

*Autonomy versus shame and doubt* is Erikson's second stage. This stage occurs in late infancy and toddlerhood (1 to 3 years). After gaining trust in their caregivers, infants begin to discover that their behavior is their own. They start to assert their sense of independence or autonomy. They realize their will. If infants and toddlers are restrained too much or punished too harshly, they are likely to develop a sense of shame and doubt.

*Initiative versus guilt*, Erikson's third stage of development, occurs during the preschool years. As preschool children encounter a widening social world, they face new challenges that require active, purposeful, responsible behavior. Feelings of guilt may arise, though, if the child is irresponsible and is made to feel too anxious.

*Industry versus inferiority* is Erikson's fourth developmental stage, occurring approximately during the elementary school years. Children now need to direct their energy toward mastering knowledge and intellectual skills. The negative

#### ERIKSON'S EIGHT LIFE-SPAN STAGES.

Like Freud, Erikson proposed that individuals go through distinct, universal stages of development. Thus, in terms of the continuity-discontinuity issue discussed in this chapter, both favor the discontinuity side of the debate. Notice that the timing of Erikson's first four stages is similar to that of Freud's stages. *What are the implications of saying that people go through stages of development?*

**Piaget's theory** Theory stating that children actively construct their understanding of the world and go through four stages of cognitive development.

outcome is that the child may develop a sense of inferiority—feeling incompetent and unproductive.

During the adolescent years, individuals need to find out who they are, what they are all about, and where they are going in life. This is Erikson's fifth developmental stage, *identity versus identity confusion*. If adolescents explore roles in a healthy manner and arrive at a positive path to follow in life, then they achieve a positive identity; if they do not, identity confusion reigns.

*Intimacy versus isolation* is Erikson's sixth developmental stage, which individuals experience during early adulthood. At this time, individuals face the developmental task of forming intimate relationships. If young adults form healthy friendships and an intimate relationship with another, intimacy will be achieved; if not, isolation will result.

*Generativity versus stagnation*, Erikson's seventh developmental stage, occurs during middle adulthood. By generativity Erikson means primarily a concern for helping the younger generation to develop and lead useful lives. The feeling of having done nothing to help the next generation is stagnation.

*Integrity versus despair* is Erikson's eighth and final stage of development, which individuals experience in late adulthood. During this stage, a person reflects on the past. If the person's life review reveals a life well spent, integrity will be achieved; if not, the retrospective glances likely will yield doubt or gloom—the despair Erikson described.

#### Evaluating Psychoanalytic Theories

Contributions of psychoanalytic theories include an emphasis on a developmental framework, family relationships, and unconscious aspects of the mind. Criticisms include a lack of scientific support, too much emphasis on sexual underpinnings, and an image of people that is too negative.

## COGNITIVE THEORIES

Whereas psychoanalytic theories stress the importance of the unconscious, cognitive theories emphasize conscious thoughts. Three important cognitive theories are Jean Piaget's cognitive developmental theory, Lev Vygotsky's sociocultural cognitive theory, and the information-processing theory.

**Piaget's Cognitive Developmental Theory** Piaget's theory states that children go through four stages of cognitive development as they actively construct their understanding of the world. Two processes underlie this cognitive construction of the world: organization and adaptation. To make sense of our world, we organize our experiences. For example, we separate important ideas from less important ideas, and we connect one idea to another. In addition to organizing our observations and experiences, we adapt, adjusting to new environmental demands (Miller, 2015).

Piaget (1954) identified four stages in understanding the world (see Figure 12). Each stage is age-related and consists of a distinct way of thinking, a different way of understanding the world. Thus, according to Piaget (1896–1980), the child's cognition is qualitatively different from one stage to another. What are Piaget's four stages of cognitive development?

- The *sensorimotor stage*, which lasts from birth to about 2 years of age, is the first Piagetian stage. In this stage, infants construct an understanding of the world by coordinating sensory experiences (such as seeing and hearing) with physical, motoric actions—hence the term *sensorimotor*.

#### Sensorimotor Stage

The infant constructs an understanding of the world by coordinating sensory experiences with physical actions. An infant progresses from reflexive, instinctual action at birth to the beginning of symbolic thought toward the end of the stage.

**Birth to 2 Years of Age**

#### Preoperational Stage

The child begins to represent the world with words and images. These words and images reflect increased symbolic thinking and go beyond the connection of sensory information and physical action.

**2 to 7 Years of Age**

#### Concrete Operational Stage

The child can now reason logically about concrete events and classify objects into different sets.

**7 to 11 Years of Age**

#### Formal Operational Stage

The adolescent reasons in more abstract, idealistic, and logical ways.

**11 Years of Age Through Adulthood**

**FIGURE 12**

**PIAGET'S FOUR STAGES OF COGNITIVE DEVELOPMENT.** According to Piaget, how a child thinks—not how much the child knows—determines the child's stage of cognitive development.

- The *preoperational stage*, which lasts from approximately 2 to 7 years of age, is Piaget's second stage. In this stage, children begin to go beyond simply connecting sensory information with physical action and represent the world with words, images, and drawings. However, according to Piaget, preschool children still lack the ability to perform what he calls operations, which are internalized mental actions that allow children to do mentally what they previously could only do physically. For example, if you imagine putting two sticks together to see whether they would be as long as another stick, without actually moving the sticks, you are performing a concrete operation.
- The *concrete operational stage*, which lasts from approximately 7 to 11 years of age, is the third Piagetian stage. In this stage, children can perform operations that involve objects, and they can reason logically when the reasoning can be applied to specific or concrete examples. For instance, concrete operational thinkers cannot imagine the steps necessary to complete an algebraic equation, a task that is too abstract for individuals at this stage of development.
- The *formal operational stage*, which appears between the ages of 11 and 15 and continues through adulthood, is Piaget's fourth and final stage. In this stage, individuals move beyond concrete experiences and begin to think in abstract and more logical terms. As part of thinking more abstractly, adolescents develop images of ideal circumstances. They might think about what an ideal parent would be like and compare their parents to this ideal standard. They begin to entertain possibilities for the future and are fascinated with what they can be. In solving problems, they become more systematic, developing hypotheses about why something is happening the way it is and then testing these hypotheses. We will examine Piaget's cognitive developmental theory further in other chapters.

**Vygotsky's Sociocultural Cognitive Theory** Like Piaget, the Russian developmentalist Lev Vygotsky (1896–1934) argued that children actively construct their knowledge. However, Vygotsky (1962) gave social interaction and culture far more important roles in

Lev Vygotsky was born the same year as Piaget, but he died much earlier, at the age of 37. There is considerable interest today in Vygotsky's sociocultural cognitive theory of child development. *What are some key characteristics of Vygotsky's theory?*

cognitive development than Piaget did. **Vygotsky's theory** is a sociocultural cognitive theory that emphasizes how culture and social interaction guide cognitive development.

Vygotsky portrayed the child's development as inseparable from social and cultural activities (Daniels, 2017). He maintained that cognitive development involves learning to use the inventions of society, such as language, mathematical systems, and memory strategies. Thus in one culture, children might learn to count with the help of a computer; in another, they might learn by using beads. According to Vygotsky, children's social interaction with more-skilled adults and peers is indispensable to their cognitive development. Through this interaction, they learn to use the tools that will help them adapt and be successful in their culture (Holzman, 2017). In later chapters, we will examine ideas about learning and teaching that are based on Vygotsky's theory.

**The Information-Processing Theory** **Information-processing theory** emphasizes that individuals manipulate information, monitor it, and strategize about it. Unlike Piaget's theory, but like Vygotsky's theory, information-processing theory does not describe development as stage-like. Instead, according to this theory, individuals develop a gradually increasing capacity for processing information, which allows them to acquire increasingly complex knowledge and skills (Knapp & Morton, 2017).

Robert Siegler (2006, 2017), a leading expert on children's information processing, states that thinking is information processing. In other words, when individuals perceive, encode, represent, store, and retrieve information, they are thinking. Siegler emphasizes that an important aspect of development is learning good strategies for processing information. For example, becoming a better reader might involve learning to monitor the key themes of the material being read.

Siegler (2006, 2017) also argues that the best way to understand how children learn is to observe them while they are learning. He emphasizes the importance of using the *microgenetic method* to obtain detailed information about processing mechanisms as they are occurring from moment to moment. Siegler concludes that most research methods indirectly assess cognitive change, being more like snapshots than movies. The microgenetic method seeks to discover not just what children know but the cognitive processes involved in how they acquired the knowledge. A typical microgenetic study will be conducted across a number of trials assessed at various times over weeks or months (Miller, 2015). A number of microgenetic studies have focused on a specific aspect of academic learning, such as how children learn whole number arithmetic, fractions, and other areas of math (Braithwaite & Siegler, 2018; Braithwaite, Tian, & Siegler, 2018). Microgenetic studies also have been used to discover how children learn a particular concept in science or a key component of learning to read.

The information-processing approach often uses the computer as an analogy to help explain the connection between cognition and the brain (Radvansky & Ashcraft, 2018). They describe the physical brain as the computer's hardware, and cognition as its software. In this analogy, the sensory and perceptual systems provide an "input channel," similar to the way data are entered into the computer. As input (information) comes into the mind, mental processes, or operations, act on it, just as the computer's software acts on the data. The transformed input generates information that remains in memory much in the way a computer stores what it has worked on. Finally, the information is retrieved from memory and "printed out" or "displayed" (so to speak) as an observable response.

Computers provide a logical and concrete, but oversimplified, model of the mind's processing of information. Inanimate computers and human brains function quite differently in some respects. For example, most computers receive information from a human who has already coded the information and removed much of its ambiguity. In contrast, each brain cell, or neuron, can respond to ambiguous information transmitted through sensory receptors such as the eyes and ears.

Computers can do some things better than humans. For instance, computers can perform complex numerical calculations much faster and more accurately than humans could ever hope to. Computers can also apply and follow rules more consistently and with fewer errors than humans and can represent complex mathematical patterns better than humans.

Still, the brain's extraordinary capabilities will probably not be mimicked completely by computers at any time in the near future (Sternberg, 2017). For example, although a computer can improve its ability to recognize patterns or use rules of thumb to make decisions, it does not have the means to develop new learning goals. Furthermore, the human mind is aware

of itself; the computer is not. Indeed, no computer is likely to approach the richness of human consciousness.

Nonetheless, the computer's role in cognitive and developmental psychology continues to increase. An entire scientific field called *artificial intelligence (AI)* focuses on creating machines capable of performing activities that require intelligence when they are done by people. And a new field titled *developmental robotics* is emerging that examines various developmental topics and issues using robots, such as motor development, perceptual development, information processing, and language development (Cangelosi & Schlesinger, 2015; Faghihi & Moustafa, 2017; Morse & Cangelosi, 2017). The hope is to build robots that are as much like humans as possible in order to gain a better understanding of human development (Vujovic & others, 2017).

Above is the humanoid robot iCub created by the Italian Institute of Technology to study aspects of children's development such as perception, cognition, and motor development. In this situation, the robot, the size of a 3.5-year-old child, is catching a ball. This robot is being used by more than 20 laboratories worldwide and has 53 motors that move the head, arms and hands, waist, and legs. It also can see and hear, and has the sense of proprioception (body configuration) and movement (using gyroscopes).

**Evaluating Cognitive Theories** Contributions of cognitive theories include a positive view of development and an emphasis on the active construction of understanding. Criticisms include skepticism about the pureness of Piaget's stages and too little attention to individual variations.

## BEHAVIORAL AND SOCIAL COGNITIVE THEORIES

Behaviorism essentially holds that we can study scientifically only what can be directly observed and measured. Out of the behavioral tradition grew the belief that development is observable behavior that can be learned through experience with the environment (Maag, 2018). In terms of the continuity-discontinuity issue discussed earlier in this chapter, the behavioral and social cognitive theories emphasize continuity in development and argue that development does not occur in stage-like fashion. Let's explore two versions of behaviorism: Skinner's operant conditioning and Bandura's social cognitive theory.

**Skinner's Operant Conditioning** According to B. F. Skinner (1904–1990), through operant conditioning the consequences of a behavior produce changes in the probability of the behavior's occurrence. A behavior followed by a rewarding stimulus is more likely to recur, whereas a behavior followed by a punishing stimulus is less likely to recur. For example, when an adult smiles at a child after the child has done something, the child is more likely to engage in that behavior again than if the adult gives the child a disapproving look.

In Skinner's (1938) view, such rewards and punishments shape development. For Skinner the key aspect of development is behavior, not thoughts and feelings. He emphasized that development consists of the pattern of behavioral changes that are brought about by rewards and punishments. For example, Skinner would say that shy people learned to be shy as a result of experiences they had while growing up. It follows that modifications in an environment can help a shy person become more socially oriented.

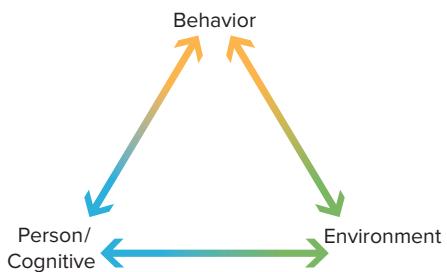

B. F. Skinner was a tinkerer who liked to make new gadgets. During her first two years of life the younger of his two daughters, Deborah, slept and played in Skinner's enclosed Air-Crib, which he invented because he wanted to control her environment completely. The Air-Crib was sound-proofed and temperature controlled. Debbie, shown here as a child with her parents, is currently a successful artist, is married, and lives in London. *What do you think about Skinner's Air-Crib?*

**Bandura's Social Cognitive Theory** Some psychologists agree with the behaviorists' notion that development is learned and is influenced strongly by environmental interactions. However, unlike Skinner, they also see cognition as important in understanding development (Mischel, 2014). **Social cognitive theory** holds that behavior, environment, and cognition are the key factors in development.

American psychologist Albert Bandura (1925– ) is the leading architect of social cognitive theory. Bandura (1986, 2004, 2010a, b, 2012, 2015) emphasizes that cognitive processes have important links with the environment and behavior. His early research program focused heavily on observational learning (also called imitation or modeling), which is learning that occurs through observing what others do. For example, a young boy might observe his father yelling in anger and treating other people with hostility; with his peers, the young boy later acts very aggressively, showing the

The arrows illustrate how relations between behavior, person/cognitive, and environment are reciprocal rather than one-way. an emphasis on scientific research and environmental determinants of behavior. Criticisms include too little emphasis on cognition in Skinner's theory and inadequate attention paid to developmental changes.

## ETHOLOGICAL THEORY

**Ethology** stresses that behavior is strongly influenced by biology, is tied to evolution, and is characterized by critical or sensitive periods. These are specific time frames during which, according to ethologists, the presence or absence of certain experiences has a long-lasting influence on individuals (Bateson, 2015).

European zoologist Konrad Lorenz (1903–1989) helped bring ethology to prominence. In his best-known research, Lorenz (1965) studied the behavior of greylag geese, which will follow their mothers as soon as they hatch. Lorenz separated the eggs laid by one goose into two groups. One group he returned to the goose to be hatched by her. The other group was hatched in an incubator. The goslings in the first group performed as predicted. They followed their mother as soon as they hatched. However, those in the second group, which saw Lorenz when they first hatched, followed him everywhere, as though he were their mother. Lorenz marked the goslings and then placed both groups under a box. Mother goose and "mother" Lorenz stood aside as the box was lifted. Each group of goslings went directly to its "mother." Lorenz called this process imprinting—the rapid, innate learning that involves attachment to the first moving object seen.

same characteristics as his father's behavior. Social cognitive theorists stress that people acquire a wide range of behaviors, thoughts, and feelings through observing others' behavior and that these observations play a central role in life-span development.

What is cognitive about observational learning in Bandura's view? He proposes that people cognitively represent the behavior of others and then sometimes adopt this behavior themselves.

Bandura's (2004, 2010a, b, 2012, 2015) most recent model of learning and development includes three elements: behavior, the person/cognition, and the environment. An individual's confidence in being able to control his or her success is an example of a person factor; strategies are an example of a cognitive factor. As shown in Figure 13, behavior, person/cognitive, and environmental factors operate interactively.

**Evaluating Behavioral and Social Cognitive Theories**

Contributions of the behavioral and social cognitive theories include

John Bowlby (1969, 1989) illustrated an important application of ethological theory to human development. Bowlby stressed that attachment to a caregiver over the first year of life has important consequences throughout the life span. In his view, if this attachment is positive and secure, the individual will likely develop positively in childhood and adulthood. If the attachment is negative and insecure, life-span development will likely not be optimal. We will explore the concept of infant attachment in much greater detail later in this edition.

In Lorenz's view, imprinting needs to take place at a certain, very early time in the life of the animal, or else it will not take place. This point in time is called a critical period. A related concept is that of a sensitive period, and an example of this is the time during infancy when, according to Bowlby, attachment should occur in order to promote optimal development of social relationships.

Another theory that emphasizes biological foundations of development—evolutionary psychology—will be presented in the chapter on “Biological Beginnings,” along with views on the role of heredity in development (Lickliter, 2018). In addition, we will examine a number of biological theories of aging in later chapters (Kauppila, Kauppila, & Larsson, 2017).

Contributions of ethological theory include a focus on the biological and evolutionary basis of development, and the use of careful observations in naturalistic settings. Criticisms include too much emphasis on biological foundations and a belief that the critical and sensitive period concepts might be too rigid.

## ECOLOGICAL THEORY

While ethological theory stresses biological factors, ecological theory emphasizes environmental factors. One ecological theory that has important implications for understanding life-span development was created by Urie Bronfenbrenner (1917–2005). **Bronfenbrenner’s ecological theory** (Bronfenbrenner, 1986, 2004; Bronfenbrenner & Morris, 1998, 2006) holds that development reflects the influence of several environmental systems. The theory identifies five environmental systems: microsystem, mesosystem, exosystem, macrosystem, and chronosystem (see Figure 14).

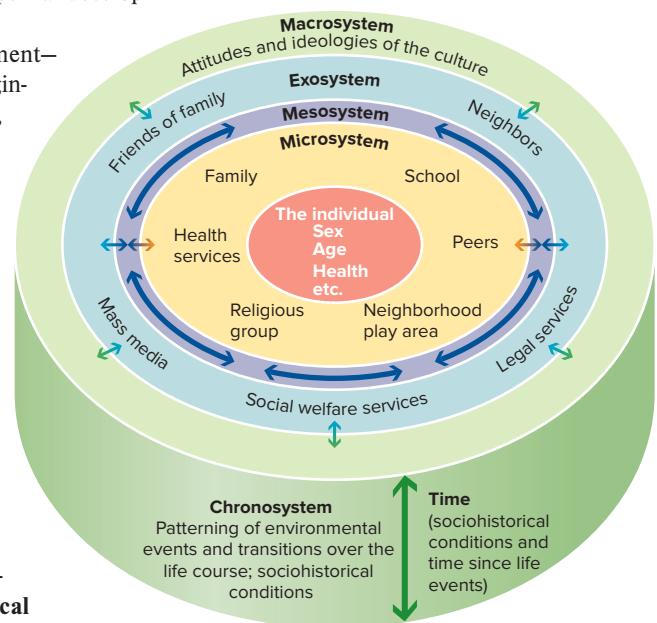

The *microsystem* is the setting in which the individual lives. These contexts include the person’s family, peers, school, and neighborhood. It is in the microsystem that the most direct interactions with social agents take place—with parents, peers, and teachers, for example. The individual is not a passive recipient of experiences in these settings, but someone who helps to construct the settings.

The *mesosystem* involves relations between microsystems or connections between contexts. Examples are the relation of family experiences to school experiences, school experiences to religious experiences, and family experiences to peer experiences. For example, children whose parents have rejected them may have difficulty developing positive relationships with teachers.

The *exosystem* consists of links between a social setting in which the individual does not have an active role and the individual’s immediate context. For example, a husband’s or child’s experiences at home may be influenced by a mother’s experiences at work. The mother might receive a promotion that requires more travel, which might increase conflict with the husband and change patterns of interaction with the child.

The *macrosystem* involves the culture in which individuals live. Remember from earlier in the chapter that culture refers to the behavior patterns, beliefs, and all other products of a group of people that are passed on from generation to generation. Remember also that cross-cultural studies—the comparison of one culture with one or more other cultures—provide information about the generality of development.

The *chronosystem* consists of the patterning of environmental events and transitions over the life course, as well as sociohistorical circumstances. For example, divorce is one transition. Researchers have found that the negative effects of divorce on children often peak during the

first year after the divorce (Hetherington, 1993, 2006). By two years after the divorce, family interaction has become more stable. As an example of sociohistorical circumstances, consider how career opportunities for women have increased since the 1960s.

Bronfenbrenner (2004; Bronfenbrenner & Morris, 2006) subsequently added biological influences to his theory, describing it as a bioecological theory. Nonetheless, it is still dominated by ecological, environmental contexts.

Contributions of ecological theory include a systematic examination of macro and micro dimensions of environmental systems, and attention to connections between environmental systems. A further contribution of Bronfenbrenner's theory is an emphasis on a range of social contexts beyond the family, such as neighborhood, religion, school, and workplace, as influential in children's development (Shelton, 2018). Criticisms include inadequate attention to biological factors, as well as too little emphasis on cognitive factors.

## AN ECLECTIC THEORETICAL ORIENTATION

No single theory described in this chapter can explain entirely the rich complexity of life-span development, but each has contributed to our understanding of development. Psychoanalytic theory best explains the unconscious mind. Erikson's theory best describes the changes that occur during adult development. Piaget's, Vygotsky's, and the information-processing views provide the most complete description of cognitive development. The behavioral and social cognitive and ecological theories have been the most adept at examining the environmental determinants of development. The ethological theories have highlighted biology's role and the importance of sensitive periods in development.

In short, although theories are helpful guides, relying on a single theory to explain development is probably a mistake. This book instead takes an **eclectic theoretical orientation**, which does not follow any one theoretical approach but rather selects from each theory whatever is considered its best features. In this way, you can view the study of development as it actually exists—with different theorists making different assumptions, stressing different empirical problems, and using different strategies to discover information. Figure 15 compares the main theoretical perspectives in terms of how they view important issues in life-span development.

If they follow an eclectic orientation, how do scholars and researchers determine that one feature of a theory is somehow better than another? Through scientific research, the features of theories can be tested and refined (Smetana, 2018; Smith & Davis, 2016).

Generally, research on life-span development is designed to test hypotheses, which in some cases are derived from the theories just described. Through research, theories are modified to reflect new data, and occasionally new theories arise. How are data about life-span development collected? What types of research designs are used to study life-span development? And what are some ethical considerations in conducting research on life-span development?

### METHODS FOR COLLECTING DATA

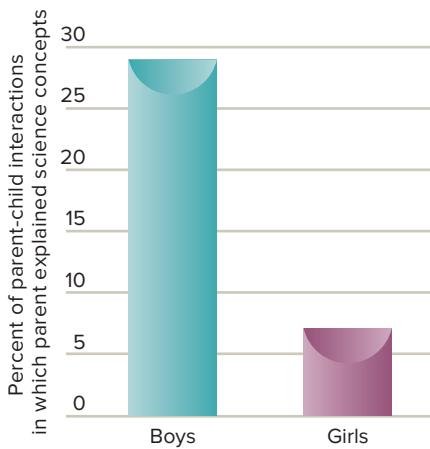

Whether we are interested in studying attachment in infants, the cognitive skills of children, or social relationships in older adults, we can choose from several ways of collecting data (Salkind, 2017). Here we outline the measures most often used, beginning with observation.

**Observation** Scientific observation requires an important set of skills. For observations to be effective, they have to be systematic. We have to have some idea of what we are looking for. We have to know whom we are observing, when and where we will observe, how the observations will be made, and how they will be recorded.

Where should we make our observations? We have two choices: the laboratory and the everyday world.

When we observe scientifically, we often need to control certain factors that determine behavior but are not the focus of our inquiry (Leary, 2017). For this reason, some research on life-span development is conducted in a **laboratory**, a controlled setting where many of the complex factors of the “real world” are absent. For example, suppose you want to observe how children react when they see other people act aggressively. If you observe children in their

**laboratory** A controlled setting in which many of the complex factors of the “real world” are removed.

**FIGURE 16**

#### PARENTS' EXPLANATIONS OF SCIENCE TO SONS AND DAUGHTERS AT A SCIENCE MUSEUM.

**MUSEUM.** In a naturalistic observation study at a children's science museum, parents were three times more likely to explain science to boys than to girls (Crowley & others, 2001). The gender difference occurred regardless of whether the father, the mother, or both parents were with the child, although the gender difference was greatest for fathers' science explanations to sons and daughters.

homes or schools, you have no control over how much aggression the children observe, what kind of aggression they see, which people they see acting aggressively, or how other people treat the children. In contrast, if you observe the children in a laboratory, you can control these and other factors and therefore have more confidence about how to interpret your observations.

Laboratory research does have some drawbacks, however, including the following:

1. It is almost impossible to conduct research without the participants knowing they are being studied.
2. The laboratory setting is unnatural and therefore can cause the participants to behave unnaturally.
3. People who are willing to come to a university laboratory may not accurately represent groups from diverse cultural backgrounds.
4. People who are unfamiliar with university settings and with the idea of "helping science" may be intimidated by the laboratory setting.

Naturalistic observation provides insights that sometimes cannot be attained in the laboratory (Babbie, 2017). **Naturalistic observation** means observing behavior in real-world settings, making no effort to manipulate or control the situation. Life-span researchers conduct naturalistic observations at sporting events, child-care centers, work settings, malls, and other places people live in and frequent.

Naturalistic observation was used in one study that focused on conversations in a children's science museum (Crowley & others, 2001). When visiting exhibits at the science museum, parents were far more likely to engage boys than girls in explanatory talk. This finding suggests a gender bias that encourages boys more than girls to be interested in science (see Figure 16).

**Survey and Interview** Sometimes the best and quickest way to get information about people is to ask them for it. One technique is to interview them directly. A related method is

the survey (sometimes referred to as a questionnaire), which is especially useful when information from many people is needed. A standard set of questions is used to obtain peoples' self-reported attitudes or beliefs about a particular topic. In a good survey, the questions are clear and unbiased, allowing respondents to answer unambiguously.

Surveys and interviews can be used to study topics ranging from religious beliefs to sexual habits to attitudes about gun control to beliefs about how to improve schools. Surveys and interviews may be conducted in person, over the telephone, and over the Internet.

One problem with surveys and interviews is the tendency of participants to answer questions in a way that they think is socially acceptable or desirable rather than to say what they truly think or feel (Madill, 2012). For example, on a survey or in an interview some individuals might say that they do not take drugs even though they do.

**Standardized Test** A **standardized test** has uniform procedures for administration and scoring. Many standardized tests allow a person's performance to be compared with that of other individuals; thus they provide information about individual differences among

people (Kaplan & Saccuzzo, 2018). One example is the Stanford-Binet intelligence test, which will be discussed in more detail later. Your score on the Stanford-Binet test tells you how your performance compares with that of thousands of other people who have taken the test.

One criticism of standardized tests is that they assume a person's behavior is consistent and stable, yet personality and intelligence—two primary targets of standardized testing—can vary with the situation. For example, a person may perform poorly on a standardized intelligence test in an office setting but score much higher at home, where he or she is less anxious.

**naturalistic observation** Studies that involve observing behavior in real-world settings.

**standardized test** A test with uniform procedures for administration and scoring. Many standardized tests allow a person's performance to be compared with the performance of other individuals.

**Case Study** A **case study** is an in-depth look at a single individual. Case studies are performed mainly by mental health professionals when, for either practical or ethical reasons, the unique aspects of an individual's life cannot be duplicated and tested in other individuals. A case study provides information about one person's experiences; it may focus on nearly any aspect of the subject's life that helps the researcher understand the person's mind, behavior, or other attributes (Yin, 2012). A researcher may gather information for a case study from interviews and medical records. In later chapters, we discuss vivid case studies, such as that of Michael Rehbein, who had much of the left side of his brain removed at 7 years of age to end severe epileptic seizures.

A case study can provide a dramatic, in-depth portrayal of an individual's life, but we must be cautious when generalizing from this information. The subject of a case study is unique, with a genetic makeup and personal history that no one else shares. In addition, case studies involve judgments of unknown reliability. Researchers who conduct case studies rarely check to see if other professionals agree with their observations or findings.

**Physiological Measures** Researchers are increasingly using physiological measures when they study development at different points in the life span (Bell & others, 2018). Hormone levels are increasingly used in developmental research.

Cortisol is a hormone produced by the adrenal gland that is linked to the body's stress level and has been measured in studies of temperament, emotional reactivity, mood, and peer relations (Bangerter & others, 2017). Also, as puberty unfolds, the blood levels of certain hormones increase. To determine the nature of these hormonal changes, researchers analyze blood samples from adolescent volunteers (Ji & others, 2016).

Another physiological measure that is increasingly being used is neuroimaging, especially *functional magnetic resonance imaging* (fMRI), in which electromagnetic waves are used to construct images of a person's brain tissue and biochemical activity (Park & Festini, 2018; Sullivan & Wilson, 2018). Figure 17 compares the brain images of two adolescents—one a non-drinker and the other a heavy drinker—while they are engaged in a memory task.

Electroencephalography (EEG) is a physiological measure that has been used for many decades to monitor overall electrical activity in the brain (Najjar & Brooker, 2017). Recent

### Gene × Environment (G × E) Interaction

Increasingly, researchers are exploring how the interaction of a specific gene and a specific aspect of the environment affects development. Connect to “Biological Beginnings.”

electroencephalograph research includes studies of infants’ attention and memory (Bell & others, 2018; Lusby & others, 2016). In many chapters of this edition, you will read about recent research on changes in the brain during prenatal development, infancy, childhood, adolescence, and aging.

Heart rate has been used as an indicator of infants’ and children’s development of perception, attention, and memory (Kim, Yang, & Lee, 2015). Further, heart rate has served as an index of different aspects of emotional development, such as inhibition, stress, and anxiety (Amole & others, 2017).

Researchers study eye movement to learn more about perceptual development and other developmental topics. Sophisticated eye-tracking equipment is especially being used to discover more detailed information about infants’ perception (Boardman & Fletcher-Watson, 2017), attention (Meng, Uto, & Hashiya, 2017), autism (Finke, Wilkinson, & Hickerson, 2017), and preterm birth effects on language development (Loi & others, 2017).

Yet another dramatic change in physiological methods is the advancement in methods to assess the actual units of hereditary information—genes—in studies of biological influences on development (Xing & others, 2018). For example, recent advances in gene assessment have revealed several specific genes that are linked to childhood obesity (Zandona & others, 2017). Also, in a later chapter you will read about the role of the ApoE4 gene in Alzheimer disease (Lancaster, Tabet, & Rusted, 2017; Parcon & others, 2018; Park & Festini, 2018).

## RESEARCH DESIGNS

When you are conducting research on life-span development, in addition to selecting a method for collecting data, you also need to choose a research design (Jackson, 2017). There are three main types of research designs: descriptive, correlational, and experimental.

**Descriptive Research** All of the data-collection methods that we have discussed can be used in **descriptive research**, which aims to observe and record behavior. For example, a researcher might observe the extent to which people are altruistic or aggressive toward each other. By itself, descriptive research cannot prove what causes some phenomenon, but it can reveal important information about people’s behavior (Gravetter & Forzano, 2017).

**Correlational Research** In contrast with descriptive research, correlational research goes beyond describing phenomena to provide information that will help us to predict how people will behave (Gravetter & Forzano, 2017). In **correlational research**, the goal is to describe the strength of the relationship between two or more events or characteristics. The more strongly the two events are correlated (or related or associated), the more accurately we can predict one event from the other (Aron, Aron, & Coups, 2017).

For example, to find out whether children of permissive parents have less self-control than other children, you would need to carefully record observations of parents’ permissiveness and their children’s self-control. You might observe that the higher a parent was in permissiveness, the lower the child was in self-control. You would then analyze these data statistically to yield a numerical measure called a **correlation coefficient**, which is a number based on a statistical analysis that describes the degree of association between two variables. The correlation coefficient ranges from  $-1.00$  to  $+1.00$ . A negative number means an inverse relation. In this example, you might find an inverse correlation between permissive parenting and children’s self-control with a coefficient of, say,  $-.30$ . By contrast, you might find a positive correlation of  $+.30$  between parental monitoring of children and children’s self-control.

The higher the correlation coefficient (whether positive or negative), the stronger the association between the two variables. A correlation of 0 means that there is no association between the variables. A correlation of  $-.40$  is stronger than a correlation of  $+.20$  because we disregard whether the correlation is positive or negative in determining the strength of the correlation.

A caution is in order, however. Correlation does not equal causation (Howell, 2017). The correlational finding just mentioned does not mean that permissive parenting necessarily causes low self-control in children. It could have that meaning, but it also could indicate that a child’s lack of self-control caused the parents to throw up their arms in despair and give up trying to control the child. It also could mean that other factors, such as heredity or poverty, caused the correlation between permissive parenting and low self-control in children. Figure 18 illustrates these possible interpretations of correlational data.

**descriptive research** Studies designed to observe and record behavior.

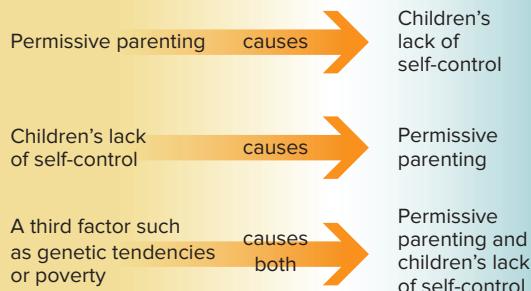

**correlational research** Research that attempts to determine the strength of the relationship between two or more events or characteristics.

**correlation coefficient** A number based on statistical analysis that is used to describe the degree of association between two variables.

**Observed Correlation:** As permissive parenting increases, children's self-control decreases.

#### Possible explanations for this observed correlation

An observed correlation between two events cannot be used to conclude that one event causes the second event. Other possibilities are that the second event causes the first event or that a third event causes the correlation between the first two events.

**Experimental Research** To study causality, researchers turn to experimental research. An **experiment** is a carefully regulated procedure in which one or more factors believed to influence the behavior being studied are manipulated while all other factors are held constant. If the behavior under study changes when a factor is manipulated, we say that the manipulated factor has caused the behavior to change. In other words, the experiment has demonstrated cause and effect. The cause is the factor that was manipulated. The effect is the behavior that changed because of the manipulation. Nonexperimental research methods (descriptive and correlational research) cannot establish cause and effect because they do not involve manipulating factors in a controlled way.

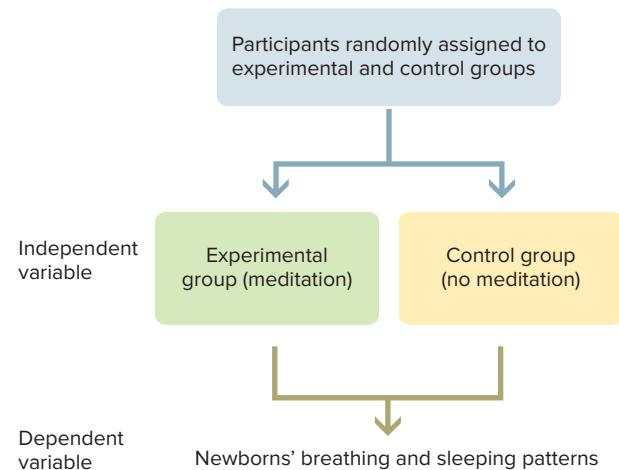

**Independent and Dependent Variables** Experiments include two types of changeable factors, or variables: independent and dependent. An independent variable is a manipulated, influential, experimental factor. It is a potential cause. The label “independent” is used because this variable can be manipulated independently of other factors to determine its effect. An experiment may include one independent variable or several of them.

A dependent variable is a factor that can change in an experiment, in response to changes in the independent variable. As researchers manipulate the independent variable, they measure the dependent variable for any resulting effect.

For example, suppose that you conducted a study to determine whether women could change the breathing and sleeping patterns of their newborn babies by meditating during pregnancy. You might require one group of pregnant women to engage in a certain amount and type of meditation each day while another group would not meditate; the meditation is thus the independent variable. When the infants are born, you would observe and measure their breathing and sleeping patterns. These patterns are the dependent variable, the factor that changes as the result of your manipulation.

**Experimental and Control Groups** Experiments can involve one or more experimental groups and one or more control groups (Gravetter & Forzano, 2017). An experimental group is a group whose experience is manipulated. A control group is a comparison group that is as similar to the experimental group as possible and that is treated in every way like the experimental group except for the manipulated factor (independent variable). The control group serves as a baseline against which the effects of the manipulated condition can be compared.

Random assignment is an important principle for deciding whether each participant will be placed in the experimental group or in the control group. Random assignment means that researchers assign participants to experimental and control groups by chance. It reduces the likelihood that the experiment’s results will be due to any preexisting differences between groups. In the example involving the effects of meditation by pregnant women on the breathing and sleeping patterns of their newborns, you would randomly assign half of the pregnant women to engage in meditation over a period of weeks (the experimental group) and the other half to not meditate over the same number of weeks (the control group). Figure 19 illustrates the nature of experimental research.

**FIGURE 19**

#### PRINCIPLES OF EXPERIMENTAL

**RESEARCH.** Imagine that you decide to conduct an experimental study of the effects of meditation by pregnant women on their newborns’ breathing and sleeping patterns. You would randomly assign pregnant women to experimental and control groups. The experimental-group women would engage in meditation over a specified number of sessions and weeks. The control group would not. Then, when the infants are born, you would assess their breathing and sleeping patterns. If the breathing and sleeping patterns of newborns whose mothers were in the experimental group are more positive than those of the control group, you would conclude that meditation caused the positive effects.

**experiment** A carefully regulated procedure in which one or more of the factors believed to influence the behavior being studied are manipulated while all other factors are held constant.

## TIME SPAN OF RESEARCH

Researchers in life-span development have a special concern with studies that focus on the relation of age to some other variable. We have several options: Researchers can study different individuals of varying ages and compare them or they can study the same individuals as they age over time.

**Cross-Sectional Approach** The **cross-sectional approach** is a research strategy that simultaneously compares individuals of different ages. A typical cross-sectional study might include three groups of children: 5-year-olds, 8-year-olds, and 11-year-olds. Another study might include groups of 15-year-olds, 25-year-olds, and 45-year-olds. The groups can be compared with respect to a variety of dependent variables: IQ, memory, peer relations, attachment to parents, hormonal changes, and so on. All of this can be accomplished in a short time. In some studies, data are collected in a single day. Even in large-scale cross-sectional studies with hundreds of subjects, data collection does not usually take longer than several months to complete.

The main advantage of the cross-sectional study is that the researcher does not have to wait for the individuals to grow up or become older. Despite its efficiency, though, the cross-sectional approach has its drawbacks. It gives no information about how individuals change or about the stability of their characteristics. It can obscure the increases and decreases of development—the hills and valleys of growth and development. For example, a cross-sectional study of life satisfaction might reveal average increases and decreases, but it would not show how the life satisfaction of individual adults waxed and waned over the years. It also would not tell us whether the same adults who had positive or negative perceptions of life satisfaction in early adulthood maintained their relative degree of life satisfaction as they became middle-aged or older adults.

**Longitudinal Approach** The **longitudinal approach** is a research strategy in which the same individuals are studied over a period of time, usually several years or more. For example, in a longitudinal study of life satisfaction, the same adults might be assessed periodically over a 70-year time span—at the ages of 20, 35, 45, 65, and 90, for example.

Longitudinal studies provide a wealth of information about vital issues such as stability and change in development and the influence of early experience on later development, but they do have drawbacks (Almy & Cicchetti, 2018). They are expensive and time-consuming. The longer the study lasts, the more participants drop out—they move, get sick, lose interest, and so forth. The participants who remain may be dissimilar to those who drop out, biasing the outcome of the study. Those individuals who remain in a longitudinal study over a number of years may be more responsible and conformity-oriented, for example, or they might lead more stable lives.

#### Intelligence

Cohort effects help to explain differences in the intelligence of people born at different points in time. Connect to “Physical and Cognitive Development in Middle Adulthood.”

**Cohort Effects** A *cohort* is a group of people who are born at a similar point in history and share similar experiences as a result, such as living through the Vietnam War or growing up in the same city around the same time. These shared experiences may produce a range of differences among cohorts (Ganguli, 2017; Messerlian & Basso, 2018; Schaie, 2016a, b). For example, people who were teenagers during the Great Depression are likely to differ from people who were teenagers during the booming 1990s in regard to their educational opportunities and economic status, how they were raised, and their attitudes toward sex and religion. In life-span development research, **cohort effects** are due to a person’s time of birth, era, or generation but not to actual age.

Cohort effects are important because they can powerfully affect the dependent measures in a study ostensibly concerned with age (Grondahl & others, 2017; MacDonald & Stawski, 2016). Researchers have shown that it is especially important to be aware of cohort effects when assessing adult intelligence (Schaie, 2016a, b). Individuals born at different points in time—such as 1920, 1940, and 1960—have had varying opportunities for education. Individuals born in earlier years had less access to education, and this fact may have a significant effect on how this cohort performs on intelligence tests. Some researchers have found that cross-sectional studies indicate more than 90 percent of cognitive decline in aging is due to a slowing of processing speed, whereas longitudinal studies reveal that 20 percent or less of cognitive decline is due to processing speed (MacDonald & others, 2003; MacDonald & Stawski, 2015, 2016; Stawski, Sliwinski, & Hofer, 2013).

A recent example of a cohort effect occurred in a study in which older adults assessed in 2013–2014 engaged in a higher level of abstract reasoning than their counterparts assessed two decades earlier in 1990–1993 (Gerstorf & others, 2015). Another study illustrated how even a 10-year difference in when people are born can produce differences in cognitive and

health outcomes (Christensen & others, 2013). In this study, Danish cohorts born in 1905 and 1915 were compared when each cohort reached their nineties, with the 1915 cohort showing significantly better cognitive and health profiles.

Cross-sectional studies can show how different cohorts respond, but they can confuse age changes and cohort effects. Longitudinal studies are effective in studying age changes but only within one cohort.

Various generations have been given labels by the popular culture. Figure 20 describes the labels given to various generations, their historical periods, and the reasons for these labels. Consider the following description of the current generation of youth and think about how they differ from earlier youth generations:

They are history's first "always connected" generation. Steeped in digital technology and social media, they treat their multi-tasking hand-held gadgets almost like a body part—for better or worse. More than 8 in 10 say they sleep with a cell phone glowing by the bed, poised to disgorge texts, phone calls, e-mails, songs, news, videos, games, and wake-up jingles. But sometimes convenience yields to temptation. Nearly two-thirds admit to texting while driving (Pew Research Center, 2010, p. 1).

Cohort effects are due to a person's time of birth or generation but not actually to age. Think for a moment about growing up in (*left*) the Great Depression and (*right*) today. *How might your development differ depending on which of these time frames has dominated your life? your parents' lives? your grandparents' lives?*

Generation	Historical Period	Reasons for Label
Millennials	Individuals born in 1980 and later	First generation to come of age and enter emerging adulthood (18 to 25 years of age) in the twenty-first century (the new millennium). Two main characteristics: (1) connection to technology, and (2) ethnic diversity.
Generation X	Individuals born between 1965 and 1980	Described as lacking an identity and savvy loners.
Baby Boomers	Individuals born between 1946 and 1964	Label used because this generation represents the spike in the number of babies born after World War II; the largest generation ever to enter late adulthood in the United States.
Silent Generation	Individuals born between 1928 and 1945	Children of the Great Depression and World War II; described as conformists and civic minded.

## CONDUCTING ETHICAL RESEARCH

Ethics in research may affect you personally if you ever serve as a participant in a study. In that event, you need to know your rights as a participant and the responsibilities of researchers to assure that these rights are safeguarded.

If you ever become a researcher in life-span development yourself, you will need an even deeper understanding of ethics. Even if you only carry out experimental projects in psychology courses, you must consider the rights of the participants in those projects (Salkind, 2017). A student might think, “I volunteer in a home for people with intellectual disabilities several hours per week. I can use the residents of the home in my study to see if a particular treatment helps improve their memory for everyday tasks.” But without proper permissions, the most well-meaning, kind, and considerate studies still violate the rights of the participants.

Today, proposed research at colleges and universities must pass the scrutiny of a research ethics committee before the research can be initiated (Kazdin, 2017; Leary, 2017). In addition, the American Psychological Association (APA) has developed ethics guidelines for its members. The code of ethics instructs psychologists to protect their participants from mental and physical harm. The participants’ best interests need to be kept foremost in the researcher’s mind. APA’s guidelines address four important issues:

1. *Informed consent.* All participants must know what their research participation will involve and what risks might develop. Even after informed consent is given, participants must retain the right to withdraw from the study at any time and for any reason.
2. *Confidentiality.* Researchers are responsible for keeping all of the data they gather on individuals completely confidential and, when possible, completely anonymous.
3. *Debriefing.* After the study has been completed, participants should be informed of its purpose and the methods that were used. In most cases, the experimenter also can inform participants in a general manner beforehand about the purpose of the research without leading participants to behave in a way they think that the experimenter is expecting.
4. *Deception.* In some circumstances, telling the participants beforehand what the research study is about substantially alters the participants’ behavior and invalidates the researcher’s data. In all cases of deception, however, the psychologist must ensure that the deception will not harm the participants and that the participants will be debriefed (told the complete nature of the study) as soon as possible after the study is completed.

## MINIMIZING BIAS

Studies of life-span development are most useful when they are conducted without bias or prejudice toward any particular group of people. Of special concern is bias based on gender and bias based on culture or ethnicity.

**Gender Bias** For most of its existence, our society has had a strong gender bias, a pre-conceived notion about the abilities of women and men that prevented individuals from pursuing their own interests and achieving their potential (Brannon, 2017; Helgeson, 2017). Gender bias also has had a less obvious effect within the field of life-span development. For example, it is not unusual for conclusions to be drawn about females’ attitudes and behaviors from research conducted with males as the only participants.

Furthermore, when researchers find gender differences, their reports sometimes magnify those differences (Denmark & others, 1988). For example, a researcher might report that 74 percent of the men in a study had high achievement expectations versus only 67 percent of the women and go on to talk about the differences in some detail. In reality, this might be a rather small difference. It also might disappear if the study were repeated, or the study might have methodological problems that don’t allow such strong interpretations.

Pam Reid is a leading researcher who studies the effects of gender and ethnic bias on development. You can read about Dr. Reid’s interests in *Connecting with Careers*.

## Pam Reid, Educational and Developmental Psychologist

When she was a child, Pam Reid liked to play with chemistry sets. Reid majored in chemistry during college and wanted to become a doctor. However, when some of her friends signed up for a psychology class as an elective, she decided to take the course. She was intrigued by learning about how people think, behave, and develop—so much so that she changed her major to psychology. Reid went on to obtain her Ph.D. in psychology (American Psychological Association, 2003, p. 16).

For a number of years, Reid was a professor of education and psychology at the University of Michigan, where she also was a research scientist at the Institute for Research on Women and Gender. Her main focus has been on how children and adolescents develop social skills, with a special interest in the development of African American girls (Reid & Zalk, 2001). She has been involved in numerous community activities, including the creation of a math and technology enrichment program for middle-school girls. In 2004, Reid became provost and executive vice-president at Roosevelt University

in Chicago. From 2008 to 2015, she was president of the University of Saint Joseph in Hartford, Connecticut, before retiring to pursue other interests.

**Cultural and Ethnic Bias** Today there is a growing realization that research on life-span development needs to include more people from diverse ethnic groups (Nieto & Bode, 2018). Historically, people from ethnic minority groups (African American, Latino, Asian American, and Native American) were excluded from most research in the United States and simply thought of as variations from the norm or average. If minority individuals were included in samples and their scores didn't fit the norm, they were viewed as confounds or "noise" in data and discounted. Given the fact that individuals from diverse ethnic groups were excluded from research on life-span development for so long, we might reasonably conclude that people's real lives are perhaps more varied than research data have indicated in the past.

Researchers also have tended to overgeneralize about ethnic groups (Schaefer, 2015). **Ethnic gloss** is using an ethnic label such as *African American* or *Latino* in a superficial way that portrays an ethnic group as being more homogeneous than it really is (Trimble, 1988). For example, a researcher might describe a research sample like this: "The participants were 60 Latinos." A more complete description of the group might be something like this: "The 60 Latino participants were Mexican Americans from low-income neighborhoods in the southwestern area of Los Angeles. Thirty-six were from homes in which Spanish is the dominant language spoken, 24 from homes in which English is the main language spoken. Thirty were born in the United States, 30 in Mexico. Twenty-eight described themselves as Mexican American, 14 as Mexican, 9 as American, 6 as Chicano, and 3 as Latino." Ethnic gloss can cause researchers to obtain samples of ethnic groups that are not representative of the group's diversity, which can lead to overgeneralization and stereotyping.

Ross Parke and Raymond Buriel (2006) described how research on ethnic minority children and their families has not been given adequate attention, especially in light of their significant rates of growth. Until recently, ethnic minority families were combined in the category "minority," which masks important differences among ethnic groups as well as diversity within an ethnic group. When research has been conducted on ethnic groups, most often they are compared to non-Latino Whites to identify group differences. An assumption in two-group studies is that ethnic minority children have not advanced far enough to be the

same as non-Latino White children and that this developmental lag contributes to ethnic minority children's problems. Recently, some researchers have replaced two-group studies with more in-depth examination of variations within a single ethnic group. For example, a researcher might study how parents in an ethnic group adapt to the challenges they face as a minority in U.S. society and how these experiences contribute to the goals they have for their children. The continued growth of minority families in the United States in approaching decades will mainly be due to the immigration of Latino and Asian families (Bas-Sarmiento & others, 2017; Lo & others, 2017). Researchers need "to take into account their acculturation level and generational status of parents and children," and consider how these factors might influence family processes and child outcomes (Parke & Burriel, 2006, p. 487). More attention also needs to be given to biculturalism because the complexity of diversity means that some children of color identify with two or more ethnic groups (Coard, 2017; Nieto & Bode, 2018). And language development research needs to focus more on second-language acquisition (usually English) and bilingualism and how they are linked to school achievement (Echevarria, Vogt, & Short, 2017).

### Introduction

#### 1 The Life-Span Perspective

The Importance of Studying Life-Span Development

Characteristics of the Life-Span Perspective

Some Contemporary Concerns

LG1

Discuss the distinctive features of a life-span perspective on development.

- Development is the pattern of change that begins at conception and continues through the human life span. It includes both growth and decline.
- Studying life-span development helps prepare us to take responsibility for children, gives us insight about our own lives, and gives us knowledge about what our lives will be like as we age.
- Life expectancy has increased dramatically in the last century, but life span has remained virtually the same.
- The life-span perspective includes these basic concepts: development is lifelong, multidimensional, multidirectional, and plastic; its study is multidisciplinary; it is contextual; it involves growth, maintenance, and regulation of loss; and it is a co-construction of biological, cultural, and individual factors.
- Three important sources of contextual influences are (1) normative age-graded influences, (2) normative history-graded influences, and (3) nonnormative life events.
- Health and well-being, parenting, education, sociocultural contexts and diversity, social policy, and technology are all areas of contemporary concern that are closely tied to life-span development.
- Important dimensions of the sociocultural context include culture, ethnicity, socioeconomic status, and gender.
- There is increasing interest in social policy issues related to children and to older adults.
- Recently, there also has been a dramatic infusion of technology in the lives of people of all ages, and the influence of technology on development is an important contemporary issue.

#### 2 The Nature of Development

Biological, Cognitive, and Socioemotional Processes

LG2

Identify the most important processes, periods, and issues in development.

- Three key categories of developmental processes are biological, cognitive, and socioemotional. Throughout development, there are extensive connections between these types of processes.

### Periods of Development

- The life span is commonly divided into the following development periods: prenatal, infancy, early childhood, middle and late childhood, adolescence, early adulthood, middle adulthood, and late adulthood.

### The Significance of Age

- Recently, life-span developmentalists have described the human life span in terms of four ages, with a special focus on the third and fourth ages, as well as a distinction between the young-old and oldest-old.

### Developmental Issues

- An important aspect of life-span development involves connections across periods of development.
- According to some experts on life-span development, too much emphasis is placed on chronological age.
- In studies covering adolescence through late adulthood, older people report the highest level of happiness.
- We often think of age only in terms of chronological age, but a full evaluation of age requires consideration of chronological, biological, psychological, and social age. Neugarten emphasizes that we are moving toward a society in which chronological age is only a weak predictor of development in adulthood.
- The nature-nurture issue focuses on the extent to which development is mainly influenced by nature (biological inheritance) or nurture (experience).
- The stability-change issue focuses on the degree to which we become older renditions of our early experience or develop into someone different from who we were earlier in development. A special aspect of the stability-change issue is the extent to which development is determined by early versus later experiences.
- Developmentalists describe development as continuous (gradual, or cumulative change) or as discontinuous (abrupt, or a sequence of stages). Most developmentalists recognize that extreme positions on the nature-nurture, stability-change, and continuity-discontinuity issues are unwise. Despite this consensus, there is still spirited debate on these issues.

## 3 Theories of Development

LG3

Describe the main theories of human development.

### Psychoanalytic Theories

- The scientific method involves four main steps: (1) conceptualize a problem, (2) collect data, (3) analyze data, and (4) draw conclusions.
- Theory is often involved in conceptualizing a problem. A theory is a coherent set of interrelated ideas that helps to explain phenomena and to facilitate predictions. Hypotheses are specific assertions and predictions, often derived from theory, that can be tested.
- According to psychoanalytic theories, development primarily depends on the unconscious mind and is heavily couched in emotion. Freud argued that individuals go through five psychosexual stages. Erikson's theory emphasizes eight psychosocial stages of development: trust versus mistrust, autonomy versus shame and doubt, initiative versus guilt, industry versus inferiority, identity versus identity confusion, intimacy versus isolation, generativity versus stagnation, and integrity versus despair.
- Contributions of psychoanalytic theories include an emphasis on a developmental framework, family relationships, and unconscious aspects of the mind. Criticisms include a lack of scientific support, too much emphasis on sexual underpinnings, and an image of people that is too negative.

### Cognitive Theories

- Three main cognitive theories are Piaget's, Vygotsky's, and information-processing. Cognitive theories emphasize thinking, reasoning, language, and other cognitive processes. Piaget proposed a cognitive developmental theory in which children use their cognition to adapt to their world. In Piaget's theory, children go through four cognitive stages: sensorimotor, preoperational, concrete operational, and formal operational. Vygotsky's sociocultural cognitive theory emphasizes how culture and social interaction guide cognitive development. The information-processing approach emphasizes that individuals manipulate information, monitor it, and strategize about it.

### Behavioral and Social Cognitive Theories

- Contributions of cognitive theories include an emphasis on the active construction of understanding and a positive view of development. Criticisms include giving too little attention to individual variations and skepticism about the pureness of Piaget's stages.
- Two main behavioral and social cognitive theories are Skinner's operant conditioning and Bandura's social cognitive theory. In Skinner's operant conditioning, the consequences of a behavior produce changes in the probability of the behavior's occurrence. In Bandura's social cognitive theory, observational learning is a key aspect of life-span development. Bandura emphasizes reciprocal interactions among person/cognition, behavior, and environment.
- Contributions of the behavioral and social cognitive theories include an emphasis on scientific research and a focus on environmental factors. Criticisms include inadequate attention to developmental changes and, in Skinner's theory, too little attention to cognition.
- Ethology stresses that behavior is strongly influenced by biology, is tied to evolution, and is characterized by critical or sensitive periods. Contributions of ethological theory include a focus on the biological and evolutionary basis of development. Criticisms include rigidity of the concepts of critical and sensitive periods.
- Ecological theory emphasizes environmental contexts. Bronfenbrenner's environmental systems view of development proposes five environmental systems: microsystem, mesosystem, exosystem, macrosystem, and chronosystem. Contributions of the theory include a systematic examination of macro and micro dimensions of environmental systems and attention to connections between them. Criticisms include inadequate attention to biological factors, as well as a lack of emphasis on cognitive factors.
- An eclectic theoretical orientation does not follow any one theoretical approach but rather selects from each theory whatever is considered the best in it.

### An Eclectic Theoretical Orientation

## 4 Research on Life-Span Development

LG4

Explain how research on life-span development is conducted.

### Methods for Collecting Data

- Methods for collecting data about life-span development include observation (in a laboratory or a naturalistic setting), survey (questionnaire) or interview, standardized test, case study, and physiological measures.

### Research Designs

- Three main research designs are descriptive, correlational, and experimental. Descriptive research aims to observe and record behavior. In correlational research, the goal is to describe the strength of the relationship between two or more events or characteristics. Experimental research involves conducting an experiment, which can determine cause and effect. An independent variable is the manipulated, influential, experimental factor. A dependent variable is a factor that can change in an experiment, in response to changes in the independent variable. Experiments can involve one or more experimental groups and control groups. In random assignment, researchers assign participants to experimental and control groups by chance.

### Time Span of Research

- When researchers decide about the time span of their research, they can conduct cross-sectional or longitudinal studies. Life-span researchers are especially concerned about cohort effects.

### Conducting Ethical Research

- Researchers' ethical responsibilities include seeking participants' informed consent, ensuring their confidentiality, debriefing them about the purpose and potential personal consequences of participating, and avoiding unnecessary deception of participants.

### Minimizing Bias

- Researchers need to guard against gender, cultural, and ethnic bias in research. Every effort should be made to make research equitable for both females and males. Individuals from varied ethnic backgrounds need to be included as participants in life-span research, and overgeneralization about diverse members within a group must be avoided.

## Careers in Life-Span Development

The field of life-span development offers an amazing breadth of careers that can provide extremely satisfying work. College and university professors teach courses in many areas of life-span development. Teachers impart knowledge, understanding, and skills to children and adolescents. Counselors, clinical psychologists, nurses, and physicians help people of different ages to cope more effectively with their lives and improve their well-being.

These and many other careers related to life-span development offer many rewards. By working in the field of life-span development, you can help people to improve their lives, understand yourself and others better, possibly advance the state of knowledge in the field, and have an enjoyable time while you are doing these things. Many careers in life-span development pay reasonably well. For example, psychologists earn well above the median salary in the United States.

If you are considering a career in life-span development, would you prefer to work with infants? children? adolescents? older adults? As you go through this term, try to spend some time with people of different ages. Observe their behavior. Talk with them about their lives. Think about whether you would like to work with people of this age in your life's work.

In addition, to find out about careers in life-span development you might talk with people who work in various jobs. For example, if you have some interest in becoming a school counselor, call a school, ask to speak with a counselor, and set up an appointment to discuss the counselor's career and work. If you have an interest in becoming a nurse, call the nursing department at a hospital and set up an appointment to speak with the nursing coordinator about a nursing career.

Another way of exploring careers in life-span development is to work in a related job while you are in college. Many colleges and universities offer internships or other work experiences for students who major in specific fields. Course credit or pay is given for some of these jobs. Take advantage of these opportunities. They can help you decide whether this is the right career for you, and they can help you get into graduate school, if you decide you want to go.

An advanced degree is not absolutely necessary for some careers in life-span development, but usually you can considerably expand your opportunities (and income) by obtaining a graduate degree. If you think you might want to go to graduate school, talk with one or more professors about your interests, keep a high grade-point average,

take appropriate courses, and realize that you likely will need to take the Graduate Record Examination at some point.

In the upcoming sections, we will profile a number of careers in four areas: education/research; clinical/counseling; medical/nursing/physical development; and families/relationships. These are not the only career options in life-span development, but the profiles should give you an idea of the range of opportunities available. For each career, we will describe the work and address the amount of education required and the nature of the training. We have provided chapter titles after some entries to help you find *Connecting with Careers*, the career profiles of people who hold some of these positions. The Web site for this book gives more detailed information about these careers in life-span development.

### Education/Research

Numerous careers in life-span development involve education or research. The opportunities range from college professor to preschool teacher to school psychologist.

#### College/University Professor

Professors teach courses in life-span development at many types of institutions, including research universities with master's or Ph.D. programs in life-span development, four-year colleges with no graduate programs, and community colleges. The courses in life-span development are offered in many different programs and schools, including psychology, education, nursing, child and family studies, social work, and medicine. In addition to teaching at the undergraduate or graduate level (or both), professors may conduct research, advise students or direct their research, and serve on college or university committees. Research is part of a professor's job description at most universities with master's and Ph.D. programs, but some college professors do not conduct research and focus instead on teaching.

Teaching life-span development at a college or university almost always requires a Ph.D. or master's degree. Obtaining a Ph.D. usually takes four to six years of graduate work; a master's degree requires approximately two years. The training involves taking graduate courses, learning to conduct research, and attending and presenting papers at professional meetings. Many graduate students work as teaching or research assistants for professors in an apprenticeship relationship that helps them to become competent teachers

and researchers. Read the profiles of professors in the "Socioemotional Development in Middle Adulthood" and "Socioemotional Development in Late Adulthood" chapters.

#### Researcher

Some individuals in the field of life-span development work in research positions. They might work for a university, a government agency such as the National Institute of Mental Health, or private industry. They generate research ideas, plan studies, carry out the research, and usually attempt to publish the research in a scientific journal. A researcher often works in collaboration with other researchers. One researcher might spend much of his or her time in a laboratory; another researcher might work in the field, such as in schools, hospitals, and so on. Most researchers in life-span development have either a master's or a Ph.D.

#### Elementary or Secondary School Teacher

Elementary and secondary school teachers teach one or more subject areas, preparing the curriculum, giving tests, assigning grades, monitoring students' progress, conducting parent-teacher conferences, and attending workshops. Becoming an elementary or secondary school teacher requires a minimum of an undergraduate degree. The training involves taking a wide range of courses with a major or concentration in education as well as completing supervised practice teaching.

#### Exceptional Children (Special Education) Teacher

Teachers of exceptional children spend concentrated time with children who have a disability such as ADHD, intellectual disabilities, or cerebral palsy, or with children who are gifted. Usually some of their work occurs outside of the students' regular classroom and some of it inside the students' regular classroom. A teacher of exceptional children works closely with the student's regular classroom teacher and parents to create the best educational program for the student. Teachers of exceptional children often continue their education after obtaining their undergraduate degree and attain a master's degree.

#### Early Childhood Educator

Early childhood educators work on college faculties and usually teach in community colleges that award an associate degree in early childhood education. They have a minimum of a master's degree in their

field. In graduate school, they take courses in early childhood education and receive supervisory training in child-care or early childhood programs.

### Preschool/Kindergarten Teacher

Preschool teachers teach mainly 4-year-old children, and kindergarten teachers primarily teach 5-year-old children. They usually have an undergraduate degree in education, specializing in early childhood education. State certification to become a preschool or kindergarten teacher usually is required.

### Family and Consumer Science Educator

Family and consumer science educators may specialize in early childhood education or instruct middle and high school students about such matters as nutrition, interpersonal relationships, human sexuality, parenting, and human development. Hundreds of colleges and universities throughout the United States offer two- and four-year degree programs in family and consumer science. These programs usually require an internship. Additional education courses may be needed to obtain a teaching certificate. Some family and consumer science educators go on to graduate school for further training, which provides a background for possible jobs in college teaching or research. **Read a profile of a family and consumer science educator in the “Physical and Cognitive Development in Adolescence” chapter.**

### Educational Psychologist

Educational psychologists most often teach in a college or university and conduct research in various areas of educational psychology such as learning, motivation, classroom management, and assessment. They help train students for positions in educational psychology, school psychology, and teaching. Most educational psychologists have a doctorate in education, which requires four to six years of graduate work. **Read a profile of an educational psychologist in the “Introduction” chapter.**

### School Psychologist

School psychologists focus on improving the psychological and intellectual well-being of elementary, middle/junior, and high school students. They give psychological tests, interview students and their parents, consult with teachers, and may provide counseling to students and their families. They may work in a centralized office in a school district or in one or more schools.

School psychologists usually have a master's or doctoral degree in school psychology. In graduate school, they take courses in counseling, assessment, learning, and other areas of education and psychology.

### Gerontologist

Gerontologists usually work in research in some branch of the federal or state government. They specialize in the study of aging with a particular

focus on government programs for older adults, social policy, and delivery of services to older adults. In their research, gerontologists define problems to be studied, collect data, interpret the results, and make recommendations for social policy. Most gerontologists have a master's or doctoral degree and have taken a concentration of coursework in adult development and aging.

### Clinical/Counseling

A wide variety of clinical and counseling jobs are linked with life-span development. These range from child clinical psychologist to adolescent drug counselor to geriatric psychiatrist.

### Clinical Psychologist

Clinical psychologists seek to help people with psychological problems. They work in a variety of settings, including colleges and universities, clinics, medical schools, and private practice. Some clinical psychologists only conduct psychotherapy; others do psychological assessment and psychotherapy; some also do research. Clinical psychologists may specialize in a particular age group, such as children (child clinical psychologist) or older adults (often referred to as a geropsychologist).

Clinical psychologists have either a Ph.D. (which involves clinical and research training) or a Psy.D. degree (which only involves clinical training). This graduate training usually takes five to seven years and includes courses in clinical psychology and a one-year supervised internship in an accredited setting toward the end of the training. Many geropsychologists pursue a year or two of postdoctoral training. Most states require clinical psychologists to pass a test in order to become licensed in the state and to call themselves clinical psychologists. **Read a profile of a clinical psychologist in the “Prenatal Development and Birth” chapter.**

### Psychiatrist

Psychiatrists obtain a medical degree and then do a residency in psychiatry. Medical school takes approximately four years and the psychiatry residency another three to four years. Unlike most psychologists (who do not go to medical school), psychiatrists can administer drugs to clients. (Recently, several states gave clinical psychologists the right to prescribe drugs.)

Like clinical psychologists, psychiatrists might specialize in working with children (child psychiatry) or with older adults (geriatric psychiatry). Psychiatrists might work in medical schools in teaching and research roles, in a medical clinic or hospital, or in private practice. In addition to administering drugs to help improve the lives of people with psychological problems, psychiatrists also may conduct psychotherapy. **Read a profile of a child psychiatrist in the “Socioemotional Development in Middle and Late Childhood” chapter.**

### Counseling Psychologist

Counseling psychologists work in the same settings as clinical psychologists and may do psychotherapy, teach, or conduct research. Many counseling psychologists do not do therapy with individuals who have severe mental disorders, such as schizophrenia.

Counseling psychologists go through much the same training as clinical psychologists, although in a graduate program in counseling rather than clinical psychology. Counseling psychologists have either a master's degree or a doctoral degree. They also must go through a licensing procedure. One type of master's degree in counseling leads to the designation of licensed professional counselor.

### School Counselor

School counselors help students cope with adjustment problems, identify their abilities and interests, develop academic plans, and explore career options. The focus of the job depends on the age of the children. High school counselors advise students about vocational and technical training and admissions requirements for college, as well as about taking entrance exams, applying for financial aid, and choosing a major. Elementary school counselors mainly counsel students about social and personal problems. They may observe children in the classroom and at play as part of their work. School counselors may work with students individually, in small groups, or even in a classroom. They often consult with parents, teachers, and school administrators when trying to help students. School counselors usually have a master's degree in counseling.

### Career Counselor

Career counselors help individuals to identify their best career options and guide them in applying for jobs. They may work in private industry or at a college or university. They usually interview individuals and give them vocational and/or psychological tests to identify appropriate careers that fit their interests and abilities. Sometimes they help individuals to create résumés or conduct mock interviews to help them feel comfortable in a job interview. They might arrange and promote job fairs or other recruiting events to help individuals obtain jobs.

### Rehabilitation Counselor

Rehabilitation counselors work with individuals to identify career options, develop adjustment and coping skills to maximize independence, and resolve problems created by a disability. A master's degree in rehabilitation counseling or guidance or counseling psychology is generally considered the minimum educational requirement.

### Social Worker

Many social workers are involved in helping people with social or economic problems. They may

investigate, evaluate, and attempt to rectify reported cases of abuse, neglect, endangerment, or domestic disputes. They may intervene in families and provide counseling and referral services to individuals and families. Some social workers specialize in a certain area. For example, a medical social worker might coordinate support services to people with a long-term disability; family-care social workers often work with families with children or an older adult who needs support services. Social workers often work for publicly funded agencies at the city, state, or national level, although increasingly they work in the private sector in areas such as drug rehabilitation and family counseling.

Social workers have a minimum of an undergraduate degree from a school of social work that includes coursework in sociology and psychology. Some social workers also have a master's or doctoral degree. For example, medical social workers have a master's degree in social work (M.S.W.) and complete graduate coursework and supervised clinical experiences in medical settings.

### **Drug Counselor**

Drug counselors provide counseling to individuals with drug-abuse problems. Some drug counselors specialize in working with adolescents or older adults. They may work on an individual basis with a substance abuser or conduct group therapy. They may work in private practice, with a state or federal government agency, for a company, or in a hospital.

At a minimum, drug counselors complete an associate's or certificate program. Many have an undergraduate degree in substance-abuse counseling, and some have master's and doctoral degrees. Most states provide a certification procedure for obtaining a license to practice drug counseling.

## **Medical/Nursing/Physical Development**

This third main area of careers in life-span development includes a wide range of choices in the medical and nursing areas, as well as jobs that focus on improving some aspect of a person's physical development.

### **Obstetrician/Gynecologist**

An obstetrician/gynecologist prescribes prenatal and postnatal care, performs deliveries in maternity cases, and treats diseases and injuries of the female reproductive system. Becoming an obstetrician/gynecologist requires a medical degree plus three to five years of residency in obstetrics/gynecology. Obstetricians may work in private practice, a medical clinic, a hospital, or a medical school.

### **Pediatrician**

A pediatrician monitors infants' and children's health, works to prevent disease or injury, helps children attain optimal health, and treats children

with health problems. Pediatricians have earned a medical degree and completed a three- to five-year residency in pediatrics.

Pediatricians may work in private practice or at a medical clinic, a hospital, or a medical school. Many pediatricians on the faculties of medical schools also teach and conduct research on children's health and diseases. **Read the profile of a pediatrician in the "Physical Development in Infancy" chapter.**

### **Geriatric Physician**

Geriatric physicians diagnose medical problems of older adults, evaluate treatment options, and make recommendations for nursing care or other arrangements. They have a medical degree and a three- to five-year residency in geriatric medicine. Like other doctors, geriatric physicians may work in private practice or at a medical clinic, a hospital, or a medical school. Those in medical school settings may not only treat older adults but also teach future physicians and conduct research.

### **Neonatal Nurse**

Neonatal nurses deliver care to newborn infants. They may work with infants born under normal circumstances or premature and critically ill neonates. A minimum of an undergraduate degree in nursing with a specialization in the newborn is required. This training involves coursework in nursing and the biological sciences, as well as supervised clinical experiences.

### **Nurse-Midwife**

A nurse-midwife formulates and provides comprehensive care to expectant mothers as they prepare to give birth, guides them through the birth process, and cares for them after the birth. The nurse-midwife also may provide care to the newborn, counsel parents on the infant's development and parenting, and provide guidance about health practices. Becoming a nurse-midwife generally requires an undergraduate degree from a school of nursing. A nurse-midwife most often works in a hospital setting. **Read the profile of a perinatal nurse in the "Prenatal Development and Birth" chapter.**

### **Pediatric Nurse**

Pediatric nurses monitor infants' and children's health, work to prevent disease or injury, and help children attain optimal health. They may work in hospitals, schools of nursing, or with pediatricians in private practice or at a medical clinic.

Pediatric nurses have a degree in nursing that takes two to five years to complete. They take courses in biological sciences, nursing care, and pediatrics, usually in a school of nursing. They also undergo supervised clinical experiences in medical settings. Some pediatric nurses go on to earn a master's or doctoral degree in pediatric nursing.

### **Geriatric Nurse**

Geriatric nurses seek to prevent or intervene in the chronic or acute health problems of older adults. They may work in hospitals, nursing homes, schools of nursing, or with geriatric medical specialists or psychiatrists in a medical clinic or in private practice. Like pediatric nurses, geriatric nurses take courses in a school of nursing and obtain a degree in nursing, which takes from two to five years. They complete courses in biological sciences, nursing care, and mental health as well as supervised clinical training in geriatric settings. They also may obtain a master's or doctoral degree in their specialty. **Read a profile of a geriatric nurse in the "Physical Development in Late Adulthood" chapter.**

### **Physical Therapist**

Physical therapists work with individuals who have a physical problem due to disease or injury to help them function as competently as possible. They may consult with other professionals and coordinate services for the individual. Many physical therapists work with people of all ages, although some specialize in working with a specific age group, such as children or older adults.

Physical therapists usually have an undergraduate degree in physical therapy and are licensed by a state. They take courses and undergo supervised training in physical therapy.

### **Occupational Therapist**

Occupational therapists initiate the evaluation of clients with various impairments and manage their treatment. They help people regain, develop, and build skills that are important for independent functioning, health, well-being, security, and happiness. An "Occupational Therapist Registered" (OTR) must have a master's and/or doctoral degree with education ranging from two to six years. Training includes occupational therapy courses in a specialized program. National certification is required, and licensing/registration is required in some states.

### **Therapeutic/Recreation Therapist**

Therapeutic/recreation therapists maintain or improve the quality of life for people with special needs through intervention, leisure education, and recreation. They work in hospitals, rehabilitation centers, local government agencies, at-risk youth programs, and other settings. Becoming a therapeutic/recreation therapist requires an undergraduate degree with coursework in leisure studies and a concentration in therapeutic recreation. National certification is usually required. Coursework in anatomy, special education, and psychology is beneficial.

### **Audiologist**

Audiologists assess and identify the presence and severity of hearing loss, as well as problems in balance. They may work in a medical clinic, with a physician in private practice, in a hospital, or in a medical school.

An audiologist completes coursework and supervised training to earn a minimum of an undergraduate degree in hearing science. Some audiologists also obtain a master's or doctoral degree.

### **Speech Therapist**

Speech therapists identify, assess, and treat speech and language problems. They may work with physicians, psychologists, social workers, and other health care professionals in a team approach to help individuals with physical or psychological problems that involve speech and language. Some speech therapists specialize in working with individuals of a particular age or people with a particular type of speech disorder. Speech therapists have a minimum of an undergraduate degree in speech and hearing science or in a specific type of communication disorder. They may work in private practice, hospitals and medical schools, and government agencies.

### **Genetic Counselor**

Genetic counselors identify and counsel families at risk for genetic disorders. They work as members of a health care team, providing information and support to families with members who have genetic defects or disorders or are at risk for a variety of inherited conditions. They also serve as educators and resource people for other health care professionals and the public. Nearly half of genetic counselors work in university medical centers; one-fourth work in private hospital settings.

Genetic counselors have specialized graduate degrees and experience in medical genetics and counseling. Most enter the field after majoring in

undergraduate school in such disciplines as biology, genetics, psychology, nursing, public health, or social work. **Read a profile of a genetic counselor in the “Biological Beginnings” chapter.**

### **Families/Relationships**

A number of careers and jobs related to life-span development focus on working with families and addressing relationship problems. These range from home health aide to marriage and family therapist.

### **Home Health Aide**

A home health aide provides services to older adults in the older adults' homes, helping them with basic self-care tasks. No higher education is required for this position. There is brief training by an agency.

### **Child Welfare Worker**

Child protective services in each state employ child welfare workers. They protect children's rights, evaluate any maltreatment, and may have children removed from their homes if necessary. A child social worker has a minimum of an undergraduate degree in social work.

### **Child Life Specialist**

Child life specialists work with children and their families when the child needs to be hospitalized. They monitor the child's activities, seek to reduce the child's stress, and help the child to cope and to enjoy the hospital experience as much as possible. Child life specialists may provide parent education and develop individualized treatment plans based on an assessment of the child's development, temperament, medical plan, and available social supports. Child life specialists have an undergraduate

degree. They have taken courses in child development and education and usually completed additional courses in a child life program. **Read a profile of a child life specialist in the “Physical and Cognitive Development in Middle and Late Childhood” chapter.**

### **Marriage and Family Therapist**

Marriage and family therapists work on the principle that many individuals who have psychological problems benefit when psychotherapy is provided in the context of a marital or family relationship. Marriage and family therapists may provide marital therapy, couple therapy to individuals in a relationship who are not married, and family therapy to two or more members of a family.

Marriage and family therapists have a master's or a doctoral degree. They complete a training program in graduate school similar to a clinical psychologist's but with the focus on marital and family relationships. In most states, it is necessary to go through a licensing procedure to practice marital and family therapy. **Read the profile of a marriage and family therapist in the “Socioemotional Development in Early Childhood” chapter.**

### **Further Careers**

These are only a handful of careers that knowledge of developmental psychology can prepare you for. The *Connecting with Careers* profiles highlight additional careers, including an infant assessment specialist, child-care director, toy designer, health psychologist, college/career counselor, parent counselor, pastoral counselor, association director, and home hospice nurse. *What other careers can you think of that require a knowledge of human development?*

## Beginnings

The rhythm and meaning of life involve beginnings. Questions are raised about how, from so simple a beginning, endless forms develop, grow, and mature. What was this organism, what is this organism, and what will this organism be? In this section, you will read two chapters: “Biological Beginnings” and “Prenatal Development and Birth.”

## Jim Springer and Jim Lewis are identical twins.

They were separated at 4 weeks of age and did not see each other again until they were 39 years old. Both worked as part-time deputy sheriffs, vacationed in Florida, drove Chevrolets, had dogs named Toy, and married and divorced women named Betty. One twin named his son James Allan, and the other named his son James Alan. Both liked math but not spelling, enjoyed carpentry and mechanical drawing, chewed their fingernails down to the nubs, had almost identical drinking and smoking habits, had hemorrhoids, put on 10 pounds at about the same point in development, first suffered headaches at the age of 18, and had similar sleep patterns.

Jim and Jim do have some differences. One wears his hair over his forehead, the other slicks it back and has sideburns. One expresses himself best orally; the other is more proficient in writing. But, for the most part, their profiles are remarkably similar.

Another pair of identical twins, Daphne and Barbara, are called the “giggle sisters” because after being reunited they were always making each other laugh. A thorough search of their adoptive families’ histories revealed no gigglers. The giggle sisters ignored stress, avoided conflict and controversy whenever possible, and showed no interest in politics.

Jim and Jim and the giggle sisters were part of the Minnesota Study of Twins Reared Apart, directed by Thomas Bouchard and his colleagues. The study brings identical twins (identical genetically because they come from the same fertilized egg) and fraternal twins (who come from different fertilized eggs) from all over the world to Minneapolis to investigate their lives. There the twins complete personality and intelligence tests, and they provide detailed medical histories, including information about diet and smoking, exercise habits, chest X-rays, heart stress tests, and EEGs. The twins are asked more than 15,000 questions about their family and childhood, personal interests, vocational orientation, values, and aesthetic judgments (Bouchard & others, 1990).

### topical connections *looking back*

The “Introduction” chapter introduced the field of life-span development, including discussion of three key categories of developmental processes: biological, cognitive, and socioemotional. In this chapter, we lay the foundation of the biological aspects of development. Biological processes, guided by genes, influence an individual’s development in every period of the human life span. The forthcoming discussion of genetics and the previous discussion of theories (psychoanalytic, cognitive, behavioral and social cognitive, ethological, and ecological) provide a knowledge base from which to examine one of life-span development’s major issues and debates—how strongly development is influenced by heredity (nature) and the environment (nurture).

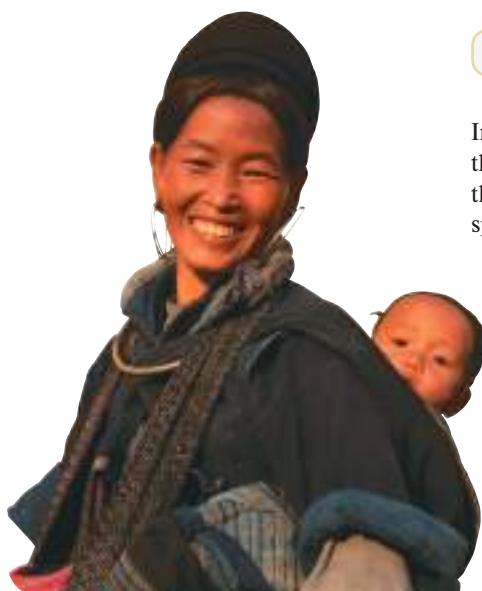

When genetically identical twins who were separated as infants show such striking similarities in their tastes and habits and choices, can we conclude that their genes must have caused the development of those tastes and habits and choices? Other possible causes need to be considered. The twins shared not only the same genes but also some experiences. Some of the separated twins lived together for several months prior to their adoption; some of the twins had been reunited prior to testing (in some cases, many years earlier); adoption agencies often place twins in similar homes; and even strangers who spend several hours together and start comparing their lives are likely to come up with some coincidental similarities (Joseph, 2006). The Minnesota study of identical twins points to both the importance of the genetic basis of human development and the need for further research on genetic and environmental factors (Lykken, 2001). We will discuss twin studies in more detail in the section on behavior genetics later in this chapter.

## preview

The examples of Jim and Jim and the giggle sisters stimulate us to think about our genetic heritage and the biological foundations of our existence. However, organisms are not like billiard balls, moved by simple external forces to predictable positions on life's table. Environmental experiences and biological foundations work together to make us who we are. Our coverage of life's biological beginnings focuses on evolution, genetic foundations, challenges and choices regarding reproduction, and the interaction of heredity and environment.

### 1 The Evolutionary Perspective

**LG1** Discuss the evolutionary perspective on life-span development.

Natural Selection and Adaptive Behavior

Evolutionary Psychology

In evolutionary time, humans are relative newcomers to Earth. As our earliest ancestors left the forest to feed on the savannahs and then to form hunting societies on the open plains, their minds and behaviors changed, and they eventually established humans as the dominant species on Earth. How did this evolution come about?

#### NATURAL SELECTION AND ADAPTIVE BEHAVIOR

*Natural selection* is the evolutionary process by which those individuals of a species that are best adapted are the ones that survive and leave the most fit offspring. To understand what this means, let's return to the middle of the nineteenth century, when British naturalist Charles Darwin was traveling around the world, observing many different species of animals in their natural surroundings. Darwin, who published his observations and thoughts in *On the Origin of Species* (1859), noted that most organisms reproduce at rates that would cause enormous increases in the population of most species and yet populations remain nearly constant. He reasoned that an intense, constant struggle for food, water, and resources must occur among the many young born each generation, because many of the young do not survive. Those that do survive and reproduce pass on some of their characteristics to the next generation. Darwin argued that these survivors are better *adapted* to their world than are the nonsurvivors (Audesirk, Audesirk, & Byers, 2017; Hoefnagels,

How does the attachment of this Vietnamese baby to its mother reflect the evolutionary process of adaptive behavior?

©Frans Lemmens/age fotostock

2018). The best-adapted individuals survive to leave the most offspring. Over the course of many generations, organisms with the characteristics needed for survival make up an increasing percentage of the population. Over many, many generations, this could produce a gradual modification of the whole population. If environmental conditions change, however, other characteristics might become favored by natural selection, moving the species in a different direction (Mader & Windelspecht, 2018; Starr, Evers, & Starr, 2018).

All organisms must adapt to particular places, climates, food sources, and ways of life (Johnson, 2017; Simon, 2017). An eagle's claws are a physical adaptation that facilitates predation. *Adaptive behavior* is behavior that promotes an organism's survival in its natural habitat (Mason & others, 2018). For example, attachment between a caregiver and a baby ensures the infant's closeness to a caregiver for feeding and protection from danger, thus increasing the infant's chances of survival.

## EVOLUTIONARY PSYCHOLOGY

Although Darwin introduced the theory of evolution by natural selection in 1859, his ideas only recently have become a popular framework for explaining behavior (Frankenhuis & Tiokhin, 2018; Raichlen & Alexander, 2017; Whiten, 2017). Psychology's newest approach, **evolutionary psychology**, emphasizes the importance of adaptation, reproduction, and "survival of the fittest" in shaping behavior (Bjorklund, 2018; Legare, Clegg, & Wen, 2018; Lewis & others, 2017). "Fit" in this sense refers to the ability to bear offspring that survive long enough to bear offspring of their own. In this view, natural selection favors behaviors that increase reproductive success—the ability to pass your genes to the next generation (Russell, Hertz, & McMillan, 2017).

David Buss (2008, 2012, 2015) has been especially influential in stimulating new interest in how evolution can explain human behavior. He reasons that just as evolution has contributed to our physical features such as body shape and height, it also pervasively influences our psychological makeup, such as how we make decisions, how aggressive we are, our fears, and our mating patterns. For example, assume that our ancestors were hunters and gatherers on the plains and that men did most of the hunting and women stayed close to home gathering seeds and plants for food. If you have to travel some distance from your home to find and slay a fleeing animal, you need certain physical traits along with the capacity for certain types of spatial thinking. Men with these traits would be more likely than men without them to survive, to bring home lots of food, and to be considered attractive mates—and thus to reproduce and pass on these characteristics to their children. In other words, if Buss' assumptions are correct, potentially these traits provide a reproductive advantage for males—over many generations, men with good spatial thinking skills might become more numerous in the population. Critics point out that these assumptions are not necessarily accurate and that this scenario might or might not have actually happened.

**Evolutionary Developmental Psychology** Recently, interest has grown in using the concepts of evolutionary psychology to understand human development (Bjorklund, 2018; Frankenhuis & Tiokhin, 2018; Legare, Clegg, & Wen, 2018). Here we discuss some ideas proposed by evolutionary developmental psychologists (Bjorklund & Pellegrini, 2002).

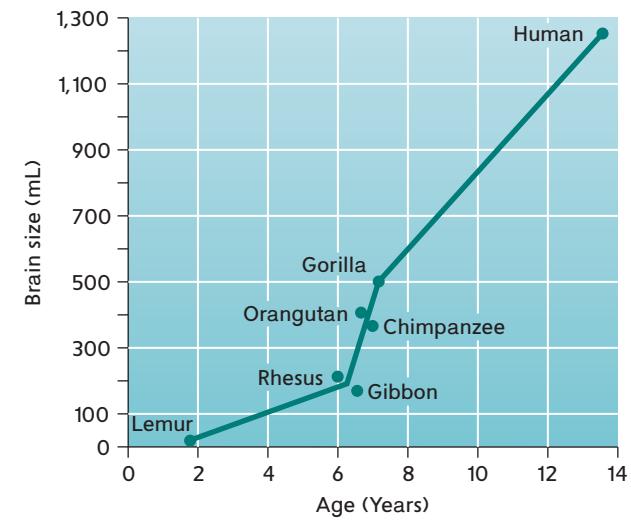

An extended childhood period might have evolved because humans require time to develop a large brain and learn the complexity of human societies. Humans take longer to become reproductively mature than any other mammal (see Figure 1). During this extended childhood period, they develop a large brain and have the experiences needed to become competent adults in a complex society.

Many of our evolved psychological mechanisms are domain-specific. That is, the mechanisms apply only to a specific aspect of a person's psychological makeup. According to evolutionary psychology, the mind is not a general-purpose device that can be applied equally to a vast array of problems. Instead, as our ancestors dealt with certain recurring problems such as hunting and finding shelter, specialized modules evolved to process information related to those problems. For example, such specialized modules might include a module for physical

Evolved mechanisms are not always adaptive in contemporary society. Some behaviors that were adaptive for our prehistoric ancestors may not serve us well today. For example, the food-scarce environment of our ancestors likely led to humans’ propensity to gorge when food is available and to crave high-caloric foods, a trait that might lead to an epidemic of obesity when food is plentiful.

**Connecting Evolution and Life-Span Development** In evolutionary theory, what matters is that individuals live long enough to reproduce and pass on their characteristics (Starr, Evers, & Starr, 2018). So why do humans live so long after reproduction? Perhaps evolution favored longevity because having older people around improves the survival rates of babies. Possibly having grandparents alive to care for the young while parents were out hunting and gathering food created an evolutionary advantage.

According to life-span developmentalist Paul Baltes (2003), the benefits conferred by evolutionary selection decrease with age. Natural selection has not weeded out many harmful conditions and nonadaptive characteristics that appear among older adults. Why? Natural selection operates primarily on characteristics that are tied to reproductive fitness, which extends through the earlier part of adulthood. Thus, says Baltes, selection primarily operates during the first half of life.

As an example, consider Alzheimer disease, an irreversible brain disorder characterized by gradual deterioration in thinking capacity. This disease typically does not appear until age 70 or later. If it were a disease that struck 20-year-olds, perhaps natural selection would have eliminated it eons ago.

Thus, unaided by evolutionary pressures against nonadaptive conditions, we suffer the aches, pains, and infirmities of aging. And as the benefits of evolutionary selection decrease with age, argues Baltes, the need for culture increases (see Figure 2). That is, as older adults weaken biologically, they need culture-based resources such as cognitive skills, literacy, medical technology, and social support. For example, older adults may need help and training from other people to maintain their cognitive skills (Park & Festini, 2017; Reuter-Lorenz & Lustig, 2017).

**Evaluating Evolutionary Psychology** Although the popular press gives a lot of attention to the ideas of evolutionary psychology, it remains just one theoretical approach among many. Like the theories described earlier, it has limitations, weaknesses, and critics (Hyde & DeLamater, 2017). Among the criticisms of evolutionary psychology are that it is one-sided, not adequately valuing social/environmental factors; that it relies on after-the-fact explanations; and that it cannot be tested scientifically.

Albert Bandura (1998), whose social cognitive theory was described earlier, acknowledges the important influence of evolution on human adaptation. However, he rejects what he calls “one-sided evolutionism,” which sees social behavior as strictly the product of evolved biology. An alternative is a bidirectional view in which environmental and biological conditions influence each other. In this view, evolutionary pressures created changes in biological structures that allowed the use of tools, which enabled our ancestors to manipulate their environment, constructing new environmental conditions. In turn, environmental innovations produced new selection pressures that led to the evolution of specialized biological systems for consciousness, thought, and language.

In other words, evolution does not dictate behavior. People have used their biological capacities to produce diverse cultures—aggressive and peace-loving, egalitarian and autocratic. As American scientist Stephen Jay Gould (1981) concluded, in most domains of human functioning, biology allows a broad range of cultural possibilities.

The “big picture” idea of natural selection leading to the development of human traits and behaviors is difficult to refute or test because evolution occurs on a time scale that does not lend itself to empirical study. Thus, studying specific genes in humans and other species—and their links to traits and behaviors—may be the best approach for testing ideas coming out of evolutionary psychology.

Children in all cultures are interested in the tools that adults in their culture use. For example, this young child is using a machete, near the Angkor Temples in Cambodia. *Might the child's behavior be evolutionary-based or be due to both biological and environmental conditions?*

**LG2**

Describe what genes are and how they influence human development.

Genetic influences on behavior evolved over time and across many species. The many traits and characteristics that are genetically influenced have a long evolutionary history that is retained in our DNA (Brooker & others, 2018). Our DNA is not just inherited from our parents; it includes what we inherited as a species from other species that were our ancestors.

How are characteristics that suit a species for survival transmitted from one generation to the next? Darwin did not know the answer because genes and the principles of genetics had not yet been discovered. Each of us carries a “genetic code” that we inherited from our parents. Because a fertilized egg carries this human code, a fertilized human egg cannot grow into an egret, eagle, or elephant.

### THE COLLABORATIVE GENE

Each of us began life as a single cell weighing about one twenty-millionth of an ounce! This tiny piece of matter housed our entire genetic code—information that helps us grow from that single cell to a person made of trillions of cells, each containing a replica of the original code. That code is carried by DNA, which includes our genes. What are genes and what do they do? For the answer, we need to look into our cells.

The nucleus of each human cell contains **chromosomes**, which are threadlike structures made up of deoxyribonucleic acid (DNA). DNA is a complex molecule that has a double helix shape, like a spiral staircase (shown in Figure 3) and contains genetic information. **Genes**, the units of hereditary information, are short segments of DNA. They help cells to reproduce themselves and to assemble proteins. Proteins, in turn, are the building blocks of cells as well as the regulators that direct the body’s processes (Goodenough & McGuire, 2017; Mason & others, 2018).

Each gene has its own location—its own designated place on a particular chromosome. Today, there is a great deal of enthusiasm about efforts to discover the specific locations of genes that are linked to certain functions and developmental outcomes (Hoefnagels, 2018; Johnson, 2017). An important step in this direction is the Human Genome Project’s efforts to map the human genome—the complete genetic content of our cells, which includes developmental

information used for creating proteins that contribute to the making of a human organism (Brooker & others, 2018).

Among the major approaches to gene identification and discovery that are being used today are the genome-wide association method, linkage analysis, next-generation sequencing, and the Thousand Genomes Project:

- Completion of the Human Genome Project has led to use of the *genome-wide association method* to identify genetic variations linked to a particular disease, such as obesity, cancer, cardiovascular disease, or Alzheimer disease (Yasukochi & others, 2018; Zhu & others, 2018). To conduct a genome-wide association study, researchers obtain DNA from individuals who have the disease and others who don't have it. Then, each participant's complete set of DNA, or genome, is purified from the blood or other cells and scanned on machines to determine markers of genetic variation. If the genetic variations occur more frequently in people who have the disease, the variations point to the region in the human genome with the disease. Genome-wide association studies have recently been conducted for cancer (Sucheston-Campbell & others, 2018), obesity (Wang & others, 2018), cardiovascular disease (Olson & others, 2018), depression, suicide (Sokolowski, Wasserman, & Wasserman, 2016), attention deficit hyperactivity disorder (Sanchez-Roige & others, 2018), autism (Ramaswami & Geschwind, 2018), glaucoma (Springelkamp & others, 2017), and Alzheimer disease (Liu & others, 2018).
- *Linkage analysis*, in which the goal is to discover the location of a gene (or genes) in relation to a marker gene (whose position is already known), is often used to search for disease-related genes (Burrello & others, 2017). Genes transmitted to offspring tend to be in close proximity to each other so that the gene(s) involved in the disease are usually located near the marker gene. Gene linkage studies are now being conducted on a wide variety of disorders, including attention deficit hyperactivity disorder (Sciberras & others, 2017), autism (Muller, Anacker, & Veenstra-VanderWeele, 2017; Ramaswami & Geschwind, 2018), depression (Mathias & others, 2016), and Alzheimer disease (Moustafa & others, 2018).
- *Next-generation sequencing* is a term used to describe the vast increase in genetic data generated at a much reduced cost and in a much shorter period of time than in the past. Using recently developed next-generation sequencing, an entire human genome can be sequenced in one day. Prior to recent improvements, deciphering the human genome took longer than ten years! The new technology sequences millions of small DNA fragments. Next-generation sequencing has considerably increased knowledge about genetic influences on development in recent years (Nishinakamura & Takasato, 2017; Pulignani & others, 2018; Tarabichi & others, 2018).
- The human genome varies between individuals in small but very important ways. Understanding these variations will require examining the whole genomes of many individuals. A current project that began in 2008, the *Thousand Genomes Project*, is the most detailed study of human genetic variation to date. This project has the goal of determining the genomic sequences of at least 1,000 individuals from different ethnic groups around the world (Li & others, 2017). Gaining access to complete descriptions of the genetic variations of many people will allow researchers to conduct more detailed studies of genetic variations in disease.

One of the big surprises of the Human Genome Project was an early report indicating that humans have only about 30,000 genes (U.S. Department of Energy, 2001). More recently, the number of human genes has been revised further downward to approximately 20,700 (Ensembl Human, 2010; Flicek & others, 2013; Science Daily, 2008). Further recent analysis proposes that humans may actually have fewer than 20,000 protein-producing genes (Ezkurdia & others, 2014). Scientists had thought that humans had as many as 100,000 or more genes. They had also maintained that each gene programmed just one protein. In fact, humans have far more proteins than they have genes, so there cannot be a one-to-one correspondence between genes and proteins (Commoner, 2002). Each gene is not translated, in automaton-like fashion, into one and only one protein (Moore, 2015, 2017). A gene does not act independently, as developmental psychologist David Moore (2001) emphasized by titling his book *The Dependent Gene*.

Rather than being a group of independent genes, the human genome consists of many genes that collaborate both with each other and with nongenetic factors inside and outside the body (Halldorsdottir & Binder, 2017; Moore, 2013, 2015, 2017). The collaboration operates at many points. For example, the cellular machinery mixes, matches, and links small pieces of DNA to reproduce the genes—and that machinery is influenced by what is going on around it.

Whether a gene is turned “on”—working to assemble proteins—is also a matter of collaboration. The activity of genes (genetic expression) is affected by their environment (Gottlieb, 2007; Moore, 2015, 2017). For example, hormones that circulate in the blood make their way into the cell where they can turn genes “on” and “off.” And the flow of hormones can be affected by environmental conditions such as light, day length, nutrition, and behavior. Numerous studies have shown that external events outside of the original cell and the person, as well as events inside the cell, can excite or inhibit gene expression (Lickliter, 2018; Moore, 2017). Recent research has documented that factors such as stress, exercise, nutrition, respiration, radiation, temperature, and sleep can influence gene expression (Kader, Ghai, & Mahraj, 2018; Poulsen & others, 2018; Stephens & Tsintzas, 2018; Turecki & Meaney, 2016; Van Bussel & others, 2016). For example, one study revealed that an increase in the concentration of stress hormones such as cortisol produced a fivefold increase in DNA damage (Flint & others, 2007). Another study also found that exposure to radiation changed the rate of DNA synthesis in cells (Lee & others, 2011). And recent research indicates that sleep deprivation can affect gene expression in negative ways such as increased inflammation, expression of stress-related genes, and impairment of protein functioning (da Costa Souza & Ribeiro, 2015).

Scientists have found that certain genes become turned on or off as a result of exercise mainly through a process called *methylation*, in which tiny atoms attached themselves to the outside of a gene (Castellano-Castillo & others, 2018; Marioni & others, 2018). This process makes the gene more or less capable of receiving and responding to biochemical signals from the body (Kader, Ghai, & Mahraj, 2018; Martin & Fry, 2018). In this way the behavior of the gene, but not its structure, is changed. Researchers also have found that diet and tobacco may affect gene behavior through the process of methylation (Chatterton & others, 2017; Zaghloul & others, 2018).

## GENES AND CHROMOSOMES

Genes are not only collaborative, they are enduring. How do the genes manage to get passed from generation to generation and end up in all of the trillion cells in the body? Three processes are at the heart of the story: mitosis, meiosis, and fertilization.

**Mitosis, Meiosis, and Fertilization** All of the cells in your body, except the sperm and egg, have 46 chromosomes arranged in 23 pairs. These cells reproduce through a process called **mitosis**. During mitosis, the cell’s nucleus—including the chromosomes—duplicates itself and the cell divides. Two new cells are formed, each containing the same DNA as the original cell, arranged in the same 23 pairs of chromosomes.

However, a different type of cell division—**meiosis**—forms eggs and sperm (which also are called gametes). During meiosis, a cell of the testes (in men) or ovaries (in women) duplicates its chromosomes but then divides twice, thus forming four cells, each of which has only half of the genetic material of the parent cell. By the end of meiosis, each egg or sperm has 23 unpaired chromosomes.

During **fertilization**, an egg and a sperm fuse to create a single cell called a **zygote** (see Figure 4). In the zygote, the 23 unpaired chromosomes from the egg and the 23 unpaired chromosomes from the sperm combine to form one set of 23 paired chromosomes—one chromosome of each pair coming from the mother’s egg and the other from the father’s sperm. In this manner, each parent contributes half of the offspring’s genetic material.

Figure 5 shows 23 paired chromosomes of a male and a female. The members of each pair of chromosomes are both similar and different: Each chromosome in the pair contains varying forms of the same genes, at the same location on the chromosome. A gene that influences hair color, for example, is located on both members of one pair of chromosomes, in the same location on each. However, one of those chromosomes might carry a gene associated with blond hair; the other chromosome in the pair might carry a gene associated with brown hair.

**mitosis** Cellular reproduction in which the cell’s nucleus duplicates itself with two new cells being formed, each containing the same DNA as the parent cell, arranged in the same 23 pairs of chromosomes.

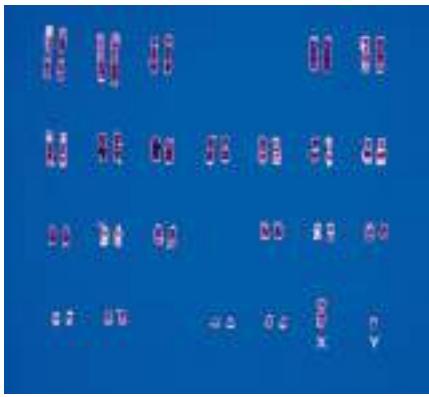

**meiosis** A specialized form of cell division that occurs to form eggs and sperm (also known as gametes).

**fertilization** A stage in reproduction when an egg and a sperm fuse to create a single cell, called a zygote.

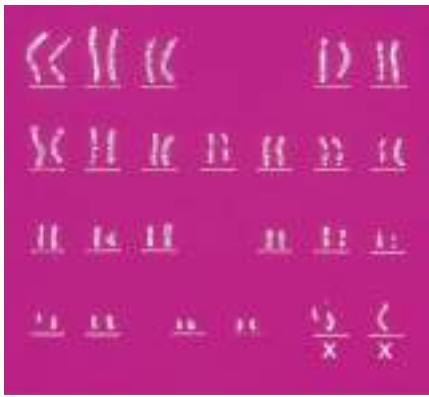

**zygote** A single cell formed through fertilization.

### THE GENETIC DIFFERENCE BETWEEN MALES AND FEMALES.

Set (a) shows the chromosome structure of a male, and set (b) shows the chromosome structure of a female. The last pair of 23 pairs of chromosomes is in the bottom right box of each set. Notice that the Y chromosome of the male is smaller than the X chromosome of the female. To obtain this kind of chromosomal picture, a cell is removed from a person's body (an easy way to obtain a cell from a body is to swab the inside of the mouth with a Q-tip). The chromosomes are stained by chemical treatment, magnified extensively, and then photographed.

Do you notice any obvious differences between the chromosomes of the male and the chromosomes of the female in Figure 5? The difference lies in the 23rd pair. Ordinarily, in females this pair consists of two chromosomes called X chromosomes; in males, the 23rd pair consists of an X and a Y chromosome. The presence of a Y chromosome is one factor that makes a person male rather than female.

**Sources of Variability** Combining the genes of two parents in offspring increases genetic variability in the population, which is valuable for a species because it provides more characteristics for natural selection to operate on (Mason & others, 2018; Simon, 2017). In fact, the human genetic process creates several important sources of *variability* (Hoefnagels, 2018).

First, the chromosomes in the zygote are not exact copies of those in the mother's ovaries or the father's testes. During the formation of the sperm and egg in meiosis, the members of each pair of chromosomes are separated, but which chromosome in the pair goes to the gamete is a matter of chance. In addition, before the pairs separate, pieces of the two chromosomes in each pair are exchanged, creating a new combination of genes on each chromosome (Mader & Windelspecht, 2018). Thus, when chromosomes from the mother's egg and the father's sperm are brought together in the zygote, the result is a truly unique combination of genes (Brooker & others, 2018).

If each zygote is unique, how do identical twins like those discussed in the opening of the chapter exist? *Identical twins* (also called monozygotic twins) develop from a single zygote that splits into two genetically identical replicas, each of which becomes a person. *Fraternal twins* (called dizygotic twins) develop when two eggs are fertilized by different sperm, creating two zygotes that are genetically no more similar than ordinary siblings.

Another source of variability comes from DNA. Chance events, a mistake by cellular machinery, or damage from an environmental agent such as radiation may produce a *mutated gene*, which is a permanently altered segment of DNA (Freeman & others, 2017; Mason & others, 2018).

There is increasing interest in studying *susceptibility genes*, those that make the individual more vulnerable to specific diseases or accelerated aging (Hartiala & others, 2017; Park & others, 2018; Patel & others, 2018), and *longevity genes*, those that make the individual less vulnerable to certain diseases and more likely to live to an older age (Blankenburg, Pramstaller, & Domingues, 2018; Dato & others, 2017). These are aspects of the individual's genotype.

In the search for longevity genes, Cynthia Kenyon (2010) has extensively studied *C. elegans*, a roundworm, the first animal to have its entire genome sequenced. In early research, she found that modifying a single gene, *daf-2*, which is linked to hormones, slows aging in the roundworm. She also discovered that another gene, *daf-16*, is necessary for the roundworm to live longer. *Daf-16* encodes a gene switch that turns on a number of genes related to stress resistance, immunity, and metabolism (McLaughlin & Broihier, 2018; Meng & others, 2017). These genes possibly can extend life by protecting and repairing body tissues (Park & others, 2017; Tullet & others, 2017). Other researchers have revealed that genetic variants in a human *daf-16* version labeled *FOX03A* are linked to greater longevity in a wide range of people, including Americans, Europeans, and Chinese (Pradhan & others, 2017; Wang, Hu, & Liu, 2017). Further, *daf-2*-type mutations extend life and slow aging not only in roundworms but also in flies and mice, resulting in delayed onset and severity of many aging diseases, including cancer, cardiovascular disease, and Alzheimer disease (Kenyon, 2010). Recently, Cynthia Kenyon has joined a think tank of scientists at Google's Calico (short for California Life Company) division, which seeks to understand the aging process and uncover ways to modify it. Kenyon believes that interventions to extend the human life span might include drugs that mimic the action of gene mutations linked to greater longevity.

Even when their genes are identical, however, people vary. The difference between genotypes and phenotypes helps us to understand this source of variability. All of a person's genetic material makes up his or her **genotype**. However, our observed and measurable characteristics reflect more than just genetic material. A **phenotype** consists of observable characteristics. Phenotypes include physical characteristics (such as height, weight, and hair color) and psychological characteristics (such as personality and intelligence).

How does the process from genotype to phenotype work? It's highly complex, but at a very basic level in a cell, DNA information is transcribed to RNA (ribonucleic acid), which in turn is translated into amino acids that will become proteins (Brooker & others, 2018; Willey, Sherwood, & Woolverton, 2017). Once proteins have been assembled, they become capable of producing phenotype traits and characteristics. Also, environments interact with genotypes to produce phenotypes.

**genotype** A person's genetic heritage; the actual genetic material.

**phenotype** The way an individual's genotype is expressed in observed and measurable characteristics.

Thus, for each genotype, a range of phenotypes can be expressed, providing another source of variability (Klug & others, 2017). An individual can inherit the genetic potential to grow very large, for example, but environmental influences involving good nutrition, among other things, will be essential for achieving that potential.

## GENETIC PRINCIPLES

What determines how a genotype is expressed to create a particular phenotype? Much is unknown about the answer to this question (Lickliter, 2018; Moore, 2017). However, a number of genetic principles have been discovered, among them those of dominant-recessive genes, sex-linked genes, genetic imprinting, and polygenically determined characteristics.

**Dominant-Recessive Genes** In some cases, one gene of a pair always exerts its effects; it is *dominant* and overrides the potential influence of the other gene, called the recessive gene. This is the *dominant-recessive genes principle*. A recessive gene exerts its influence only if the two genes of a pair are both recessive. If you inherit a recessive gene for a trait from each of your parents, you will show the trait. If you inherit a recessive gene from only one parent, you may never know you carry the gene. Brown hair, farsightedness, and dimples are dominant genes; blond hair, nearsightedness, and freckles are recessive genes.

Can two brown-haired parents have a blond-haired child? Yes, they can. Suppose that each parent has a dominant gene for brown hair and a recessive gene for blond hair. Since dominant genes override recessive genes, the parents have brown hair, but both are carriers of genes that can contribute to blondness and pass on their recessive genes for producing blond hair. With no dominant gene to override them, the recessive genes can make the child's hair blond.

**Sex-Linked Genes** Most mutated genes are recessive. When a mutated gene is carried on the X chromosome, the result is called *X-linked inheritance*. The implications for males may be very different from those for females (Freeman & others, 2017; Mader & Windelspecht, 2018). Remember that males have only one X chromosome. Thus, if there is an absent or altered disease-relevant gene on the X chromosome, males have no “backup” copy to counter the harmful gene and therefore may develop an X-linked disease. However, females have a second X chromosome, which is likely to be unchanged. As a result, they are not likely to have the X-linked disease. Thus, most individuals who have X-linked diseases are males. Females who have one abnormal copy of the gene on the X chromosome are known as “carriers,” and they usually do not show any signs of the X-linked disease. Hemophilia and fragile X syndrome, which we will discuss later in the chapter, are examples of X-linked inheritance diseases (Thurman & others, 2017).

**Genetic Imprinting** Genetic imprinting occurs when the expression of a gene has different effects depending on whether the mother or the father passed on the gene (Brooker & others, 2018; Simon, 2017). A chemical process “silences” one member of the gene pair. For example, as result of imprinting, only the maternally derived copy of the expressed gene might be active, while the paternally derived copy of the same expressed gene is silenced—or vice versa (John, 2017). Only a small percentage of human genes appear to undergo imprinting, but it is a normal and important aspect of development. When imprinting goes awry, development is disturbed, as in the case of Beckwith-Wiedemann syndrome (a growth disorder) and Wilms tumor (a type of cancer) (Bachmann & others, 2017; Okun & others, 2014).

**Polygenic Inheritance** Genetic transmission is usually more complex than the simple examples we have examined thus far (Moore, 2017). Few characteristics reflect the influence of only a single gene or pair of genes. The term *polygenic inheritance* means that many different genes determine a characteristic (Hill & others, 2018; Oreländ & others, 2017). Even a simple characteristic such as height, for example, reflects the interaction of many genes as well as the influence of the environment. Most diseases, such as cancer and diabetes, develop as a

Researcher Cynthia Kenyon found that modifying a gene called *daf-16* slows the aging in *C. elegans* (shown above). This type of roundworm was the first animal to have its entire genome sequenced.

consequence of complex gene interactions and environmental factors (Mahapatra, Asati, & Bharti, 2017; Schaefer, Hornick, & Bovee, 2018).

The term *gene-gene interaction* is increasingly used to describe studies that focus on the interdependent process by which two or more genes influence characteristics, behavior, diseases, and development (Lovely & others, 2017; Yip & others, 2018). For example, recent studies have documented gene-gene interaction in immune system functioning (Heinonen & others, 2015), asthma (Hua & others, 2016), obesity (Bordoni & others, 2017), type 2 diabetes (Saxena, Srivastava, & Banerjee, 2017), alcoholism (Chen & others, 2017), cancer (Su & others, 2018), cardiovascular disease (De & others, 2017), arthritis (Hohman & others, 2016), and Alzheimer disease (Yin & others, 2018).

## CHROMOSOMAL AND GENE-LINKED ABNORMALITIES

Abnormalities characterize the genetic process in some individuals. Some of these abnormalities involve whole chromosomes that do not separate properly during meiosis. Other abnormalities are produced by harmful genes.

**Chromosomal Abnormalities** Sometimes a gamete is formed in which the male's sperm and/or the female's ovum do not have their normal set of 23 chromosomes. The most notable examples involve Down syndrome and abnormalities of the sex chromosomes (see Figure 6).

**Down Syndrome** **Down syndrome** is a form of intellectual disability caused by the presence of an extra copy of chromosome 21 (Lewanda & others, 2016; Popadin & others, 2018). It is not known why the extra chromosome is present, but the health of the male sperm or the female ovum may be involved. An individual with Down syndrome has a round face, a flattened skull, an extra fold of skin over the eyelids, a protruding tongue, short limbs, and impaired motor and mental abilities.

Down syndrome appears approximately once in every 700 live births. Women between the ages of 16 and 34 are less likely to give birth to a child with Down syndrome than are younger or older women. African American children are rarely born with Down syndrome.

**Sex-Linked Chromosomal Abnormalities** Recall that a newborn normally has either an X and a Y chromosome, or two X chromosomes. Human embryos must possess at

least one X chromosome to be viable. The most common sex-linked chromosomal abnormalities involve the presence of an extra chromosome (either an X or Y) or the absence of one X chromosome in females.

**Klinefelter syndrome** is a chromosomal disorder in which males have an extra X chromosome, making them XXY instead of XY (Skuse, Printzlau, & Wolstencroft, 2018). Males with this disorder have undeveloped testes, and they usually have enlarged breasts and become tall (Belling & others, 2017; Flannigan & Schlegel, 2017). Klinefelter syndrome occurs approximately once in every 1,000 live male births. Only 10 percent of individuals with Klinefelter syndrome are diagnosed before puberty, with the majority not identified until adulthood (Aksela & others, 2013).

**Fragile X syndrome (FXS)** is a genetic disorder that results from an abnormality in the X chromosome, which becomes constricted and often breaks (Niu & others, 2017). An intellectual difficulty frequently is an outcome, which may take the form of an intellectual disability, autism, a learning disability, or a short attention span (Hall & Berry-Kravis, 2018; Thurman & others, 2017). This disorder occurs more frequently in males than in females, possibly because the second X chromosome in females negates the effects of the abnormal X chromosome (Mila & others, 2018). A recent study found that a higher level of maternal responsiveness to the adaptive behavior of children with FXS had a positive effect on the children's communication skills (Warren & others, 2017).

**Turner syndrome** is a chromosomal disorder in females in which either an X chromosome is missing, making the person XO instead of XX, or part of one X chromosome is deleted (Murdock & others, 2017; Skuse, Printzlau, & Wolstencroft, 2018). Females with Turner syndrome are short in stature and have a webbed neck (Reddy Danda & others, 2017). They might be infertile and have difficulty in mathematics, but their verbal ability is often quite good (Lleo & others, 2012). Turner syndrome occurs in approximately 1 of every 2,500 live female births (Culen & others, 2017).

**XYY syndrome** is a chromosomal disorder in which a male has an extra Y chromosome (Tartaglia & others, 2017). Early interest in this syndrome focused on the belief that the extra Y chromosome found in some males contributed to aggression and violence. However, researchers subsequently found that XYY males are no more likely to commit crimes than are normal XY males (Witkin & others, 1976).

**Gene-Linked Abnormalities** Abnormalities can be produced not only by an abnormal number of chromosomes but also by harmful genes. More than 7,000 such genetic disorders have been identified, although most of them are rare. Two widely studied *gene-linked abnormalities* are phenylketonuria and sickle-cell anemia.

**Phenylketonuria (PKU)** is a genetic disorder in which the individual cannot properly metabolize phenylalanine, an amino acid. It results from a recessive gene and occurs about once in every 10,000 to 20,000 live births. Today, phenylketonuria is easily detected during infancy, and it is treated by a diet that prevents an excess accumulation of phenylalanine (Medford & others, 2017; Micich & others, 2018). If phenylketonuria is left untreated, however, excess phenylalanine builds up in the child, producing intellectual disability and hyperactivity. Phenylketonuria accounts for approximately 1 percent of institutionalized individuals with intellectual disabilities, and it occurs primarily in non-Latino Whites.

The story of phenylketonuria has important implications for the nature-nurture issue. Although phenylketonuria is often described as a genetic disorder (nature), how or whether a gene's influence in phenylketonuria is played out depends on environmental influences since the disorder can be treated (nurture) using an environmental manipulation (Garcia & others, 2017). That is, the presence of a genetic defect does not inevitably lead to the development of the disorder if the individual develops in the right environment (one free of phenylalanine). This is one example of the important principle of heredity-environment interaction. Under one environmental condition (phenylalanine in the diet), intellectual disability results, but when other nutrients replace phenylalanine, intelligence develops in the normal range. The same genotype has different outcomes depending on the environment (in this case, the nutritional environment).

**Sickle-cell anemia**, which occurs most often in African Americans, is a genetic disorder that impairs the functioning of the body's red blood cells. More than 300,000 infants worldwide are born with sickle-cell anemia each year (Azar & Wong, 2017). Red blood cells carry oxygen to the body's other cells and are usually disk-shaped. In sickle-cell anemia, a recessive gene

**Klinefelter syndrome** A chromosomal disorder in which males have an extra X chromosome, making them XXY instead of XY.

**fragile X syndrome** A genetic disorder involving an abnormality in the X chromosome, which becomes constricted and often breaks.

**Turner syndrome** A chromosome disorder in females in which either an X chromosome is missing, making the person XO instead of XX, or the second X chromosome is partially deleted.

**XYY syndrome** A chromosomal disorder in which males have an extra Y chromosome.

**phenylketonuria (PKU)** A genetic disorder in which an individual cannot properly metabolize an amino acid called phenylalanine. PKU is now easily detected but, if left untreated, results in intellectual disability and hyperactivity.

**sickle-cell anemia** A genetic disorder that affects the red blood cells and occurs most often in people of African descent.

Name	Description	Treatment	Incidence
Cystic fibrosis	Glandular dysfunction that interferes with mucus production; breathing and digestion are hampered, resulting in a shortened life span.	Physical and oxygen therapy, synthetic enzymes, and antibiotics; most individuals live to middle age.	1 in 2,000 births
Diabetes	Body does not produce enough insulin, which causes abnormal metabolism of sugar.	Early onset can be fatal unless treated with insulin.	1 in 2,500 births
Hemophilia	Delayed blood clotting causes internal and external bleeding.	Blood transfusions/injections can reduce or prevent damage due to internal bleeding.	1 in 10,000 males
Huntington's disease	Central nervous system deteriorates, producing problems in muscle coordination and mental deterioration.	Does not usually appear until age 35 or older; death likely 10 to 20 years after symptoms appear.	1 in 20,000 births
Phenylketonuria (PKU)	Metabolic disorder that, left untreated, causes intellectual disability and hyperactivity.	Special diet can result in average intelligence and normal life span.	1 in 10,000 to 1 in 20,000 births
Sickle-cell anemia	Blood disorder that limits the body's oxygen supply; it can cause joint swelling, as well as heart and kidney failure.	Penicillin, medication for pain, antibiotics, blood transfusions, and hydroxyurea.	1 in 400 African American children (lower among other groups)
Spina bifida	Neural tube disorder that causes brain and spine abnormalities.	Corrective surgery at birth, orthopedic devices, and physical/medical therapy.	2 in 1,000 births
Tay-Sachs disease	Deceleration of mental and physical development caused by an accumulation of lipids in the nervous system.	Medication and special diet are used, but death is likely by 5 years of age.	1 in 30 American Jews is a carrier.

**SOME GENE-LINKED ABNORMALITIES**

causes the red blood cell to become a hook-shaped “sickle” that cannot carry oxygen properly and dies quickly (Patterson & others, 2018; Powell & others, 2018). As a result, the body’s cells do not receive adequate oxygen, causing anemia and early death (Fernandes, 2017). About 1 in 400 African American babies is affected by sickle-cell anemia. One in 10 African Americans is a carrier, as is 1 in 20 Latin Americans. Recent research strongly supports the use of hydroxyurea therapy for infants with sickle cell anemia, beginning at 9 months of age (Azar & Wong, 2017; Nevitt, Jones, & Howard, 2017).

Other diseases that result from genetic abnormalities include cystic fibrosis, some forms of diabetes, hemophilia, Huntington disease, spina bifida, and Tay-Sachs disease. Figure 7 provides further information about these diseases. Someday scientists may be able to identify why these and other genetic abnormalities occur and discover how to cure them. The Human Genome Project has already linked specific DNA variations with increased risk of a number of diseases and conditions, including Huntington disease (in which the central nervous system deteriorates), some forms of cancer, asthma, diabetes, hypertension, and Alzheimer disease (Huang & others, 2017; Wang & others, 2017).

**Dealing with Genetic Abnormalities** Every individual carries DNA variations that might predispose the person to serious physical disease or mental disorder. But not all individuals who carry an abnormal genetic variation develop the disorder. Other genes or developmental events sometimes compensate for genetic abnormalities (Russell, Hertz, & McMillan, 2017). For example, recall the earlier example of phenylketonuria: Even though individuals might carry the abnormal genetic variation associated with phenylketonuria, the abnormal phenotype does not develop when phenylalanine is replaced by other nutrients in their diet.

Thus, genes are not destiny, but genes that are missing, nonfunctional, or mutated can contribute to disorders (Lu & others, 2017; Valiente-Palleja & others, 2018). Identifying such genetic flaws could enable doctors to predict an individual’s risks, recommend healthy practices, and prescribe the safest and most effective drugs (Kobow & Blumcke, 2018; Wang & others, 2018). A decade or two from now, parents of a newborn baby may

## Jennifer Leonhard, Genetic Counselor

Jennifer Leonhard is a genetic counselor at Sanford Bemidji Health Clinic, in Bemidji, Minnesota. She obtained an undergraduate degree from Western Illinois University and a master's degree in genetic counseling from the University of Arkansas for Medical Sciences.

Genetic counselors like Leonhard work as members of a health care team, providing information and support to families with birth defects or genetic disorders. They identify families at risk by analyzing inheritance patterns and then explore options with the family. Some genetic counselors, like Leonhard, specialize in prenatal and pediatric genetics while others focus on cancer genetics or psychiatric genetic disorders.

Genetic counselors have specialized graduate degrees in medical genetics and counseling. They enter graduate school from undergraduate programs in a variety of disciplines, including biology, genetics, psychology, public health, and social work. There are approximately 30 graduate genetic counseling programs in the

be able to leave the hospital with a full genome analysis of their offspring that identifies disease risks.

However, this knowledge might bring important costs as well as benefits. Who would have access to a person's genetic profile? An individual's ability to land and hold jobs or obtain insurance might be threatened if she or he is known to be at risk for some disease. For example, should an airline pilot or a neurosurgeon who is predisposed to develop a disorder that makes one's hands shake be required to leave that job early, before showing any symptoms of the disorder?

Genetic counselors, usually physicians or biologists who are well-versed in the field of medical genetics, understand the kinds of problems just described, the odds of encountering them, and helpful strategies for offsetting some of their effects (Besser & Mounts, 2017; Jacher & others, 2017; Omaggio, Baker, & Conway, 2018; Sharony & others, 2018). The facts and principles we have discussed regarding meiosis, genetics, and genetic abnormalities are a small part of the recent explosion of knowledge about human biology. This knowledge not only helps us understand human development but also opens up many new choices to prospective parents—choices that can also raise ethical questions.

#### PRENATAL DIAGNOSTIC TESTS

One choice open to prospective mothers is the extent to which they will undergo prenatal testing. A number of tests can indicate whether a fetus is developing normally, including ultrasound sonography, fetal MRI, chorionic villus sampling, amniocentesis, and maternal blood screening.

**Ultrasound Sonography** An ultrasound test is often conducted seven weeks into a pregnancy and at various times later in pregnancy. *Ultrasound sonography* is a prenatal medical procedure in which high-frequency sound waves are directed into the pregnant woman's abdomen (Tamai & others, 2018). The echo from the sounds is transformed into a visual representation of the fetus's inner structures. This technique can detect many abnormalities in the fetus, including microcephaly, in which an abnormally small brain can produce intellectual disability; it can also determine the number of fetuses (that is, detect whether a woman is carrying twins or triplets) and give clues to the baby's sex (Calvo-Garcia, 2016; Larsson & others, 2018).

A recent research review concluded that many aspects of the developing prenatal brain can be detected by ultrasound in the first trimester and that about 50 percent of spina bifida cases can be identified at this time, most of these being severe cases (Engels & others, 2016). There is virtually no risk to the woman or fetus in using ultrasound.

**Brain-Imaging Techniques** The development of brain-imaging techniques has led to increasing use of *fetal MRI* to diagnose fetal malformations (Cheong & Miller, 2018; Choudhri & others, 2018; Kang & others, 2017) (see Figure 8). MRI, which stands for magnetic resonance imaging, uses a powerful magnet and radio images to generate detailed images of the body's organs and structures. Currently, ultrasound is still the first choice in fetal screening, but fetal MRI can provide more detailed images than ultrasound. In many instances, ultrasound will indicate a possible abnormality and then fetal MRI will be used to obtain a clearer, more detailed image (Griffiths & others, 2018). Among the fetal malformations that fetal MRI may be able to detect better than ultrasound sonography are certain abnormalities of the central nervous system, chest, gastrointestinal tract, genital/urinary organs, and placenta (Malinge & Lerman-Sagie, 2015). In a recent review, it was concluded that fetal MRI

often does not provide good results in the first trimester of pregnancy because of small fetal structures and movement artifacts (Wataganara & others, 2016). Also, in this review, it was argued that fetal MRI can be especially beneficial in assessing central nervous system abnormalities in the third semester of pregnancy.

**Chorionic Villus Sampling** At some point between the 10th and 12th weeks of pregnancy, chorionic villus sampling may be used to detect genetic defects and chromosomal abnormalities such as those discussed in the previous section. *Chorionic villus sampling (CVS)* is a prenatal medical procedure in which a small sample of the placenta (the vascular organ that links the fetus to the mother's uterus) is removed (Carlson & Vora, 2017). Diagnosis takes about 10 days. There is a small risk of limb deformity when CVS is used.

**Amniocentesis** Between the 15th and 18th weeks of pregnancy, amniocentesis may be performed. *Amniocentesis* is a prenatal medical procedure in which a sample of amniotic fluid is withdrawn by syringe and tested for chromosomal or metabolic disorders (Jung & others, 2017). The amniotic fluid is found within the amnion, a thin sac in which the embryo is suspended. Ultrasound sonography is often used during amniocentesis so that the syringe can be placed precisely. The later amniocentesis is performed, the better its diagnostic potential. The earlier it is performed, the more useful it is in deciding how to handle a pregnancy. It may take two weeks for enough cells to grow to allow amniocentesis test results to be obtained. Amniocentesis brings a small risk of miscarriage: About 1 woman in every 200 to 300 miscarries after amniocentesis.

Both amniocentesis and chorionic villus sampling provide valuable information about the presence of birth defects, but they also raise difficult issues for parents about whether an abortion should be obtained if birth defects are present. Chorionic villus sampling allows a decision to be made earlier, near the end of the first 12 weeks of pregnancy, when abortion is safer and less traumatic.

**Maternal Blood Screening** During the 15th to 19th weeks of pregnancy, maternal blood screening may be performed. *Maternal blood screening* identifies pregnancies that have an elevated risk for birth defects such as spina bifida (a defect in the spinal cord) and Down syndrome (Byeon, Ki, & Han, 2015; le Ray & others, 2018). Recent research also indicates that maternal blood screening can be used to detect congenital heart disease risk in the fetus (Sun & others, 2016). The current blood test is called the *triple screen* because it measures three substances in the mother's blood. After an abnormal triple screen result, the next step is usually an ultrasound examination. If an ultrasound does not explain the abnormal triple screen results, amniocentesis is typically used.

**Fetal Sex Determination** Chorionic villus sampling has often been used to determine the sex of the fetus at some point from 11 to 13 weeks of gestation. Also, in a recent study, ultrasound accurately identified the sex of the fetus at 11 to 13 weeks of gestation (Manzanares & others, 2016). Recently, though, some noninvasive techniques have been able to detect the sex of the fetus at an earlier point (Breviglieri & others, 2016; Degrelle & Fournier, 2018; Skrzypek & Hui, 2017). A meta-analysis of studies confirmed that a baby's sex can be detected as early as 7 weeks into pregnancy (Devaney & others, 2011). Being able to detect an offspring's sex as well as the presence of various diseases and defects at such an early stage raises ethical concerns about couples' motivation to terminate a pregnancy (Browne, 2017).

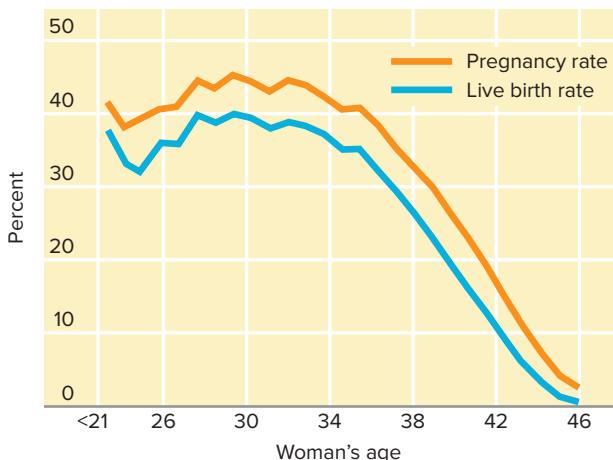

## INFERTILITY AND REPRODUCTIVE TECHNOLOGY

Recent advances in biological knowledge have also opened up many choices for infertile individuals (Dorfeshan & others, 2018; Liebermann, 2017; Florencio & others, 2018; Silber, 2017). Approximately 10 to 15 percent of couples in the United States experience *infertility*, which is defined as the inability to conceive a child after 12 months of regular intercourse without contraception. The cause of infertility can rest with the woman or the man (Namgoog & Kim, 2018; Sunderam & others, 2017). The woman may not be ovulating (releasing eggs to be fertilized), she may be producing abnormal ova, her fallopian tubes through which ova normally reach the womb may be blocked, or she may have a disease that prevents implantation of the embryo into the uterus. The man may produce too few sperm, the sperm may lack motility (the ability to move adequately), or he may have a blocked passageway (Xu & others, 2016; Zalzali & others, 2018).

**FIGURE 9**  
SUCCESS RATES OF IN VITRO FERTILIZATION VARY  
ACCORDING TO THE WOMAN'S AGE

In the United States, more than 2 million couples seek help for infertility every year. In some cases of infertility, surgery may correct the cause; in others, hormone-based drugs may improve the probability of having a child. Of the 2 million couples who seek help for infertility every year, about 40,000 try high-tech assisted reproduction. By far the most common technique used is *in vitro fertilization (IVF)*, in which eggs and sperm are combined in a laboratory dish. If any eggs are successfully fertilized, one or more of the resulting zygotes is transferred into the woman's uterus. As indicated in Figure 9, the success rate of IVF depends on the mother's age.

The creation of families by means of the new reproductive technologies raises important questions about the physical and psychological consequences for children (Golombok, 2017; Golombok & others, 2018). One result of fertility treatments is an increase in multiple births. Twenty-five to 30 percent of pregnancies achieved by fertility treatments—including in vitro fertilization—now result in multiple births. A *meta-analysis* (a statistical technique that combines the results of multiple studies to determine the strength of the effect) revealed that twins conceived by in vitro fertilization have a slightly increased risk of low birth weight (McDonald & others, 2010) and another meta-analysis found that in vitro fertilization singletons have a significant risk of low birth weight (McDonald & others, 2009). Any multiple birth increases

the likelihood that the babies will have life-threatening and costly problems, such as extremely low birth weight (March of Dimes, 2018). In a recent national study, rates of low birth weight and preterm birth were significantly higher among infants conceived through assisted-reproduction technology (Sunderam & others, 2017). However, research reviews conclude that children and adolescents conceived through new reproductive technologies—such as in vitro fertilization—are as well adjusted as their counterparts conceived by natural means (Golombok, 2011a, b, 2017; Golombok & others, 2018; Golombok & Tasker, 2010).

## ADOPTION

Although surgery and fertility drugs can sometimes solve infertility problems, another choice is to adopt a child (Compton, 2016; Farr, 2017; Farr & Goldberg, 2018; Farr & others, 2018). Adoption is a social and legal process that establishes a parent-child relationship between persons unrelated at birth.

**The Increased Diversity of Adopted Children and Adoptive Parents** A number of changes have characterized adoptive children and adoptive parents during the last three to four decades (Brodzinsky & Pinderhughes, 2002; Compton, 2016; Farr, 2017; Farr & Goldberg, 2018; Thomas, 2016). In the first half of the twentieth century, most U.S. adopted children were healthy, non-Latino White infants who were adopted at birth or soon after; however, in recent decades as abortion became legal and contraception increased, fewer of these infants became available for adoption. Increasingly, U.S. couples adopted a much wider diversity of children—from other countries, from other ethnic groups, children with physical and/or mental problems, and children who had been neglected or abused (Compton, 2016; Pinderhughes, Zhang, & Agerbak, 2015).

Changes also have characterized adoptive parents in the last three to four decades (Brodzinsky & Pinderhughes, 2002). In the first half of the twentieth century, most adoptive parents were from non-Latino White, middle or upper socioeconomic status backgrounds who were married and did not have any type of disability. However, in recent decades, increased diversity has characterized adoptive parents. Many adoption agencies today have no income requirements for adoptive parents and now allow adults from a wide range of backgrounds to adopt children, including single adults, gay and lesbian adults, and older adults (Farr, 2017; Farr, Oakley, & Ollen, 2016; Farr & others, 2018). Further, many adoptions involve other family members (aunts/uncles/grandparents); currently, 30 percent of U.S. adoptions are made by relatives (Ledesma, 2012). And slightly more than 50 percent of U.S. adoptions occur through the foster care system; one survey found that more than 100,000 children in the U.S. foster care system were waiting for someone to adopt them (Ledesma, 2012).

Three pathways to adoption are (1) domestic adoption from the public welfare system, (2) domestic infant adoption through private agencies and intermediaries, and (3) international adoption (Grotevant & McDermott, 2014). In the next decade, the mix of U.S. adoptions is likely to include fewer domestic infant and international adoptions and more adoptions via the child welfare system (Grotevant & McDermott, 2014).

**Outcomes for Adopted Children** How well do adopted children fare in comparison with children who are raised by one or both of their birth parents? In a recent study of post-institutionalized 3- to 5-year-old children, adoptive parents' secure attachment increased the likelihood that their children would have a secure attachment pattern, with mothers' secure attachment more strongly associated with children's secure attachment than was fathers' secure attachment (Barone, Lionetti, & Green, 2017). An earlier research review concluded that adopted children are at higher risk for externalizing (aggression and conduct problems, for example), internalizing (anxiety and depression, for example), and attention problems (ADHD, for example) (Grotevant & McDermott, 2014). A more recent research review of internationally adopted adolescents found that although a majority were well adjusted, adoptees had a higher level of mental health problems than their non-adopted counterparts (Askeland & others, 2017). However, a majority of adopted children and adolescents (including those adopted at older ages, transracially, and across national borders) adjust effectively, and their parents report considerable satisfaction with their decision to adopt (Brodzinsky & Pinderhughes, 2002; Compton, 2016).

Adopted children fare much better than children raised in long-term foster care or in an institutional environment (Bernard & Dozier, 2008). A study of infants in China revealed that their cognitive development improved two to six months following their adoption from foster homes and institutions (van den Dries & others, 2010).

Children who are adopted very early in their lives are more likely to have positive outcomes than children adopted later in life (Bernard & Dozier, 2008; Julian, 2013). A Danish study indicated that being adopted was not a risk for juvenile delinquency if the individual was adopted at 12 months of age or earlier (Laubjerg & Petersson, 2011). However, those adopted after 12 months of age had a three to four times higher risk of becoming a juvenile delinquent than their nonadopted counterparts. Also, a recent study found that the mother's secure attachment during adulthood, but not the father's, predicted infant adoptees' secure attachment (Lionetti, 2014). Further, in a recent study, the adjustment of school-aged children who were adopted during infancy by gay, lesbian, and heterosexual parents showed no differences (Farr, 2017). Rather, children's behavior patterns and family functioning were predicted by earlier child adjustment issues and parental stress. And in another recent study of lesbian and gay adoptive parents, 98 percent of the adoptive parents reported that their children had adjusted well to school (Farr, Oakley, & Ollen, 2016). Keep in mind that the changes in adoption practice over the last several decades make it difficult to generalize about the average adopted child or average adoptive parent.

An ongoing issue in adopting children is whether there should be any contact with children's biological parents (Farr, 2017; Farr & others, 2014; French & others, 2014; Grant-Marsney, Grotevant, & Sayer, 2015). Open adoption involves sharing identifying information and having contact with the biological parents; in contrast, closed adoption involves not having such sharing and contact. Most adoption agencies today offer adoptive parents the opportunity to have either an open or a closed adoption. A longitudinal study found that when their adopted children reached adulthood, adoptive parents described open adoption positively and saw it as serving the child's best interests (Siegel, 2013). Another longitudinal study found that birth mothers, adoptive parents, and adopted children who had contact were more satisfied with their arrangements than those who did not have contact (Grotevant & others, 2013). Also, in this study, contact was linked to more optimal adjustment for adolescents and emerging adults. Further, birth mothers who were more satisfied with their contact arrangements had less unresolved grief 12 to 20 years after placement. In a study of adoptees in emerging adulthood, perceptions of secure parent-child attachment relationships, as well as sensitive and open communication about birth parent contact, were linked to greater satisfaction with life (Farr, Grant-Marsney, & Grotevant, 2014).

To read more about adoption, see *Connecting Development to Life*, in which we discuss effective parenting strategies with adopted children.

## Parenting Adopted Children

Many of the keys to effectively parenting adopted children are no different from those for effectively parenting biological children: be supportive and caring, be involved and monitor the child's behavior and whereabouts, be a good communicator, and help the child learn to develop self-control. However, parents of adopted children face some unique circumstances (Grotevant & McDermott, 2014; Farr & others, 2018; Pace & others, 2015; Salcuni & others, 2015; Tan & others, 2017). These parents need to recognize the differences involved in adoptive family life, communicate about these differences, show respect for the birth family, and support the child's search for self and identity.

Following are some of the problems parents may face when their adopted children are at different points in development and some recommendations for handling these problems (Brodzinsky & Pinderhughes, 2002):

- **Infancy.** Researchers have found few differences in the attachment that adopted and nonadopted infants form with their parents. However, attachment can become problematic if parents have unresolved fertility issues or the child does not meet the parents' expectations. Counselors can help prospective adoptive parents develop realistic expectations.
- **Early childhood.** Because many children begin to ask where they came from when they are about 4 to 6 years old, this is a natural time to begin to talk in simple ways to children about their adoption status (Warshak, 2017). Some parents (although not as many as in the past) decide not to tell their children about the adoption. This secrecy may create psychological risks for the child if he or she later finds out about the adoption.

What are some strategies for parenting adopted children at different points in their development?  
©Don Mason/Getty Images

- **Middle and late childhood.** During the elementary school years, children begin to show more interest in their origins and may ask questions related to where they came from, what their birth parents looked like, and why their birth parents placed them for adoption. As they grow older, children may develop mixed feelings about being adopted and question their adoptive parents' explanations. It is important for adoptive parents to recognize that this ambivalence is normal. Also, problems may arise from the desire of adoptive parents to make life too perfect for the adoptive child and to present a perfect image of themselves to the child. The result too often is that adopted children feel that they cannot release any angry feelings or openly discuss problems.
- **Adolescence.** Adolescents are likely to develop more abstract and logical thinking, to focus their attention on their bodies, and to search for an identity. These characteristics provide the foundation for adopted adolescents to reflect on their adoption status in more complex ways, such as focusing on the fact that they look different from their adoptive parents. As they explore their

identity, adopted adolescents may have difficulty incorporating their adopted status into their identity in positive ways. It is important for adoptive parents to understand the complexity of the adopted adolescent's identity exploration and be patient with the adolescent's lengthy identity search.

LG4

Explain some of the ways that heredity and environment interact to produce individual differences in development.

Behavior Genetics

Heredity-Environment Correlations

The Epigenetics View and Gene-Environment ( $G \times E$ ) Interaction

Conclusions about Heredity-Environment Interaction

Is it possible to untangle the influence of heredity from that of environment and discover the role of each in producing individual differences in development? When heredity and environment interact, how does heredity influence the environment and vice versa?

### BEHAVIOR GENETICS

**Behavior genetics** is the field that seeks to discover the influence of heredity and environment on individual differences in human traits and development (Charney, 2017; Machalek & others, 2017; Pinheiro & others, 2018; Rana & others, 2018). Note that behavior genetics *does not* identify the extent to which genetics or the environment affects an individual's traits. Instead, what behavior geneticists try to do is to figure out what is responsible for the differences among people—that is, to what extent people vary because of differences in genes, environment, or a combination of these factors (Finkel, Sternang, & Wahlin, 2017; Meier & others, 2018; Rana & others, 2018; Wu & others, 2017). To study the influence of heredity on behavior, behavior geneticists often use either twins or adoption situations.

In the most common **twin study**, the behavioral similarity of identical twins (who are genetically identical) is compared with the behavioral similarity of fraternal twins. Recall that although fraternal twins share the same womb, they are no more genetically alike than non-twin siblings. Thus, by comparing groups of identical and fraternal twins, behavior geneticists capitalize on the basic knowledge that identical twins are more similar genetically than are fraternal twins (Inderkum & Tarokh, 2018; Li & others, 2016; Rosenstrom & others, 2018; Wertz & others, 2018). For example, one study found that conduct problems were more prevalent in identical twins than fraternal twins; the researchers concluded that the study demonstrated an important role for heredity in conduct problems (Scourfield & others, 2004).

What are some of the thoughts and feelings people have about being a twin? In college freshman Colin Kunzweiler's (2007) view,

As a monozygotic individual, I am used to certain things. "Which one are you?" happens to be the most popular question I'm asked, which is almost always followed by "You're Colin. No, wait, you're Andy!" I have two names: one was given to me at birth, the other thrust on me in a random, haphazard way . . . My twin brother and I are as different from each other as caramel sauce is from gravy. We have different personalities, we enjoy different kinds of music, and I am even taller than he is (by a quarter of an inch). We are different; separate; individual. I have always been taught that I should maintain my own individuality; that I should be my own person. But if people keep constantly mistaking me for my twin, how can I be my own person with my own identity?

"Am I an 'I' or 'We'?" was the title of an article written by Lynn Perlman (2008) about the struggle twins have in developing a sense of being an individual. Of course, triplets have the same issue, possibly even more strongly so. One set of triplets entered a beauty contest as one person and won the contest!

Perlman, an identical twin herself, is a psychologist who works with twins (her identical twin also is a psychologist). She says that how twins move from a sense of "we" to "I" is a critical task for them as children and sometimes even as adults. For non-twins, separating oneself from a primary caregiver—mother and/or father—is an important developmental task in childhood, adolescence, and emerging adulthood. When a child has a

Twin studies compare identical twins with fraternal twins. Identical twins develop from a single fertilized egg that splits into two genetically identical organisms. Fraternal twins develop from separate eggs, making them genetically no more similar than non-twin siblings.

twin, the separation process is likely more difficult because of the constant comparison with a twin. Because they are virtually identical in their physical appearance, identical twins are likely to have more problems in distinguishing themselves from their twin than are fraternal twins.

The twin separation process often accelerates in adolescence when one twin is likely to mature earlier than the other (Pearlman, 2013). However, for some twins it may not occur until emerging adulthood when they may go to different colleges and/or live apart for the first time. And for some twins, even separation during adulthood can be emotionally painful. One 28-year-old identical twin female got a new boyfriend but the new relationship caused a great deal of stress and conflict with her twin sister (Friedman, 2013).

In Lynn Perlman's (2008) view, helping twins develop their own identities needs to be done on a child-by-child basis, taking into account their preferences and what is in their best interests. She commented that most of the twins she has counselled consider having a twin a positive experience and while they also are usually strongly attached to each other they are intensely motivated to be regarded as unique individuals.

Several issues complicate interpretation of twin studies. For example, perhaps the environments of identical twins are more similar than the environments of fraternal twins. Adults might stress the similarities of identical twins more than those of fraternal twins, and identical twins might perceive themselves as a "set" and play together more than fraternal twins do. If so, the influence of the environment on the observed similarities between identical and fraternal twins might be very significant.

In an **adoption study**, investigators seek to discover whether the behavior and psychological characteristics of adopted children are more like those of their adoptive parents, who have provided a home environment, or more like those of their biological parents, who have contributed their DNA (McAdams & others, 2015; Salvatore & others, 2018). Another form of the adoption study compares adoptive and biological siblings (Kendler & others, 2016).

## HEREDITY-ENVIRONMENT CORRELATIONS

The difficulties that researchers encounter when they interpret the results of twin studies and adoption studies reflect the complexities of heredity-environment interaction. Some of these interactions are heredity-environment correlations, which means that individuals' genes may be systematically related to the types of environments to which they are exposed (Jaffee, 2016). In a sense, individuals "inherit," seek out, or "construct" environments that may be related or linked to genetic "propensities." Behavior geneticist Sandra Scarr (1993) described three ways that heredity and environment can be correlated (see Figure 10):

- **Passive genotype-environment correlations** occur because biological parents, who are genetically related to the child, provide a rearing environment for the child. For example, the parents might have a genetic predisposition to be intelligent and read skillfully. Because they read well and enjoy reading, they provide their children with books to read. The likely outcome is that their children, because of both their own inherited predispositions and their book-filled environment, will become skilled readers.
- **Evocative genotype-environment correlations** occur because a child's genetically influenced characteristics elicit certain types of environments. For example, active, smiling children receive more social stimulation than passive, quiet children do. Cooperative, attentive children evoke more pleasant and instructional responses from the adults around them than uncooperative, distractible children do.
- **Active (niche-picking) genotype-environment correlations** occur when children seek out environments that they find compatible and stimulating. *Niche-picking* refers to finding a setting that is suited to one's genetically influenced abilities. Children select from their surrounding environment certain aspects that they respond to, learn about, or ignore. Their active selections of environments are related to their particular genotype. For example, outgoing children tend to seek out social contexts in which to interact with people, whereas shy children don't. Children who are musically inclined are likely to select musical environments in which they can successfully perform their skills. How these "tendencies" come about will be discussed shortly under the topic of the epigenetic view.

**adoption study** A study in which investigators seek to discover whether, in behavior and psychological characteristics, adopted children are more like their adoptive parents, who provided a home environment, or more like their biological parents, who contributed their heredity. Another form of the adoption study compares adoptive and biological siblings.

**passive genotype-environment correlations** Correlations that exist when the natural parents, who are genetically related to the child, provide a rearing environment for the child.

**evocative genotype-environment correlations** Correlations that exist when the child's genetically influenced characteristics elicit certain types of environments.

**active (niche-picking) genotype-environment correlations** Correlations that exist when children seek out environments they find compatible and stimulating.

Heredity-Environment Correlation	Description	Examples
<b>Passive</b>	Children inherit genetic tendencies from their parents, and parents also provide an environment that matches their own genetic tendencies.	Musically inclined parents usually have musically inclined children, and they are likely to provide an environment rich in music for their children.
<b>Evocative</b>	The child's genetic tendencies elicit stimulation from the environment that supports a particular trait. Thus genes evoke environmental support.	A happy, outgoing child elicits smiles and friendly responses from others.
<b>Active (niche-picking)</b>	Children actively seek out "niches" in their environment that reflect their own interests and talents and are thus in accord with their genotype.	Libraries, sports fields, and a store with musical instruments are examples of environmental niches children might seek out if they have intellectual interests in books, talent in sports, or musical talents, respectively.

**FIGURE 10**  
EXPLORING HEREDITY-ENVIRONMENT CORRELATIONS

Scarr observes that the relative importance of the three genotype-environment correlations changes as children develop from infancy through adolescence. In infancy, much of the environment that children experience is provided by adults. Thus, passive genotype-environment correlations are more common in the lives of infants and young children than they are in the lives of older children and adolescents who can extend their experiences beyond the family's influence and create or select their environments to a greater degree.

## THE EPIGENETIC VIEW AND GENE $\times$ ENVIRONMENT (G $\times$ E) INTERACTION

Critics argue that the concept of heredity-environment correlation gives heredity too much of a one-sided influence in determining development because it does not consider the role of prior environmental influences in shaping the correlation itself (Gottlieb, 2007). Consistent with this view, earlier in the chapter we discussed how genes are collaborative, not determining an individual's traits independently but in conjunction with the environment.

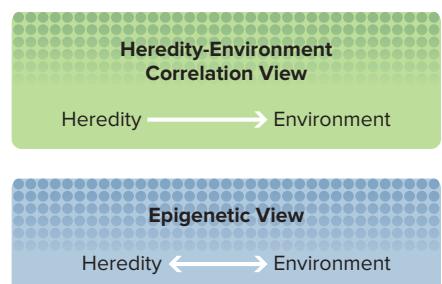

**The Epigenetic View** In line with the concept of a collaborative gene, Gilbert Gottlieb (2007) emphasizes the **epigenetic view**, which states that development reflects an ongoing, *bidirectional* interchange between heredity and the environment. Figure 11 compares the heredity-environment correlation and epigenetic views of development.

Let's look at an example that reflects the epigenetic view. A baby inherits genes from both parents at conception. During prenatal development, environmental experiences such as toxins, nutrition, and stress can influence some genes to stop functioning while others become more active or less active. During infancy, environmental experiences such as exposure to toxins, nutrition, stress, learning, and encouragement continue to modify genetic activity and influence the activity of the nervous system that directly underlies behavior. Heredity and environment operate together—or collaborate—to produce a person's well-being, intelligence, temperament, height, weight, ability to pitch a baseball, ability to read, and so on (Moore, 2017).

**epigenetic view** Emphasizes that development is the result of an ongoing, bidirectional interchange between heredity and environment.

**Gene  $\times$  Environment (G  $\times$  E) Interaction** An increasing number of studies are exploring how the interaction between heredity and environment influences development, including interactions that involve specific DNA sequences (Bakusic & others, 2017; Grunblatt & others, 2018; Halldorsdottir & Binder, 2017; Quereshi & Mehler, 2018). The epigenetic mechanisms involve the actual molecular modification of the DNA strand as a result of environmental inputs in ways that alter gene functioning (Moore, 2017; Kalashnikova, Goswami, & Burnham, 2018; Rozenblat & others, 2017; Szutorisz & Hurd, 2018).

One study found that individuals who have a short version of a gene labeled 5-HTTLPR (a gene involving the neurotransmitter serotonin) have an elevated risk of developing

depression only if they *also* lead stressful lives (Caspi & others, 2003). Thus, the specific gene did not directly cause the development of depression; rather, the gene interacted with a stressful environment in a way that allowed the researchers to predict whether individuals would develop depression. A meta-analysis indicated that the short version of 5-HTTLPR was linked with higher cortisol stress reactivity (Miller & others, 2013). Researchers also have found support for the interaction between the 5-HTTLPR gene and stress levels in predicting depression in adolescents and older adults (Petersen & others, 2012; Zannas & others, 2012).

Other research on interactions between genes and environmental experiences has focused on attachment, parenting, and supportive child-rearing environments (Labella & Masten, 2018). In one study, adults who experienced parental loss as young children were more likely to have unresolved attachment issues as adults only when they had the short version of the 5-HTTLPR gene (Caspers & others, 2009). The long version of the serotonin transporter gene apparently provided some protection and ability to cope better with parental loss. Other researchers have found that variations in dopamine-related genes interact with supportive or unsupportive rearing environments to influence children’s development (Bakermans-Kranenburg & van IJzendoorn, 2011). The type of research just described is referred to as studies of **gene × environment ( $G \times E$ ) interaction**—the interaction of a specific measured variation in DNA and a specific measured aspect of the environment (Moore, 2017; Naumova & others, 2016; Samek & others, 2017).

Although there is considerable enthusiasm about the concept of gene × environment interaction ( $G \times E$ ), a research review concluded that the area is plagued by difficulties in replicating results, inflated claims, and other weaknesses (Manuck & McCaffery, 2014). The science of  $G \times E$  interaction is very young and over the next several decades it will likely produce more precise findings (Fumagalli & others, 2018; Marioni & others, 2018).

## CONCLUSIONS ABOUT HEREDITY-ENVIRONMENT INTERACTION

If an attractive, popular, intelligent girl is elected president of her senior class in high school, is her success due to heredity or to environment? Of course, the answer is “both.”

The relative contributions of heredity and environment are not additive. That is, we can’t say that such-and-such a percentage of nature and such-and-such a percentage of experience make us who we are. Nor is it accurate to say that full genetic expression happens once, around conception or birth, after which we carry our genetic legacy into the world to see how far it takes us. Genes produce proteins throughout the life span, in many different environments. Or they don’t produce these proteins, depending in part on how harsh or nourishing those environments are.

The emerging view is that complex behaviors are influenced by genes and environments in a way that gives people a propensity for a particular developmental trajectory (Knyazev & others, 2018; Zabaneh & others, 2017). The actual development requires both genes and an environment. And that environment is complex, just like the mixture of genes we inherit (Almy & Cicchetti, 2018; Nicolaisen & Thorsen, 2017; Tremblay, Vitaro, & Cote, 2018). Environmental influences range from the things we lump together under “nurture” (such as parenting, family dynamics, schooling, and neighborhood quality) to biological encounters (such as viruses, birth complications, and even biological events occurring at the cellular level).

In developmental psychologist David Moore’s (2013, 2015, 2017) view, the biological systems that generate behaviors are extremely complex but too often these systems have been described in overly simplified ways that can be misleading. Thus, although genetic factors clearly contribute to behavior and psychological processes, they don’t determine these phenotypes independently from the contexts in which they develop. From Moore’s (2015, 2017) perspective, it is misleading to talk about “genes for” eye color, intelligence, personality, or other characteristics. Moore commented that in retrospect we should not have expected to be able to make the giant leap from DNA’s molecules to a complete understanding of human behavior any more than we should anticipate being able to make the leap from understanding how sound waves move air molecules in a concert hall to a full-blown appreciation of a symphony’s wondrous experience.

### Life-Span Perspective

An important aspect of the life-span perspective is the co-construction of biology, environment, and the individual. Connect to “Introduction.”

Imagine for a moment a cluster of genes somehow associated with youth violence (this example is hypothetical because we don't know of any such combination). The adolescent who carries this genetic mixture might experience a world of loving parents, regular nutritious meals, lots of books, and a series of masterful teachers. Or the adolescent's world might include parental neglect, a neighborhood in which gunshots and crime are everyday occurrences, and inadequate schooling. In which of these environments is the adolescent likely to become a criminal?

If heredity and environment interact to determine the course of development, is that all there is to answering the question of what causes development? Are humans completely at the mercy of their genes and environment as they develop through the life span? Our genetic heritage and environmental experiences are pervasive influences on development (Denhardt, 2018; Lockhart & others, 2017; Masten & Kalstabakken, 2018; Simon, 2017). But in thinking about what causes development, recall from the "Introduction" chapter our discussion of development as the co-construction of biology, culture, *and* the individual. Not only are we the outcomes of our heredity and the environment we experience, but we also can author a unique developmental path by changing the environment. As one psychologist concluded:

In reality, we are both the creatures and creators of our worlds. We are . . . the products of our genes and environments. Nevertheless, . . . the stream of causation that shapes the future runs through our present choices . . . Mind matters . . . Our hopes, goals, and expectations influence our future. (Myers, 2010, p. 168)

In the following chapters, we will continue to explore biological influences on development, especially in the chapters on physical development, but also in the chapters on cognitive and socioemotional development. For instance, biology's influence on infants' gross and fine motor skills may be obvious, but we will also discuss research questions such as "Is there a biological basis for sexual orientation?" In addition, we will examine reproduction when we look at adolescents and young adults who become parents. Finally, we will touch on the dual influence of nature and nurture in every period of life-span development.

## Biological Beginnings

### 1 The Evolutionary Perspective

Natural Selection and Adaptive Behavior

Evolutionary Psychology

LG1

Discuss the evolutionary perspective on life-span development.

- Natural selection is the process by which those individuals of a species that are best adapted survive and reproduce. Darwin proposed that natural selection fuels evolution. In evolutionary theory, adaptive behavior is behavior that promotes the organism's survival in a natural habitat.
- Evolutionary psychology holds that adaptation, reproduction, and "survival of the fittest" are important in shaping behavior. Ideas proposed by evolutionary developmental psychology include the view that an extended childhood period is needed to develop a large brain and learn the complexity of human social communities.
- According to Baltes, the benefits resulting from evolutionary selection decrease with age mainly because of a decline in reproductive fitness. At the same time, cultural needs increase.
- Like other theoretical approaches to development, evolutionary psychology has limitations. Bandura rejects "one-sided evolutionism" and argues for a bidirectional link between biology and environment. Biology allows for a broad range of cultural possibilities.

### 2 Genetic Foundations of Development

The Collaborative Gene

Genes and Chromosomes

Genetic Principles

Chromosomal and Gene-Linked Abnormalities

LG2

Describe what genes are and how they influence human development.

- Short segments of DNA constitute genes, the units of hereditary information that help cells to reproduce and manufacture proteins. Genes act collaboratively, not independently.
- Genes are passed on to new cells when chromosomes are duplicated during the processes of mitosis and meiosis, which are two ways in which new cells are formed. When an egg and a sperm unite in the fertilization process, the resulting zygote contains the genes from the chromosomes in the father's sperm and the mother's egg. Despite this transmission of genes from generation to generation, variability is created in several ways, including through the exchange of chromosomal segments during meiosis, through mutations, and through environmental influences.
- Genetic principles include those involving dominant-recessive genes, sex-linked genes, genetic imprinting, and polygenic inheritance.
- Chromosomal abnormalities produce Down syndrome, which is caused by the presence of an extra copy of chromosome 21. Sex-linked conditions include Klinefelter syndrome, fragile X syndrome, Turner syndrome, and XYY syndrome. Gene-linked abnormalities involve harmful or absent genes. Gene-linked disorders include phenylketonuria (PKU) and sickle-cell anemia. Genetic counseling offers couples information about their risk of having a child with inherited abnormalities.

### 3 Reproductive Challenges and Choices

Prenatal Diagnostic Tests

LG3

Identify some important reproductive challenges and choices.

- Ultrasound sonography, fetal MRI, chorionic villus sampling, amniocentesis, and maternal blood screening are used to determine whether a fetus is developing normally. Determination of the sex of the fetus is occurring earlier in prenatal development through noninvasive methods.

- Approximately 10 to 15 percent of U.S. couples have infertility problems, some of which can be corrected through surgery or fertility drugs. An additional option is in vitro fertilization.
- A majority of adopted children adapt effectively. When adoption occurs very early in development, the outcomes for the child are improved. Because of the dramatic changes that occurred in adoption in recent decades, it is difficult to generalize about the average adopted child or average adoptive family.

## 4 Heredity-Environment Interaction: The Nature-Nurture Debate

LG4

Explain some of the ways that heredity and environment interact to produce individual differences in development.

Behavior Genetics

Heredity-Environment Correlations

The Epigenetic View and Gene  $\times$  Environment ( $G \times E$ ) Interaction

Conclusions About Heredity-Environment Interaction

- Behavior genetics is the field concerned with the influence of heredity and environment on individual differences in human traits and development. Research methods used by behavior geneticists include twin studies and adoption studies.
- In Scarr's heredity-environment correlations view, heredity directs the types of environments that children experience. She describes three genotype-environment correlations: passive, evocative, and active (niche-picking). Scarr argues that the relative importance of these three genotype-environment correlations changes as children develop.
- The epigenetic view emphasizes that development is the result of an ongoing, bidirectional interchange between heredity and environment. Gene  $\times$  environment interaction involves the interaction of a specific measured variation in the DNA and a specific measured aspect of the environment. An increasing number of  $G \times E$  studies are being conducted.
- Behaviors are influenced by genes and environments in a way that gives people a propensity for a particular developmental trajectory. The actual development requires both genes and an environment, and that environment is complex. The interaction of heredity and environment is extensive. Much remains to be discovered about the specific ways that heredity and environment interact to influence development. Heredity and environment are pervasive influences on development, but humans can author a unique developmental path by changing their environments.

Diana and Roger married when he was 38 and she was 34. Both worked full-time and were excited when Diana became pregnant. Two months later,

Diana began to have some unusual pains and bleeding. Just two months into her pregnancy she lost the baby. Although most early miscarriages are the result of embryonic defects, Diana thought deeply about why she had been unable to carry the baby to full term, and felt guilty that she might have done something “wrong.”

Six months later, Diana became pregnant again. Because she was still worried about her prior loss, she made sure to follow every government recommendation such as getting enough folic acid, avoiding certain types of dairy products that might harbor bacteria, and letting someone else change their cat’s litterbox to avoid toxoplasmosis. She and Roger read about pregnancy and signed up for birth preparation classes. Each Friday night for eight weeks they practiced techniques for dealing with contractions. They talked about what kind of parents they wanted to be and discussed what changes in their lives the baby would make. When they found out that their offspring was going to be a boy, they gave him a nickname: Mr. Littles.

This time, Diana’s pregnancy went well, and Alex, also known as Mr. Littles, was born. During the birth, however, Diana’s heart rate dropped precipitously, and she was given a stimulant to raise it. Apparently the stimulant also increased Alex’s heart rate and breathing to a dangerous point, and he had to be placed in a neonatal intensive care unit (NICU).

Several times a day, Diana and Roger visited Alex in the NICU. A number of babies in the NICU with very low birth weights had been in intensive care for weeks, and some of the babies were not doing well. Fortunately, Alex was in better health. After he had spent several days in the NICU, his parents were permitted to take home a very healthy Alex.

## topical connections *looking back*

Genes form the biological basis of our development. They are passed on through mitosis, meiosis, and, ultimately, fertilization. The impact of our genes involves the genetic principles of dominant-recessive genes, sex-linked genes, genetic imprinting, and polygenically determined characteristics. Approximately 10 to 15 percent of U.S. couples have problems with fertility. Some of these problems can be solved through surgery, drugs, or in vitro fertilization. Whether a pregnancy occurs naturally or with assistance, the resulting infant’s development is shaped both by his or her genes (nature) and environment (nurture).

# preview

This chapter chronicles the truly remarkable developments from conception through birth. Imagine . . . at one time you were an organism floating in a sea of fluid in your mother's womb. Let's now explore what your development was like from the time you were conceived through the time you were born. We will explore normal development in the prenatal period, as well as the period's hazards (such as high levels of mercury that were mentioned in the preceding story). We also will study the birth process and tests used to assess the newborn; discuss parents' adjustment during the postpartum period; and evaluate parent-infant bonding.

The history of man for the nine months preceding his birth would, probably, be far more interesting, and contain events of greater moment, than all the three score and ten years that follow it.

—SAMUEL TAYLOR COLERIDGE  
English Poet and Essayist, 19th Century

Imagine how Alex ("Mr. Littles") came to be. Out of thousands of eggs and millions of sperm, one egg and one sperm united to produce him. Had the union of sperm and egg come a day or even an hour earlier or later, he might have been very different—maybe even of the opposite sex. Conception occurs when a single sperm cell from the male unites with an ovum (egg) in the female's fallopian tube in a process called fertilization. Over the next few months, the genetic code discussed in the "Biological Beginnings" chapter directs a series of changes in the fertilized egg, but many events and hazards will influence how that egg develops and becomes tiny Alex.

### THE COURSE OF PRENATAL DEVELOPMENT

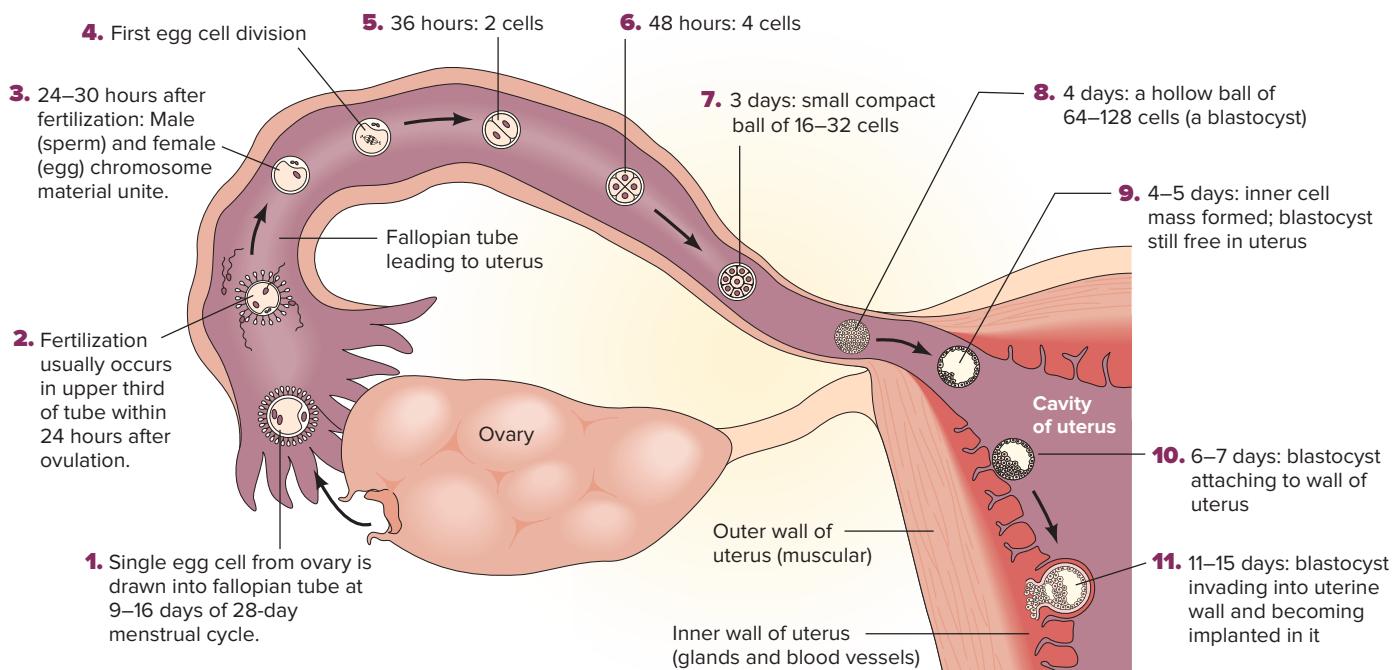

Typical prenatal development, which begins with fertilization and ends with birth, takes between 266 and 280 days (38 to 40 weeks). It can be divided into three periods: germinal, embryonic, and fetal.

**The Germinal Period** The **germinal period** is the period of prenatal development that takes place during the first two weeks after conception. It includes the creation of the fertilized egg, called a zygote; cell division; and the attachment of the zygote to the uterine wall.

Rapid cell division by the zygote continues throughout the germinal period (recall that this cell division occurs through a process called mitosis). *Differentiation*—specialization of cells to perform various tasks—starts to take place by approximately one week after conception. At this stage, the group of cells, now called the **blastocyst**, consists of an inner mass of cells that will eventually develop into the embryo, and the **trophoblast**, an outer layer of cells that later provides nutrition and support for the embryo. Implantation, the attachment of the zygote to the uterine wall, takes place about 11 to 15 days after conception. Figure 1 illustrates some of the most significant developments during the germinal period.

**The Embryonic Period** The **embryonic period** is the period of prenatal development that occurs from two to eight weeks after conception. During the embryonic period, the rate of cell differentiation intensifies, support systems for cells form, and organs appear.

This period begins as the blastocyst attaches to the uterine wall. The mass of cells is now called an *embryo*, and three layers of cells form. The embryo's *endoderm* is the inner layer of cells, which will develop into the digestive and respiratory systems. The *mesoderm* is the middle layer, which will become the circulatory system, bones, muscles, excretory system, and reproductive system. The *ectoderm* is the outermost layer, which will become the nervous system and brain, sensory receptors (ears, nose, and eyes, for example), and skin parts (hair and nails, for example). Every body part eventually develops from these three layers. The endoderm primarily produces internal body parts, the mesoderm primarily produces parts that surround the internal areas, and the ectoderm primarily produces surface parts.

**FIGURE 1**

**SIGNIFICANT DEVELOPMENTS IN THE GERMINAL PERIOD.** Just one week after conception, cells of the blastocyst have already begun specializing. The germinal period ends when the blastocyst attaches to the uterine wall. Which of the steps shown in the drawing occur in the laboratory when IVF is used?

As the embryo's three layers form, life-support systems for the embryo develop rapidly. These life-support systems include the amnion, the umbilical cord (both of which develop from the fertilized egg, not the mother's body), and the placenta. The **amnion** is a sac (bag or envelope) that contains a clear fluid in which the developing embryo floats. The amniotic fluid provides an environment that is temperature and humidity controlled, as well as shockproof. The **umbilical cord** contains two arteries and one vein, and connects the baby to the placenta. The **placenta** consists of a disk-shaped group of tissues in which small blood vessels from the mother and the offspring intertwine but do not join.

Figure 2 illustrates the placenta, the umbilical cord, and the blood flow in the expectant mother and developing organism. Very small molecules—oxygen, water, salt, food from the mother's blood, as well as carbon dioxide and digestive wastes from the offspring's blood—pass back and forth between the mother and embryo or fetus (Cuffe & others, 2017; Dube, Desparois, & Lafond, 2018). Virtually any drug or chemical substance the pregnant woman ingests can cross the placenta to some degree, unless it is metabolized or altered during passage, or the molecules are too large to pass through the placental wall (Pfeifer & Bunders, 2016). Of special concern is the transfer through the placenta of drugs that can be harmful to the fetus, such as alcohol, nicotine, marijuana, and cocaine (Koren & Ornoy, 2018). For example, one study confirmed that ethanol crosses the human placenta and primarily reflects maternal alcohol use (Matlow & others, 2013). Another study revealed that cigarette smoke weakened and increased the oxidative stress of fetal membranes, from which the placenta develops (Menon & others, 2011). The stress hormone cortisol also can cross the placenta (Parrott & others, 2014). Large molecules that cannot pass through the placental wall include red blood cells and harmful substances, such as most bacteria, maternal wastes, and hormones. The complex mechanisms that govern the transfer of substances across the placental barrier are still not entirely understood (Huckle, 2017; Jeong & others, 2018; Vaughan & others, 2017; Zhang & others, 2018).

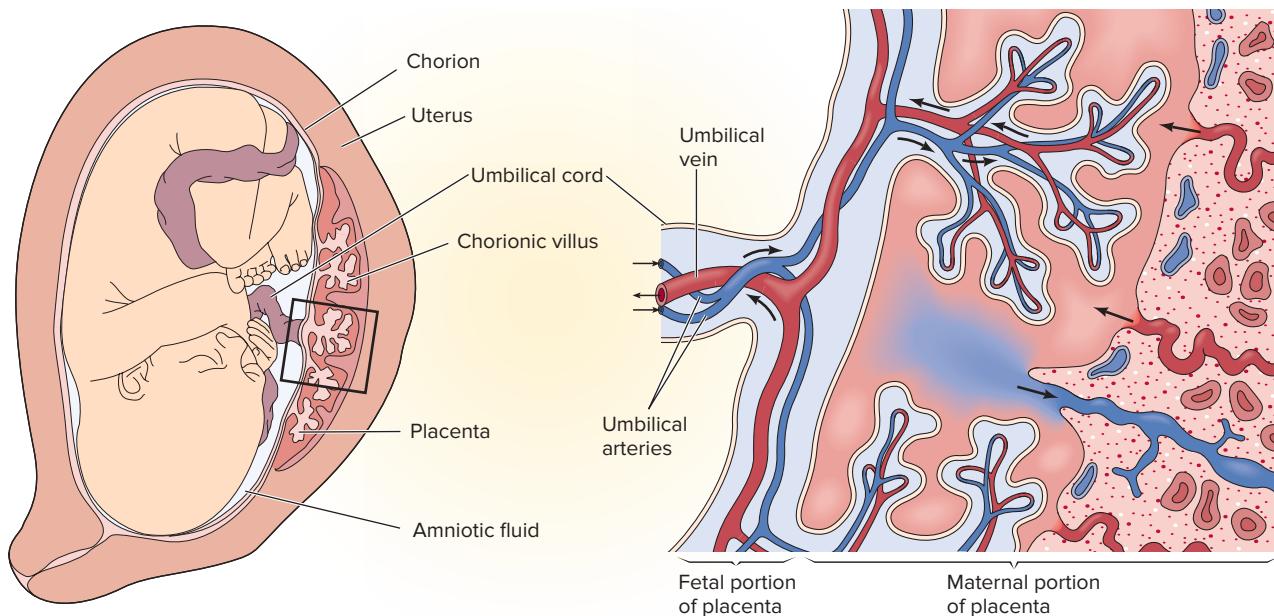

By the time most women know they are pregnant, the major organs have begun to form. **Organogenesis** is the name given to the process of organ formation during the first two months of prenatal development. While they are being formed, the organs are especially vulnerable to environmental changes (Rios & Clevers, 2018; Schittny, 2017). In the third week after conception, the neural tube that eventually becomes the spinal cord forms. At about 21 days, eyes begin to appear, and at 24 days the cells for the heart begin to differentiate. During the fourth

**umbilical cord** Part of the prenatal life-support system that contains two arteries and one vein that connect the baby to the placenta.

**THE PLACENTA AND THE UMBILICAL CORD.** The area bound by the square is enlarged in the right half of the illustration. Arrows indicate the direction of blood flow. Maternal blood flows through the uterine arteries to the spaces housing the placenta, and it returns through the uterine veins to the maternal circulation. Fetal blood flows through the umbilical arteries into the capillaries of the placenta and returns through the umbilical vein to the fetal circulation. The exchange of materials takes place across the layer separating the maternal and fetal blood supplies, so the bloods never come into contact. *What is known about how the placental barrier works and its importance?*

week, the urogenital system becomes apparent, and arm and leg buds emerge. Four chambers of the heart take shape, and blood vessels appear. From the fifth to the eighth week, arms and legs differentiate further; at this time, the face starts to form but still is not very recognizable. The intestinal tract develops and the facial structures fuse. At eight weeks, the developing organism weighs about 1/30 ounce and is just over 1 inch long.

**The Fetal Period** The **fetal period**, lasting about seven months, is the prenatal period between two months after conception and birth in typical pregnancies. Growth and development continue their dramatic course during this time.

Three months after conception (13 weeks), the fetus is about 3 inches long and weighs about four-fifths of an ounce. Its arms, legs, and head move randomly (or spontaneously), and its mouth opens and closes. The face, forehead, eyelids, nose, and chin are distinguishable, as are the upper arms, lower arms, hands, and lower limbs. In most cases, the genitals can be identified as male or female. By the end of the fourth month of pregnancy (17 weeks), the fetus has grown to about 5.5 inches in length and weighs about 5 ounces. At this time, a growth spurt occurs in the body's lower parts. For the first time, the mother can feel the fetus move.

By the end of the fifth month (22 weeks), the fetus is about 12 inches long and weighs close to a pound. Structures of the skin have formed—toenails and fingernails, for example. The fetus is more active, showing a preference for a particular position in the womb. By the end of the sixth month (26 weeks), the fetus is about 14 inches long and has gained another half pound to a pound. The eyes and eyelids are completely formed, and a fine layer of hair covers the head. A grasping reflex is present and irregular breathing movements occur.

As early as six months of pregnancy (about 24 to 25 weeks after conception), the fetus for the first time has a chance of surviving outside the womb—that is, it is viable. Infants who are born early, or between 24 and 37 weeks of pregnancy, usually need help breathing because their lungs are not yet fully mature. By the end of the seventh month, the fetus is about 16 inches long and weighs about 3 pounds.

During the last two months of prenatal development, fatty tissues develop, and the functioning of various organ systems—heart and kidneys, for example—steps up. During the eighth and ninth months, the fetus grows longer and gains substantial weight—about another 4 pounds. At birth, the average American baby weighs 8 pounds and is about 20 inches long.

# Prenatal Growth

## First trimester (first 3 months)

### Conception to 4 weeks

- Is less than 1/10 inch long
- Beginning development of spinal cord, nervous system, gastrointestinal system, heart, and lungs
- Amniotic sac envelops the preliminary tissues of entire body
- Is called a “zygote”

### 8 weeks

- Is about 0.6 inch long
- Face is forming with rudimentary eyes, ears, mouth, and tooth buds
- Arms and legs are moving
- Brain is forming
- Fetal heartbeat is detectable with ultrasound
- Is called an “embryo”

### 12 weeks

- Is about 2 inches long and weighs about 0.5 ounce
- Can move arms, legs, fingers, and toes
- Fingerprints are present
- Can smile, frown, suck, and swallow
- Sex is distinguishable
- Can urinate
- Is called a “fetus”

## Second trimester (middle 3 months)

### 16 weeks

- Is about 5 inches long and weighs about 3.5 ounces
- Heartbeat is strong
- Skin is thin, transparent
- Downy hair (lanugo) covers body
- Fingernails and toenails are forming
- Has coordinated movements; is able to roll over in amniotic fluid

### 20 weeks

- Is about 6.5 inches long and weighs about 11 ounces
- Heartbeat is audible with ordinary stethoscope
- Sucks thumb
- Hiccups
- Hair, eyelashes, eyebrows are present

### 24 weeks

- Is about 12 inches long and weighs about 1.3 pounds
- Skin is wrinkled and covered with protective coating (vernix caseosa)
- Eyes are open
- Waste matter is collected in bowel
- Has strong grip

## Third trimester (last 3 months)

### 28 weeks

- Is about 15 inches long and weighs about 2.3 pounds
- Is adding body fat
- Is very active
- Rudimentary breathing movements are present

### 32 weeks

- Is about 17 inches long and weighs about 4 pounds
- Has periods of sleep and wakefulness
- Responds to sounds
- May assume the birth position
- Bones of head are soft and flexible
- Iron is being stored in liver

### 36 to 38 weeks

- Is 19 to 20 inches long and weighs 6 to 7½ pounds
- Skin is less wrinkled
- Vernix caseosa is thick
- Lanugo is mostly gone
- Is less active
- Is gaining immunities from mother

Figure 3 gives an overview of the main events during prenatal development. Notice that instead of describing development in terms of germinal, embryonic, and fetal periods, Figure 3 divides prenatal development into equal periods of three months, called trimesters. Remember that the three trimesters are not the same as the three prenatal periods we have discussed. The germinal and embryonic periods occur in the first trimester. The fetal period begins toward the end of the first trimester and continues through the second and third trimesters. *Viability* (the chances of surviving outside the womb) begins at the end of the second trimester.

**Brain Development** One of the most remarkable aspects of the prenatal period is the development of the brain (Andescavage & others, 2017). By the time babies are born, it has been estimated that they have as many as 20 to 100 billion **neurons**, or nerve cells, which handle information processing at the cellular level in the brain. During prenatal development, neurons spend time moving to the right locations and are starting to become connected. The basic architecture of the human brain is assembled during the first two trimesters of prenatal development.

In typical development, the third trimester of prenatal development and the first two years of postnatal life are characterized by gradual increases in connectivity and functioning of neurons.

Four important phases of the brain's development during the prenatal period involve: (1) the neural tube, (2) neurogenesis, (3) neuronal migration, and (4) neural connectivity.

**Neural Tube** As the human embryo develops inside its mother's womb, the nervous system begins forming as a long, hollow tube located on the embryo's back. This pear-shaped neural tube, which forms at about 18 to 24 days after conception, develops out of the ectoderm. The tube closes at the top and bottom ends at about 27 days after conception (Keunen, Counsell, & Bender, 2017). Figure 4 shows that the nervous system still has a tubular appearance six weeks after conception.

Two birth defects related to a failure of the neural tube to close are anencephaly and spina bifida. The highest regions of the brain fail to develop when fetuses have anencephaly or when the head end of the neural tube fails to close, and these fetuses die in the womb, during childbirth, or shortly after birth (Steric & others, 2015). Spina bifida results in varying degrees of paralysis of the lower limbs (Li & others, 2018; Miller, 2017). Individuals with spina bifida usually need assistive devices such as crutches, braces, or wheelchairs (Grivell, Andersen, & Dodd, 2014). Both maternal diabetes and obesity place the fetus at risk for developing neural tube defects (Yu, Wu, & Yang, 2016). Also, one study found that maternal exposure to second-hand tobacco smoke was linked to neural tube defects (Suarez & others, 2011). Further, one study revealed that a high level of maternal stress during pregnancy was associated with neural tube defects in offspring (Li & others, 2013). A strategy that can help to prevent neural tube defects is for pregnant women to take adequate amounts of the B vitamin folic acid (Li & others, 2018; Viswanathan & others, 2017). A recent large-scale study in Brazil found that fortifying flour with folic acid significantly reduced the rate of neural tube defects (Santos & others, 2016).

**Neurogenesis** In a normal pregnancy, once the neural tube has closed, a massive proliferation of new immature neurons begins to takes place at about the fifth prenatal week and continues throughout the remainder of the prenatal period. The generation of new neurons is called *neurogenesis*, a process that continues through the remainder of the prenatal period but is largely complete by the end of the fifth month after conception (Keunen, Counsell, & Benders, 2017). At the peak of neurogenesis, it is estimated that as many as 200,000 neurons are generated every minute.

**Neuronal Migration** At approximately 6 to 24 weeks after conception, *neuronal migration* occurs. This involves cells moving outward from their point of origin to their appropriate locations and creating the different levels, structures, and regions of the brain (Keunen, Counsell, & Benders, 2017). Once a cell has migrated to its target destination, it must mature and develop a more complex structure.

**Neural Connectivity** At about the 23rd prenatal week, connections between neurons begin to occur, a process that continues postnatally (Miller, Huppi, & Mallard, 2016). We will have much more to say about the structure of neurons, their connectivity, and the development of the infant brain in the chapter on "Physical Development in Infancy."

## TERATOLOGY AND HAZARDS TO PRENATAL DEVELOPMENT

For Alex, the baby discussed at the opening of this chapter, the course of prenatal development went smoothly. His mother's womb protected him as he developed. Despite this protection, the environment can affect the embryo or fetus in many well-documented ways.

**General Principles** A **teratogen** is any agent that can potentially cause a birth defect or negatively alter cognitive and behavioral outcomes. (The word comes from the Greek word *terata*, meaning "monster.") So many teratogens exist that practically every fetus is exposed to at least some teratogens. For this reason, it is difficult to determine which teratogen causes which problem. In addition, it may take a long time for the effects of a teratogen to show up. Only about half of all potential effects appear at birth.

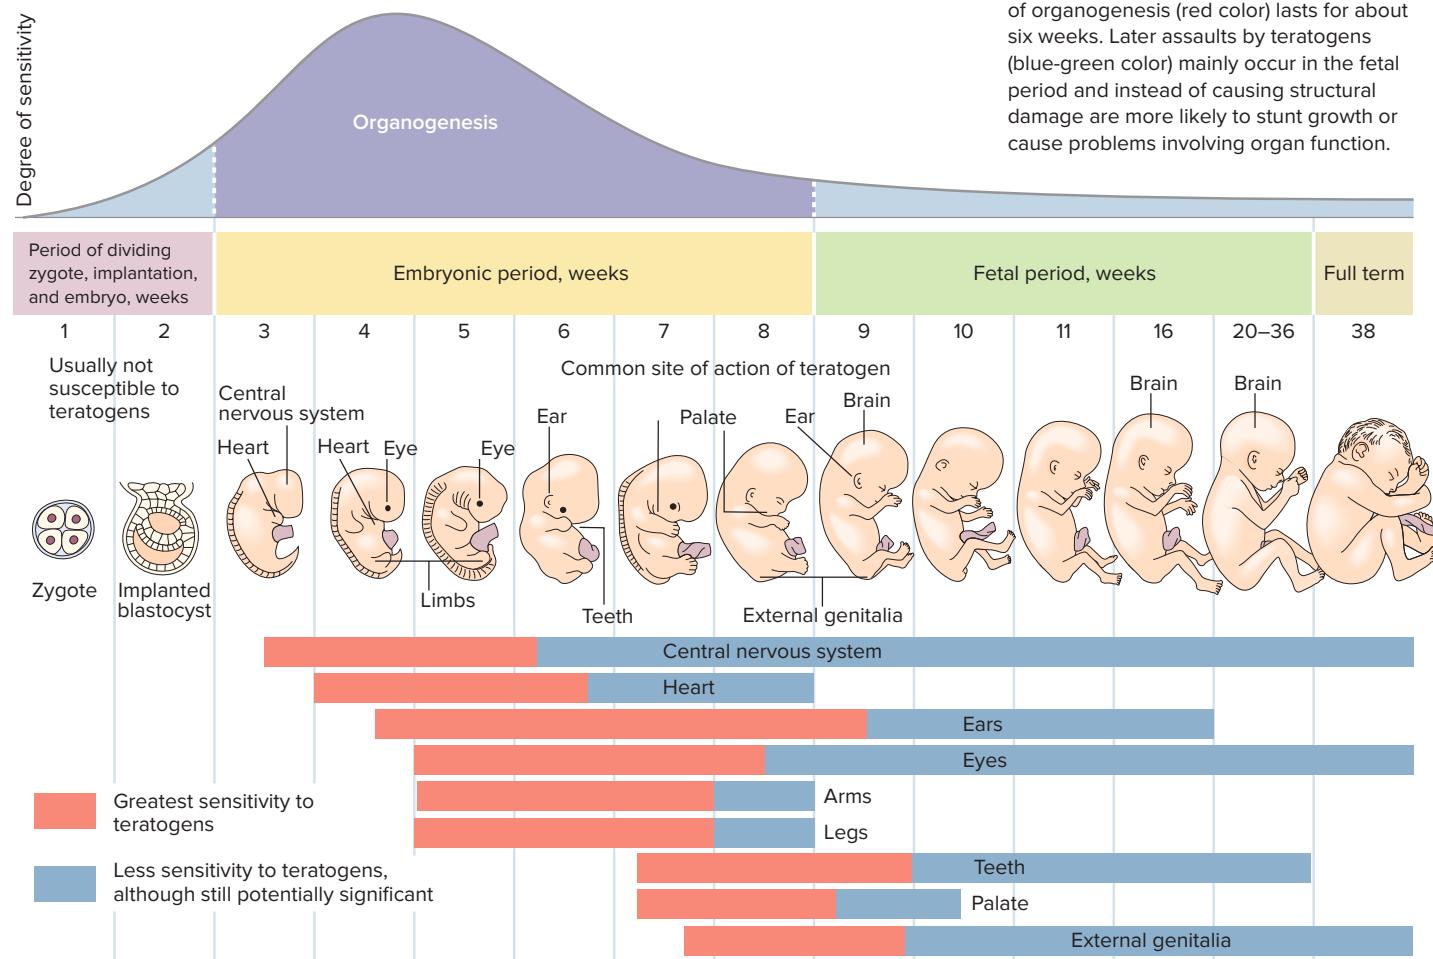

The field of study that investigates the causes of birth defects is called teratology (Boschen & others, 2018; Cassina & others, 2017). Some exposures to teratogens do not cause physical birth defects but can alter the developing brain and influence cognitive and behavioral functioning. These deficits in functioning are explored by researchers in the field of behavioral teratology.

The dose, genetic susceptibility, and the time of exposure to a particular teratogen influence both the severity of the damage to an embryo or fetus and the type of defect:

- **Dose.** The dose effect is rather obvious—the greater the dose of an agent, such as a drug, the greater the effect.
- **Genetic susceptibility.** The type or severity of abnormalities caused by a teratogen is linked to the genotype of the pregnant woman and the genotype of the embryo or fetus (Lin & others, 2017). For example, how a mother metabolizes a particular drug can influence the degree to which the drug's effects are transmitted to the embryo or fetus. The extent to which an embryo or fetus is vulnerable to a teratogen may also depend on its genotype (Middleton & others, 2017). Also, for unknown reasons, male fetuses are far more likely to be affected by teratogens than female fetuses.
- **Time of exposure.** Exposure to teratogens does more damage when it occurs at some points in development than at others (Feldkamp & others, 2017). Damage during the germinal period may even prevent implantation. In general, the embryonic period is more vulnerable than the fetal period.

Figure 5 summarizes additional information about the effects of time of exposure to a teratogen. The probability of a structural defect is greatest early in the *embryonic period*, when organs are being formed (Mazzu-Nascimento & others, 2017). Each body structure has its own critical period of formation. Recall from earlier discussions that a critical period is a fixed time period very early in development during which certain experiences or events can have a

**teratogen** From the Greek word *teras*, meaning “monster.” Any agent that causes a birth defect. The field of study that investigates the causes of birth defects is called teratology.

long-lasting effect on development. The critical period for the nervous system (week 3) is earlier than for arms and legs (weeks 4 and 5). Exposure to teratogens in the *fetal period* is more likely to cause problems in how organs function and may result in stunted growth rather than structural damage.

After organogenesis is complete, teratogens are less likely to cause anatomical defects. Instead, exposure during the fetal period is more likely to stunt growth or to create problems in the way organs function. This is especially true for the developing fetal brain, which continues to develop connections throughout pregnancy. To examine some key teratogens and their effects, let's begin with drugs.

**Prescription and Nonprescription Drugs** Many U.S. women are given prescriptions for drugs while they are pregnant—especially antibiotics, analgesics, and asthma medications. Prescription as well as nonprescription drugs, however, may have effects on the embryo or fetus that the women never imagine.

Prescription drugs that can function as teratogens include antibiotics, such as streptomycin and tetracycline; some antidepressants; certain hormones, such as progestin and synthetic estrogen; and Accutane (the trade name for isotretinoin, a form of Vitamin A that is often used to treat acne) (Brown & others, 2018; Dathe & Schaefer, 2018). Among the birth defects caused by Accutane are heart defects, eye and ear abnormalities, and brain malformation. In a recent study, isotretinoin was the fourth most common drug given to female adolescents who were seeking contraception advice from a physician (Stancil & others, 2017). However, physicians did not give the adolescent girls adequate information about the negative effects of isotretinoin on offspring if the girls were to become pregnant. In a recent review of teratogens that should never be taken during the first trimester of pregnancy, isotretinoin was on the prohibited list (Eltonsy & others, 2016).

Nonprescription drugs that can be harmful include diet pills and high dosages of aspirin (Cadavid, 2017). Research indicates that low doses of aspirin pose no harm for the fetus but that high doses can contribute to maternal and fetal bleeding (Osikoya & others, 2017).

**Psychoactive Drugs** *Psychoactive drugs* act on the nervous system to alter states of consciousness, modify perceptions, and change moods. Examples include caffeine, alcohol, and nicotine, as well as illicit drugs such as cocaine, marijuana, and heroin.

**Caffeine** People often consume caffeine when they drink coffee, tea, or cola, or when they eat chocolate. Somewhat mixed results have been found for the extent to which maternal caffeine intake influences an offspring's development (Adams, Keisberg, & Safranek, 2016; de Medeiros & others, 2017). However, a large-scale study of almost 60,000 women revealed that maternal caffeine intake was linked to lower birth weight and babies being born small for gestational age (Sengpiel & others, 2013). Also, the influence of maternal consumption of highly caffeinated energy drinks on the development of offspring has not yet been studied. The U.S. Food and Drug Administration recommends that pregnant women either not consume caffeine or consume it only sparingly.

**Alcohol** Heavy drinking by pregnant women can be devastating to their offspring (Jacobson & others, 2017). **Fetal alcohol spectrum disorders (FASD)** are a cluster of abnormalities and problems that appear in the offspring of mothers who drink alcohol heavily during pregnancy (Del Campo & Jones, 2017; Helgesson & others, 2018). The abnormalities include facial deformities and defects of the limbs and heart (Pei & others, 2017; Petrenko & Alto, 2017). Most children with FASD have learning problems and many are below average in intelligence, with some having an intellectual disability (Khoury & Milligan, 2017). Also, in a recent study in the United Kingdom, the life expectancy of individuals with FASD was only 34 years of age, about 42 percent of the average life expectancy in the general population (Thanh & Jonsson, 2016). In this study, the most common causes of death among individuals with FASD were suicide (15 percent), accidents (14 percent), and poisoning by illegal drugs or alcohol (7 percent). A recent research review concluded that FASD is linked to a lower level of executive function in children, especially in planning (Kingdon, Cardoso, & McGrath, 2016). And in a recent study, FASD was associated with both externalized and internalized behavior problems in childhood (Tsang & others, 2016). Although many mothers of FASD infants are heavy drinkers, many mothers who are heavy drinkers do not have children with FASD or have one child with FASD and other children who do not have it.

Fetal alcohol spectrum disorders (FASD) are characterized by a number of physical abnormalities and learning problems. Notice the wide-set eyes, flat cheekbones, and thin upper lip in this child with FASD.

**fetal alcohol spectrum disorders (FASD)** A cluster of abnormalities that appear in the offspring of some mothers who drink alcohol heavily during pregnancy.

What are some guidelines for alcohol use during pregnancy? Even drinking just one or two servings of beer or wine or one serving of hard liquor a few days a week can have negative effects on the fetus, although it is generally agreed that this level of alcohol use will not cause fetal alcohol syndrome (Valenzuela & others, 2012; Sarman, 2018). The U.S. Surgeon General recommends that no alcohol be consumed during pregnancy, as does the French Alcohol Society (Rolland & others, 2016). Despite such recommendations, a recent large-scale U.S. study found that 11.5 percent of adolescent and 8.7 percent of adult pregnant women reported using alcohol in the previous month (Oh & others, 2017).

However, in Great Britain, the National Institutes of Care and Health Excellence have concluded that it is safe to consume one to two drinks not more than twice a week during pregnancy (O'Keeffe, Greene, & Kearney, 2014). Nonetheless, some research suggests that it may not be wise to consume alcohol at the time of conception.

**Nicotine** Cigarette smoking by pregnant women can also adversely influence prenatal development, birth, and postnatal development (Shisler & others, 2017). Preterm births and low birth weights, fetal and neonatal deaths, respiratory problems, and sudden infant death syndrome (SIDS, also known as crib death) are all more common among the offspring of mothers who smoked during pregnancy (Zhang & others, 2017). Prenatal smoking has been implicated in as many as 25 percent of infants being born with a low birth weight (Brown & Graves, 2013).

Maternal smoking during pregnancy also has been identified as a risk factor for the development of attention deficit hyperactivity disorder in offspring (Pohlabein & others, 2017; Weissenberger & others, 2017). A recent meta-analysis of 15 studies concluded that smoking during pregnancy increased the risk that children would have ADHD, and the risk of ADHD was greater for children whose mothers were heavy smokers (Huang & others, 2018). And in a recent study, maternal cigarette smoking during pregnancy was linked to higher rates of cigarette smoking among offspring at 16 years of age (De Genna & others, 2016). Further, a recent study revealed that daughters whose mothers smoked during their pregnancy were more likely to subsequently smoke during their own pregnancy (Ncube & Mueller, 2017). Studies also indicate that environmental tobacco smoke is linked to impaired connectivity of the thalamus and prefrontal cortex in newborns (Salzwedel & others, 2016). Another study found that maternal exposure to environmental tobacco smoke during prenatal development increased the risk of stillbirth (Varner & others, 2014). Also, one study found that maternal smoking during pregnancy was associated with increased risk of asthma and wheezing in adolescence (Hollams & others, 2014).

Despite the plethora of negative outcomes for maternal smoking during pregnancy, a recent large-scale U.S. study revealed that 23 percent of adolescent and 15 percent of adult pregnant women reported using tobacco in the previous month (Oh & others, 2017). And a final point about nicotine use during pregnancy involves the recent dramatic increase in the use of e-cigarettes (Wagner, Camerota, & Propper, 2017; Tegin & others, 2018). A recent study found that misconceptions about e-cigarettes were common among pregnant women (Mark & others, 2015). Women who were using e-cigarettes during pregnancy often stated that e-cigarettes were less harmful than regular cigarettes (74 percent) and helpful in easing smoking cessation (72 percent).

**Cocaine** Does cocaine use during pregnancy harm the developing embryo and fetus? A research review concluded that cocaine quickly crosses the placenta to reach the fetus (De Giovanni & Marchetti, 2012). The most consistent finding is that cocaine exposure during prenatal development is associated with reduced birth weight, length, and head circumference (Gouin & others, 2011). Also, in other studies, prenatal cocaine exposure has been linked to impaired connectivity of the thalamus and prefrontal cortex in newborns (Salzwedel & others, 2016); impaired motor development at 2 years of age and a slower rate of growth through 10 years of age (Richardson, Goldschmidt, & Willford, 2008); self-regulation problems at age 12 (Minnes & others, 2016); elevated blood pressure at 9 years of age (Shankaran & others, 2010); impaired language development and information processing (Beeghly & others, 2006), including attention deficits (especially impulsivity) (Accornero & others, 2006; Richardson & others, 2011); learning disabilities at age 7 (Morrow & others, 2006); increased likelihood of being in a special education program that involves supportive services (Levine & others, 2008); and increased behavioral problems, especially externalizing problems such as high rates of aggression and delinquency (Minnes & others, 2010; Richardson & others, 2011).

Some researchers argue that these findings should be interpreted cautiously (Accornero & others, 2006). Why? Because other factors in the lives of pregnant women who use cocaine (such as poverty, malnutrition, and other substance abuse) often cannot be ruled out as

possible contributors to the problems found in their children (Hurt & others, 2005; Messiah & others, 2011). For example, cocaine users are more likely than nonusers to smoke cigarettes, use marijuana, drink alcohol, and take amphetamines.

Despite these cautions, the weight of research evidence indicates that children born to mothers who use cocaine are likely to have neurological, medical, and cognitive deficits (Cain, Bornick, & Whiteman, 2013; Field, 2007; Martin & others, 2016; Mayer & Zhang, 2009; Parcianello & others, 2018; Richardson & others, 2011; Scott-Goodwin, Puerto, & Moreno, 2016). Cocaine use by pregnant women is never recommended.

**Marijuana** An increasing number of studies find that marijuana use by pregnant women also has negative outcomes for offspring (Ruisch & others, 2018; Volkow, Compton, & Wargo, 2017). For example, researchers found that prenatal marijuana exposure was related to lower intelligence in children (Goldschmidt & others, 2008). Research reviews concluded that marijuana use during pregnancy alters brain functioning in the fetus (Calvignoni & others, 2014; Jaques & others, 2014). In a recent meta-analysis, marijuana use during pregnancy was linked to offsprings' low birth weight and greater likelihood of being placed in a neonatal intensive care unit (Gunn & others, 2016). One study also indicated that prenatal exposure to marijuana was linked to marijuana use at 14 years of age (Day, Goldschmidt, & Thomas, 2006). Another study discovered that marijuana use by pregnant women was associated with stillbirth (Varner & others, 2014). In sum, marijuana use is not recommended for pregnant women.

Despite increasing evidence of negative outcomes, a recent survey found that marijuana use by pregnant women increased from 2.4 percent in 2002 to 3.85 percent in 2014 (Brown & others, 2016). And there is considerable concern that marijuana use by pregnant women may increase further given the growing number of states that have legalized marijuana (Chasnoff, 2017; Hennessy, 2018).

**Heroin** It is well documented that infants whose mothers are addicted to heroin show several behavioral difficulties at birth (Angelotta & Appelbaum, 2017). The difficulties include withdrawal symptoms, such as tremors, irritability, abnormal crying, disturbed sleep, and impaired motor control. Many still show behavioral problems at their first birthday, and attention deficits may appear later in development. The most common treatment for heroin addiction, methadone, is associated with very severe withdrawal symptoms in newborns (Lai & others, 2017).

**Incompatible Blood Types** Incompatibility between the mother's and father's blood types poses another risk to prenatal development (Yogev-Lifshitz & others, 2016). Blood types are created by differences in the surface structure of red blood cells. One type of difference in the surface of red blood cells creates the familiar blood groups—A, B, O, and AB. A second difference creates what is called Rh-positive and Rh-negative blood. If a surface marker, called the Rh-factor, is present in an individual's red blood cells, the person is said to be Rh-positive; if the Rh-marker is not present, the person is said to be Rh-negative. If a pregnant woman is Rh-negative and her partner is Rh-positive, the fetus may be Rh-positive. If the fetus' blood is Rh-positive and the mother's is Rh-negative, the mother's immune system may produce antibodies that will attack the fetus. This can result in any number of problems, including miscarriage or stillbirth, anemia, jaundice, heart defects, brain damage, or death soon after birth (Fasano, 2017).

Generally, the first Rh-positive baby of an Rh-negative mother is not at risk, but with each subsequent pregnancy the risk increases. A vaccine (RhoGAM) may be given to the mother within three days of the first child's birth to prevent her body from making antibodies that will attack any future Rh-positive fetuses in subsequent pregnancies (Aitken & Tichy, 2015). Also, babies affected by Rh incompatibility can be given blood transfusions before or right after birth (Fasano, 2017).

**Environmental Hazards** Many aspects of our modern industrial world can endanger the embryo or fetus. Some specific hazards to the embryo or fetus include radiation, toxic wastes, and other chemical pollutants (Jeong & others, 2018; Sreetharan & others, 2017).

X-ray radiation can affect the developing embryo or fetus, especially in the first several weeks after conception, when women do not yet know they are pregnant. Women and their physicians should weigh the risk of an X-ray when an actual or potential pregnancy is involved (Rajaraman & others, 2011). However, a routine diagnostic X-ray of a body area other than

the abdomen, with the woman's abdomen protected by a lead apron, is generally considered safe (Brent, 2009, 2011).

Environmental pollutants and toxic wastes are also sources of danger to unborn children. Among the dangerous pollutants are carbon monoxide, mercury, and lead, as well as certain fertilizers and pesticides (Wang & others, 2017).

**Maternal Diseases** Maternal diseases and infections can produce defects in offspring by crossing the placental barrier, or they can cause damage during birth (Cuffe & others, 2017; Koren & Ornoy, 2018). Rubella (German measles) is one disease that can cause prenatal defects. A recent study found that cardiac defects, pulmonary problems, and microcephaly (a condition in which the baby's head is significantly smaller and less developed than normal) were among the most common fetal and neonatal outcomes when pregnant women have rubella (Yazigi & others, 2017). Women who plan to have children should have a blood test before they become pregnant to determine whether they are immune to the disease.

Syphilis (a sexually transmitted infection) is more damaging later in prenatal development—four months or more after conception. Damage to offspring includes stillbirth, eye lesions (which can cause blindness), skin lesions, and congenital syphilis (Braccio, Sharland, & Ladhami, 2016). Penicillin is the only known treatment for syphilis during pregnancy (Moline & Smith, 2016).

Another infection that has received widespread attention is genital herpes. Newborns contract this virus when they are delivered through the birth canal of a mother with genital herpes (Sampath, Maduro, & Schillinger, 2017). About one-third of babies delivered through an infected birth canal die; another one-fourth become brain damaged. If an active case of genital herpes is detected in a pregnant woman close to her delivery date, a cesarean section can be performed (in which the infant is delivered through an incision in the mother's abdomen) to keep the virus from infecting the newborn (Pinninti & Kimberlin, 2013).

AIDS is a sexually transmitted infection that is caused by the human immunodeficiency virus (HIV), which destroys the body's immune system (Taylor & others, 2017). A mother can infect her offspring with HIV/AIDS in three ways: (1) during gestation across the placenta, (2) during delivery through contact with maternal blood or fluids, and (3) postpartum (after birth) through breast feeding. The transmission of AIDS through breast feeding is especially problematic in many developing countries (UNICEF, 2013). Babies born to HIV-infected mothers can be (1) infected and symptomatic (show HIV symptoms), (2) infected but asymptomatic (not show HIV symptoms), or (3) not infected at all. An infant who is infected and asymptomatic may still develop HIV symptoms through 15 months of age.

The more widespread disease of diabetes, characterized by high levels of sugar in the blood, also affects offspring (Briana & others, 2018; Haertel & others, 2017; Kaseva & others, 2018). A research review indicated that newborns with physical defects are more likely to have diabetic mothers (Eriksson, 2009). Women who have gestational diabetes also may deliver very large infants (weighing 10 pounds or more), and the infants are at risk for diabetes (Alberico & others, 2014) and cardiovascular disease (Amirthraj & others, 2017). One study found that 5- to 16-year-old Mexican American children were more likely to be obese if their mothers had gestational diabetes (women who have never had diabetes before but have high blood sugar levels during pregnancy) (Page & others, 2014). Also, a recent research review concluded that pregestational diabetes increases the risk of fetal heart disease (Pauliks, 2015).

**Other Parental Factors** So far we have discussed a number of drugs, environmental hazards, maternal diseases, and incompatible blood types that can harm the embryo or fetus. Here we will explore other characteristics of the mother and father that can affect prenatal and child development, including nutrition, age, and emotional states and stress.

**Maternal Diet and Nutrition** A developing embryo or fetus depends completely on its mother for nutrition, which comes from the mother's blood (Kominiarek & Peaceman, 2017).

The greatest incidence of HIV/AIDS is in sub-Saharan Africa, where as many as 30 percent of mothers have HIV; many are unaware that they are infected with the virus. Connect to "Physical Development in Infancy."

Because the fetus depends entirely on its mother for nutrition, it is important for pregnant women to have good nutritional habits. In Kenya, this government clinic provides pregnant women with information about how their diet can influence the health of their fetus and offspring. *What might the information about diet be like?*

## developmental connection

**Conditions, Diseases, and Disorders**  
What are some key factors that influence whether individuals will become obese? Connect to “Physical and Cognitive Development in Early Adulthood.”

The nutritional status of the embryo or fetus is determined by the mother’s total caloric intake as well as her intake of proteins, vitamins, and minerals. Children born to malnourished mothers are more likely than other children to be malformed.

Maternal obesity adversely affects pregnancy outcomes through increased rates of hypertension, diabetes, respiratory complications, infections, and depression in the mother (Kumpulainen & others, 2018; Preston, Reynolds, & Pearson, 2018). A recent study revealed that at 14 weeks following conception fetuses of obese pregnant women had less efficient cardiovascular functioning (Ingul & others, 2016). An earlier study found that maternal overweight and obesity during pregnancy were associated with an increased risk of preterm birth, especially extremely preterm delivery (Cnattingius & others, 2013). Further, research indicates that maternal obesity during pregnancy is linked to cardiovascular disease and type 2 diabetes in the adolescent and adult offspring of these mothers (Agarwal & others, 2018; Slack & others, 2018). Research studies have found that maternal obesity is linked to an increase in stillbirth (Gardosi & others, 2013) and increased likelihood that the newborn will be placed in a neonatal intensive care unit (Minsart & others, 2013). Further, two recent research reviews concluded that maternal obesity during pregnancy is associated with an increased likelihood of offspring being obese in childhood and adulthood (Pinto Pereira & others, 2016; Santangeli, Sattar, & Huda, 2015). Management of obesity that includes weight loss and increased exercise prior to pregnancy is likely to benefit the mother and the baby (Dutton & others, 2018; Hanson & others, 2017). Limiting gestational weight gain to 11 to 20 pounds among pregnant women is likely to improve outcomes for the mother and the child (Simmons, 2011).

One aspect of maternal nutrition that is important for normal prenatal development is folic acid, a B-complex vitamin (Li & others, 2018; Viswanathan & others, 2017). A study of more than 34,000 women showed that taking folic acid either alone or as part of a multivitamin for at least one year prior to conceiving was linked with a 70 percent lower risk of delivering between 20 and 28 weeks and a 50 percent lower risk of delivering between 28 and 32 weeks (Bukowski & others, 2008). Also, as indicated earlier in the chapter, a lack of folic acid is related to neural tube defects in offspring, such as spina bifida (a defect in the spinal cord) (Li & others, 2018; Santos & others, 2016). And a recent research study in China found that folic acid supplementation during pregnancy reduced the risk of preterm birth (Liu & others, 2016). The U.S. Department of Health and Human Services (2018) recommends that pregnant women consume a minimum of 400 micrograms of folic acid per day (about twice the amount the average woman gets in one day). Orange juice and spinach are examples of foods rich in folic acid.

Eating fish is often recommended as part of a healthy diet, but pollution has made many fish a risky choice for pregnant women (Lipp & others, 2017). Some fish contain high levels of mercury, which is released into the air both naturally and by industrial pollution. When mercury falls into the water it can become toxic and accumulate in large fish, such as shark, swordfish, king mackerel, and some species of large tuna (American Pregnancy Association, 2018; Mayo Clinic, 2018). Mercury is easily transferred across the placenta, and the embryo’s developing brain and nervous system are highly sensitive to the metal. Researchers have found that prenatal mercury exposure is linked to adverse outcomes, including reduced placental and fetal growth, miscarriage, preterm birth, and lower intelligence (Jeong & others, 2017).

Recently, the American Pregnancy Association (2018) revised its conclusions about fish consumption during pregnancy but continued to recommend avoiding fish with a high mercury content, such as tilefish from the Gulf of Mexico, swordfish, shark, and king mackerel. The association and the FDA now recommend that pregnant women increase their consumption of fish that have a low mercury content, such as salmon, shrimp, tilapia, and cod.

**Maternal Age** When possible harmful effects on the fetus and infant are considered, two maternal age groups are of special interest: adolescents and women 35 years and older (Gockley & others, 2016; Kingsbury, Plotnikova, & Najman, 2018). The mortality rate of infants born to adolescent mothers is double that of infants born to mothers in their twenties. Adequate prenatal care decreases the probability that a child born to an adolescent girl will have physical problems. However, adolescents are the least likely of women in all age groups to obtain prenatal assistance from clinics and health services.

Maternal age is also linked to risk for adverse pregnancy outcomes. When a pregnant woman is older than 35, there is an increased risk that her child will have Down syndrome (Jaruratanasirikul & others, 2017). An individual with *Down syndrome* has distinctive facial

characteristics, short limbs, intellectual disability, and motor difficulties. A baby with Down syndrome rarely is born to a mother 16 to 34 years of age. However, when the mother reaches 40 years of age, the probability is slightly over 1 in 100 that a baby born to her will have Down syndrome, and by age 50 it is almost 1 in 10. When mothers are 35 years and older, risks also increase for low birth weight, preterm delivery, and fetal death (Koo & others, 2012; Mbugua Gitau & others, 2009). Also, in two recent studies, very advanced maternal age (40 years and older) was linked to adverse perinatal outcomes, including spontaneous abortion, preterm birth, stillbirth, and fetal growth restriction (Trairisilp & Tongsong, 2015; Waldenstrom & others, 2015).

We still have much to learn about the influence of the mother's age on risks of adverse outcomes during pregnancy and childbirth. As women remain active, exercise regularly, and are careful about their nutrition, their reproductive systems may remain healthier at older ages than was thought possible in the past.

**Emotional States and Stress** When a pregnant woman experiences intense fears, anxieties, and other emotions or negative mood states, physiological changes occur that may affect her fetus (Fatima, Srivastav, & Mondal, 2017). A mother's stress may also influence the fetus indirectly by increasing the likelihood that the mother will engage in unhealthy behaviors such as taking drugs and receiving poor prenatal care.

High maternal anxiety and stress during pregnancy can have long-term consequences for the offspring (Isgut & others, 2017; Pinto & others, 2017). One study found that high levels of depression, anxiety, and stress during pregnancy were linked to internalizing problems in adolescence (Betts & others, 2014). A research review indicated that pregnant women with high levels of stress are at increased risk for having a child with emotional or cognitive problems, attention deficit hyperactivity disorder (ADHD), and language delay (Taige & others, 2007). Maternal emotions and stress also can influence the fetus indirectly by increasing the likelihood that the mother will engage in unhealthy behaviors such as taking drugs and receiving inadequate prenatal care. Further, a recent research review concluded that regardless of the form of maternal prenatal stress or anxiety and the prenatal trimester in which the stress or anxiety occurred, during the first two years of life their offspring displayed lower levels of self-regulation (Korja & others, 2017).

Maternal depression can have an adverse effect on birth outcomes and children's development (Park & others, 2018). A research review concluded that maternal depression during pregnancy is linked to preterm birth (Mparmpakas & others, 2013), and another study linked maternal depression during pregnancy to low birth weight in full-term offspring (Chang & others, 2014). Another study revealed that maternal depression during pregnancy was related to increased risk for depression in offspring at age 18 (Pearson & others, 2013). Also, a recent study found that taking antidepressants early in pregnancy was linked to an increased risk of miscarriage (Almeida & others, 2016). In another study, when fetuses were exposed to serotonin-based antidepressants, they were more likely to be born preterm (Podrebarac & others, 2017). Further, a recent study revealed that taking antidepressants in the second or third trimesters of pregnancy was linked to an increased risk of autism spectrum disorders in children (Boukhris & others, 2016).

**Paternal Factors** So far, we have discussed how characteristics of the mother—such as drug use, disease, diet and nutrition, age, and emotional states—can influence prenatal development and the development of the child. Might there also be some paternal risk factors? Indeed, there are several (Sigman, 2017). Men's exposure to lead, radiation, certain pesticides, and petrochemicals may cause abnormalities in sperm that lead to miscarriage or to diseases such as childhood cancer (Cordier, 2008). The father's smoking during the mother's pregnancy also can cause problems for the offspring (Han & others, 2015). A recent research review concluded that tobacco smoking is linked to impaired male fertility, as well as increased DNA damage, aneuploidy (abnormal number of chromosomes in a cell), and mutations in sperm (Beal, Yauk, & Marchetti, 2017). Also, in one study, heavy paternal smoking was associated with the risk of early pregnancy loss (Venners & others, 2004). This negative outcome may be related to the effects of secondhand smoke. And in another study, paternal smoking around the time of the child's conception was linked to an increased risk of the child developing leukemia

(Milne & others, 2012). Researchers have found that increasing paternal age decreases the success rate of in vitro fertilization and increases the risk of preterm birth (Sharma & others, 2015). Also, a research review concluded that there is an increased risk of spontaneous abortion, autism, and schizophrenic disorders when the father is 40 years of age or older (Reproductive Endocrinology and Infertility Committee & others, 2012). A research study revealed that children born to fathers who were 40 years of age or older had increased risk of developing autism because of higher rates of random gene mutations in the older fathers (Kong & others, 2012). However, the age of the mother was not linked to development of autism in children.

Another way that the father can influence prenatal and birth outcomes is through his relationship with the mother. By being supportive, helping with chores, and having a positive attitude toward the pregnancy, the father can improve the physical and psychological well-being of the mother. Conversely, a conflictual relationship with the mother is likely to bring adverse outcomes (Molgora & others, 2018). For example, a recent study found that intimate partner violence increased the mother's stress level (Fonseca-Machado Mde & others, 2015).

## PREGNATAL CARE

Although prenatal care varies enormously, it usually involves a defined schedule of visits for medical care, which typically includes screening for manageable conditions and treatable diseases that can affect the baby or the mother (Flanagan & others, 2018; Goldenberg & McClure, 2018; Jarris & others, 2017; Sheeder & Weber Yorga, 2017). In addition to medical care, prenatal programs often include comprehensive educational, social, and nutritional services (Yeo, Crandell, & Jones-Vessey, 2016).

An increasing number of studies are finding that exercise either benefits the mother's health and has positive neonatal outcomes or that there are no differences in outcomes (Barakat & others, 2017; Huang & others, 2017). Exercise during pregnancy helps prevent constipation, conditions the body, reduces the likelihood of excessive weight gain, lowers the risk of developing hypertension, improves immune system functioning, and is associated with a more positive mental state, including reduced levels of stress and depression (Bacchi & others, 2017; Barakat & others, 2016; Magro-Malosso & others, 2017; Marques & others, 2015). For example, a recent study found that two weekly 70-minute yoga sessions reduced pregnant women's stress and enhanced their immune system functioning (Chen & others, 2017).

Exercise during pregnancy can also have positive benefits for offspring. For example, a recent study revealed that regular exercise by pregnant women was linked to more advanced development of the neonatal brain (Laborte-Lemoyne, Currier, & Ellenberg, 2017).

Does prenatal care matter? Information about pregnancy, labor, delivery, and caring for the newborn can be especially valuable for first-time mothers (Liu & others, 2017; Yun & others, 2014).

Prenatal care is also very important for women in poverty and immigrant women because it links them with other social services (Gabbe & others, 2018; Kim & others, 2018; Mazul, Salm Ward, & Ngu, 2017).

An innovative program that is rapidly expanding in the United States is CenteringPregnancy (Chae & others, 2017; Heberlein & others, 2016; Liu & others, 2017). This program is relationship-centered and provides complete prenatal care in a group setting. CenteringPregnancy replaces traditional 15-minute physician visits with 90-minute peer group support settings and self-examination led by a physician or certified nurse-midwife. Groups of up to 10 women (and often their partners) meet regularly beginning at 12 to 16 weeks of pregnancy. The sessions emphasize empowering women to play an active role in experiencing a positive pregnancy. One study revealed that CenteringPregnancy groups made more prenatal visits, had higher breast feeding rates, and were more satisfied with their prenatal care than women in individual care (Klima & others, 2009). In a research review, participation in CenteringPregnancy increased breast feeding

initiation by 53 percent overall and by 71 percent in African American women (Robinson, Garnier-Villarreal, & Hanson, 2018). Also, a recent study of adolescent mothers revealed that CenteringPregnancy was successful in getting participants to attend meetings, have appropriate weight gain, increase the use of highly effective contraceptive methods, and increase breast feeding (Trotman & others, 2015). And research has revealed that CenteringPregnancy group prenatal care is associated with reduced rates of preterm birth (Novick & others, 2013), as well as reduced rates of low birth weight and placement in a neonatal intensive care unit (Crockett & others, 2017; Gareau & others, 2016).

## NORMAL PREGNATAL DEVELOPMENT

Much of our discussion so far in this chapter has focused on what can go wrong with prenatal development. Prospective parents should take steps to avoid the vulnerabilities to fetal development that we have described. But it is important to keep in mind that most of the time, prenatal development does not go awry, and development occurs along the positive path that we described at the beginning of the chapter.

The increasingly popular CenteringPregnancy program alters routine prenatal care by bringing women out of exam rooms and into relationship-oriented groups.

### 2 Birth

**LG2** Describe the birth process.

The Birth Process

Assessing the Newborn

Preterm and Low Birth Weight Infants

Nature writes the basic script for how birth occurs, but parents make important choices about conditions surrounding birth. We look first at the sequence of physical stages that occur when a child is born.

## THE BIRTH PROCESS

The birth process occurs in stages, takes place in different contexts, and in most cases involves one or more attendants.

**Stages of Birth** The birth process occurs in three stages. The first stage is the longest of the three. Uterine contractions are 15 to 20 minutes apart at the beginning and last up to a minute. These contractions cause the woman's cervix to stretch and open. As the first stage

progresses, the contractions come closer together, appearing every two to five minutes. Their intensity increases. By the end of the first birth stage, contractions dilate the cervix to an opening of about 10 centimeters (4 inches), so that the baby can move from the uterus to the birth canal. For a woman having her first child, the first stage lasts an average of 6 to 12 hours; for subsequent children, this stage typically is much shorter.

The second birth stage begins when the baby's head starts to move through the cervix and the birth canal. It terminates when the baby completely emerges from the mother's body. With each contraction, the mother bears down hard to push the baby out of her body. By the time the baby's head is out of the mother's body, the contractions come almost every minute and last for about a minute. This stage typically lasts approximately 45 minutes to an hour.

**Afterbirth** is the third stage, at which time the placenta, umbilical cord, and other membranes are detached and expelled. This final stage is the shortest of the three birth stages, lasting only minutes.

**Childbirth Setting and Attendants** In 2015 in the United States, 98.5 percent of births took place in hospitals (Martin & others, 2017). Of the 1.5 percent of births occurring outside of a hospital, 63 percent took place in homes and almost 31 percent in free-standing birthing centers. The percentage of U.S. births at home is the highest since reporting of this context began in 1989. This increase in home births has occurred mainly among non-Latino White women, especially those who were older and married. For these non-Latino White women, two-thirds of their home births are attended by a midwife.

The people who help a mother during birth vary across cultures. In U.S. hospitals, it has become the norm for fathers or birth coaches to remain with the mother throughout labor and delivery. In the East African Nigoni culture, men are completely excluded from the childbirth process. When a woman is ready to give birth, female relatives move into the woman's hut and the husband leaves, taking his belongings (clothes, tools, weapons, and so on) with him. He is not permitted to return until after the baby is born. In some cultures, childbirth is an open, community affair. For example, in the Pukapukan culture in the Pacific Islands, women give birth in a shelter that is open for villagers to observe.

**Midwives** *Midwifery* is a profession that provides health care to women during pregnancy, birth, and the postpartum period (Christensen & Overgaard, 2017; Cohen, Sumersille, & Friedman, 2018; Faucher, 2018). Midwives also may give women information about reproductive health and annual gynecological examinations. They may refer women to general practitioners or obstetricians if a pregnant woman needs medical care beyond a midwife's expertise and skill.

Midwifery is practiced in most countries throughout the world (Arabi & others, 2018; Miyake & others, 2017). In Holland, more than 40 percent of babies are delivered by midwives rather than doctors. However, in the United States, recently only 8 percent of all hospital births in the United States were attended by a midwife (Martin & others, 2017). Nonetheless, the 8 percent figure represents a substantial increase from less than 1 percent in 1975. A research review concluded that for low-risk women, midwife-led care was characterized by a reduction in procedures during labor and increased satisfaction with care (Sutcliffe & others, 2012). Also, in this study no adverse outcomes were found for midwife-led care compared with physician-led care.

**Doulas** In some countries, a doula attends a childbearing woman. *Doula* is a Greek word that means "a woman who helps." A **doula** is a caregiver who provides continuous physical, emotional, and educational support for the mother before, during, and after childbirth (McLeish & Redshaw, 2018). Doulas remain with the parents throughout labor, assessing and responding to the mother's needs. Researchers have found positive effects when a doula is present at the birth of a child (Wilson & others, 2017). One study found that doula-assisted mothers were four times less likely to have a low birth weight baby and two times less likely

to have experienced a birth complication involving themselves or their baby (Gruber, Cupito, & Dobson, 2013). Another study revealed that for Medicaid recipients the odds of having a cesarean delivery were 41 percent lower for doula-supported births in the United States (Kozhimmanil & others, 2013). Thus, increasing doula-supported births could substantially lower the cost of a birth by reducing cesarean rates.

In the United States, most doulas work as independent providers hired by the expectant parents. Doulas typically function as part of a “birthing team,” serving as an adjunct to the midwife or the hospital’s obstetrical staff.

**Methods of Childbirth** U.S. hospitals often allow the mother and her obstetrician a range of options regarding the method of delivery. Key choices involve the use of medication, whether to use any of a number of nonmedicated techniques to reduce pain, and when to have a cesarean delivery.

**Medication** Three basic kinds of drugs that are used for labor are analgesia, anesthesia, and oxytocin/Pitocin.

**Analgesia** is used to relieve pain. Analgesics include tranquilizers, barbiturates, and narcotics (such as Demerol).

**Anesthesia** is used in late first-stage labor and during delivery to block sensation in an area of the body or to block consciousness. There is a trend toward not using general anesthesia, which blocks consciousness, in normal births because general anesthesia can be transmitted through the placenta to the fetus (Edwards & Jackson, 2017). An *epidural block* is regional anesthesia that numbs the woman’s body from the waist down. A research review concluded that epidural analgesia provides effective pain relief but increases the likelihood of having to use instruments during vaginal birth (Jones & others, 2012). Researchers are continuing to explore safer drug mixtures for use at lower doses to improve the effectiveness and safety of epidural anesthesia (Kobayashi & others, 2017; Wilson & others, 2018).

**Oxytocin** is a hormone that promotes uterine contractions; a synthetic form called Pitocin® is widely used to decrease the duration of the first stage of labor. The relative benefits and risks of administering synthetic forms of oxytocin during childbirth continue to be debated (Carlson, Corwin, & Lowe, 2017).

Predicting how a drug will affect an individual woman and her fetus is difficult (Ansari & others, 2016). A particular drug might have only a minimal effect on one fetus yet have a much stronger effect on another. The drug’s dosage also is a factor (Rankin, 2017). Stronger doses of tranquilizers and narcotics given to decrease the mother’s pain potentially have a more negative effect on the fetus than mild doses. It is important for the mother to assess her level of pain and have a voice in deciding whether she receives medication.

**Natural and Prepared Childbirth** For a brief time not long ago, the idea of avoiding all medication during childbirth gained favor in the United States. Instead, many women chose to reduce the pain of childbirth through techniques known as natural childbirth and prepared childbirth. Today, at least some medication is used in the typical childbirth, but elements of natural childbirth and prepared childbirth remain popular (Skowronski, 2015).

**Natural childbirth** is the method that aims to reduce the mother’s pain by decreasing her fear by providing information about childbirth and teaching her and her partner to use breathing methods and relaxation techniques during delivery (Bacon & Tomich, 2017; London & others, 2017). One type of natural childbirth that is used today is the *Bradley Method*, which involves husbands as coaches, relaxation for easier birth, and prenatal nutrition and exercise.

French obstetrician Ferdinand Lamaze developed a method similar to natural childbirth that is known as **prepared childbirth**, or the Lamaze method. It includes a special breathing technique to control pushing in the final stages of labor, as well as more detailed education about anatomy and physiology. The Lamaze method has become very popular in the United States (Podgurski, 2016). The pregnant woman’s partner usually serves as a coach who attends childbirth classes with her and helps with her breathing and relaxation during delivery.

**natural childbirth** This method of childbirth attempts to reduce the mother’s pain by decreasing her fear through information about childbirth and instruction in relaxation techniques to reduce pain during delivery.

**prepared childbirth** Developed by French obstetrician Ferdinand Lamaze, this childbirth strategy is similar to natural childbirth but includes a special breathing technique to control pushing in the final stages of labor and a more detailed anatomy and physiology course.

### Linda Pugh, Perinatal Nurse

Perinatal nurses work with childbearing women to support health and growth during the childbearing experience. Linda Pugh, Ph.D., R.N.C., is a perinatal nurse on the faculty at The Johns Hopkins University School of Nursing. She is certified as an inpatient obstetric nurse and specializes in the care of women during labor and delivery. She teaches undergraduate and graduate students, educates professional nurses, and conducts research. In addition, Pugh consults with hospitals and organizations about women's health issues and topics we discuss in this chapter. Her research interests include nursing interventions with low-income breast-feeding women, ways to prevent and ameliorate fatigue during childbearing, and the use of breathing exercises during labor.

In sum, proponents of current natural and prepared childbirth methods conclude that when information and support are provided, women know how to give birth. To read about one nurse whose research focuses on fatigue during childbearing and breathing exercises during labor, see the *Connecting with Careers* profile. And to read about the wide variety of techniques now being used to reduce stress and control pain during labor, see *Connecting Development to Life*.

**Cesarean Delivery** In a **cesarean delivery**, the baby is removed from the mother's uterus through an incision made in her abdomen. Cesarean deliveries are performed if the baby is lying crosswise in the uterus, if the baby's head is too large to pass through the mother's pelvis, if the baby develops complications, or if the mother is bleeding vaginally. Because of increased rates of respiratory complications, elective cesarean delivery is not recommended prior to 39 weeks of gestation unless there is an indication of fetal lung maturity (Greene, 2009). The benefits and risks of cesarean deliveries continue to be debated in the United States and around the world (Kupari & others, 2016; Ladewig, London, & Davidson, 2017). Some critics believe that too many babies are delivered by cesarean section in the United States (Blakey, 2011). The World Health Organization states that a country's cesarean section rate should be 10 percent or less. The U.S. cesarean birth rate in 2015 was 32 percent, the lowest rate since 2007 (Martin & others, 2017). The highest cesarean rates are in the Dominican Republic and Brazil (56 percent); the lowest in New Zealand and the Czech Republic (26 percent) (McCullough, 2016).

What are some of the specific reasons why physicians do a cesarean delivery? The most common reasons are failure to progress through labor (hindered by epidurals, for example) and fetal distress. Normally, the baby's head comes through the vagina first. But if the baby is in a **breech position**, the baby's buttocks are the first part to emerge from the vagina. In 1 of every 25 deliveries, the baby's head is still in the uterus when the rest of the body is out. Breech births can cause respiratory problems. As a result, if the baby is in a breech position, a cesarean delivery is usually performed (Glavind & Uldbjerg, 2015).

**cesarean delivery** Surgical procedure in which the baby is removed from the mother's uterus through an incision made in her abdomen.

**breech position** The baby's position in the uterus that causes the buttocks to be the first part to emerge from the vagina.

**Apgar Scale** A widely used method of assessing the health of newborns at one and five minutes after birth. The Apgar Scale evaluates an infant's heart rate, respiratory effort, muscle tone, body color, and reflex irritability.

## ASSESSING THE NEWBORN

Almost immediately after birth, after the baby and its parents have been introduced, a newborn is taken to be weighed, cleaned up, and tested for signs of developmental problems that might require urgent attention. The **Apgar Scale** is widely used to assess the health of newborns at one and five minutes after birth. The Apgar Scale evaluates an infant's heart rate, respiratory effort, muscle tone, body color, and reflex irritability. An obstetrician or a nurse does the evaluation and gives the newborn a score, or reading, of 0, 1, or 2 on each of these five health signs (see Figure 6). A total score of 7 to 10 indicates that the newborn's condition is good. A score of 5 indicates there may be developmental difficulties. A score of 3 or below signals an emergency and indicates that the baby might not survive.

## From Waterbirth to Music Therapy

The effort to reduce stress and control pain during labor has recently led to an increased use of older and newer nonmedicated techniques (Bindler & others, 2017; Cooper, Warland, & McCutcheon, 2018; Lewis & others, 2018a, b). These include waterbirth, massage, acupuncture, hypnosis, and music therapy.

### Waterbirth

Waterbirth involves giving birth in a tub of warm water. Some women go through labor in the water and get out for delivery; others remain in the water for delivery. The rationale for waterbirth is that the baby has been in an amniotic sac for many months and that delivery in a similar environment is likely to be less stressful for the baby and the mother (Kavosi & others, 2015). Mothers get into the warm water when contractions become closer together and more intense. Getting into the water too soon can cause labor to slow or stop. An increasing number of studies either show no differences in neonatal and maternal outcomes for waterbirth and non-waterbirth deliveries or positive outcomes for waterbirth (Davies & others, 2015; Taylor & others, 2016). For example, in a recent Swedish study, women who gave birth in water had a lower risk of vaginal tears, made quicker progress through the second stage of labor, needed fewer drugs for pain relief and interventions for medical problems, and rated their birth experience more positively than women who had conventional spontaneous vaginal births (Ulfsdottir, Saltvedt, & Georgsson, 2018). Waterbirth has been practiced more often in European countries such as Switzerland and Sweden in recent decades than in the United States but is increasingly being included in U.S. birth plans.

### Massage

Massage is increasingly used prior to and during delivery (Frawley & others, 2016; Withers, Kharazmi, & Lim, 2018). Researchers have found that massage therapy reduces pain during labor (Gallo & others, 2018; Jones & others, 2012; Shahoei & others, 2017). For example, a recent study found that lower back massage reduced women's labor pain and increased their satisfaction with the birth experience (Unalmis Erdogan, Yanikkerem, & Goker, 2018).

### Acupuncture

Acupuncture, the insertion of very fine needles into specific locations in the body, is used as a standard procedure to reduce the pain of childbirth in China, although it only recently has begun to be used in the United States for this purpose (Jo & Lee, 2018; Mollart & others,

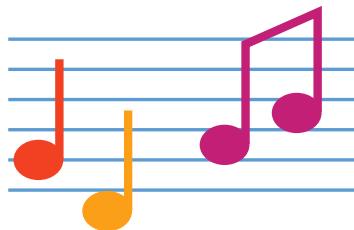

*What characterizes the use of waterbirth in delivering a baby?*

2018). Recent research indicates that acupuncture can have positive effects on labor and delivery (Akbarzadeh & others, 2015; Smith, Armour, & Ee, 2016). For example, in a recent study acupuncture was successful in reducing labor pain 30 minutes after the intervention (Allameh, Tehrani, & Ghasemi, 2015).

### Hypnosis

Hypnosis, the induction of a psychological state of altered attention and awareness in which the individual is unusually responsive to suggestions, is also increasingly being used during childbirth (Howell, 2014; Mollart & others, 2018). Some studies have indicated positive effects of hypnosis for reducing pain during childbirth (Madden & others, 2016; McAllister & others, 2017).

### Music Therapy

Music therapy during childbirth, which involves the use of music to reduce stress and manage pain, is becoming more common (Dehcheshmeh & Rafiel, 2015). More research is needed to determine its effectiveness (Laopaiboon & others, 2009).

*What are some reasons that natural childbirth methods such as these might be chosen instead of medication?*

The Apgar Scale is especially good at assessing the newborn's ability to cope with the stress of delivery and the demands of a new environment (London & others, 2017). It also identifies high-risk infants who need resuscitation. One study revealed that compared with children who have

### Brazelton Neonatal Behavioral Assessment Scale (NBAS)

**Scale (NBAS)** A measure that is used in the first month of life to assess the newborn's neurological development, reflexes, and reactions to people and objects.

### Neonatal Intensive Care Unit Network Neurobehavioral Scale (NNNS)

**An “offspring” of the NBAS,** the NNNS provides an assessment of the newborn's behavior, neurological and stress responses, and regulatory capacities (Aubuchon-Endsley & others, 2017; Spittle & others, 2017). The NBAS is especially designed to assess at-risk infants.

**low birth weight infants** An infant that weighs less than 5 pounds 8 ounces at birth.

**preterm infants** Those born before the completion of 37 weeks of gestation (the time between fertilization and birth).

**small for date infants** Also called small for gestational age infants, these infants' birth weights are below normal when the length of pregnancy is considered. Small for date infants may be preterm or full term.

a high Apgar score (9 to 10), the risk of developing attention deficit hyperactivity disorder (ADHD) in childhood was 75 percent higher for newborns with a low Apgar score (1 to 4) and 63 percent higher for newborns with an Apgar score of 5 to 6 (Li, Olsen, & others, 2011). Recent studies have found that low Apgar scores are associated with long-term needs for additional support in education and decreased educational attainment (Tweed & others, 2016), increased risk of developmental vulnerability at 5 years of age (Razaz & others, 2016), and increased risk for developing ADHD (Hanc & others, 2016).

Another assessment of the newborn is the **Brazelton Neonatal Behavioral Assessment Scale (NBAS)**, which is typically performed within 24 to 36 hours after birth. It is also used as a sensitive index of *neurological competence* up to one month after birth for typical infants and as a measure in many studies of infant development (Braithwaite & others, 2017). The NBAS assesses the newborn's neurological development, reflexes, and reactions to people and objects.

The NBAS is designed to assess normal, healthy, full-term infants. An “offspring” of the NBAS, the **Neonatal Intensive Care Unit Network Neurobehavioral Scale (NNNS)** provides another assessment of the newborn's behavior, neurological and stress responses, and regulatory capacities (Aubuchon-Endsley & others, 2017; Spittle & others, 2017). The NBAS is especially designed to assess at-risk infants.

## PRETERM AND LOW BIRTH WEIGHT INFANTS

Various conditions that pose threats for newborns have been given different labels. We will examine these conditions and discuss interventions for improving outcomes of preterm infants.

**Preterm and Small for Date Infants** Three related conditions pose threats to many newborns: low birth weight, being born preterm, and being small for date:

- **Low birth weight infants** weigh less than 5 pounds 8 ounces at birth. *Very low birth weight* newborns weigh less than 3 pounds 4 ounces, and *extremely low birth weight* newborns weigh less than 2 pounds.
- **Preterm infants** are those born three weeks or more before the pregnancy has reached its full term—in other words, before the completion of 37 weeks of gestation (the time between fertilization and birth).
- **Small for date infants** (also called *small for gestational age infants*) are those whose birth weight is below normal when the length of the pregnancy is considered. They weigh less than 90 percent of all babies of the same gestational age. Small for date infants may be preterm or full term. One study found that small for date infants had more than a fourfold increased risk of death (Regev & others, 2003).

In 2015, 9.6 percent of babies born in the United States were born preterm (Martin & others, 2017). The preterm birth rate was 8.8 percent for non-Latino White infants, down from 11.4 percent in 2011 (Martin & others, 2017). In 2015, the preterm birth rate was 13.4 percent for African American infants (down from 16.7 percent in 2011) and 9.1 percent for Latino infants (down from 11.6 percent in 2011) (Martin & others, 2017).

Recently, considerable attention has been directed to the role that progestin (a synthetic hormone similar to progesterone) might play in reducing preterm births (Awwad & others, 2015; Iams & others, 2018). One study found that progestin treatment was associated with a decrease in preterm birth for women with a history of one or more spontaneous births (Markham & others, 2014). Increasing use of progestin and decreasing rates of smoking are among the factors that likely account for the recent decrease in preterm births (Schoen & others, 2015).

Might exercise during pregnancy reduce the likelihood of preterm birth? One study found that compared with sedentary pregnant women, women who engaged in light leisure time physical activity had a 24 percent reduced likelihood of preterm delivery and those who participated in moderate to heavy leisure time physical activity had a 66 percent reduced risk of preterm delivery (Hegaard & others, 2008).

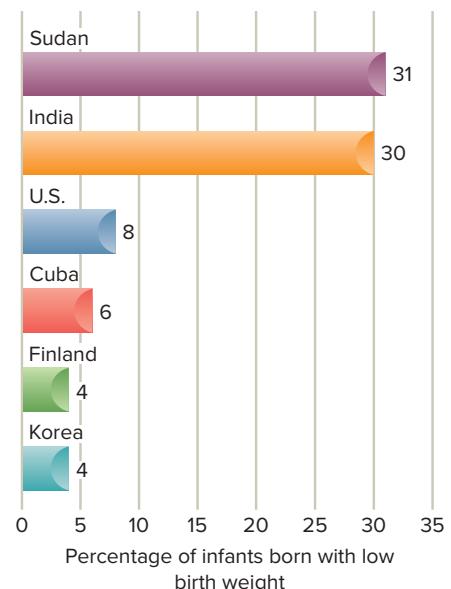

The incidence of low birth weight varies considerably from country to country. In some countries, such as India and Sudan, where poverty is rampant and the health and nutrition of mothers are poor, the percentage of low birth weight babies reaches as high as 31 percent (see Figure 7). In the United States, there has been an increase in low birth weight infants in the last two decades, and the U.S. low birth weight rate of 9.6 percent in 2015 is considerably higher than that of many other developed countries (Martin & others, 2017). For example, only 4 percent of the infants born in Sweden, Finland, Norway, and South Korea are low birth weight, and only 5 percent of those born in New Zealand, Australia, and France are low birth weight.

In both developed and developing countries, adolescents who give birth when their bodies have not fully matured are at risk for having low birth weight babies (Bird & others, 2017; Kirbas, Gulerman, & Daglar, 2016). In the United States, the increase in the number of low birth weight infants is due to factors such as drug use, poor nutrition, multiple births, reproductive technologies, and improved technology and prenatal care that result in more high-risk babies surviving (National Center for Health Statistics, 2012; Pereira & others, 2017). Poverty also continues to be a major factor in preterm births in the United States (Huynh & others, 2017; Wallace & others, 2016). Women living in poverty are more likely to be obese, have diabetes and hypertension, and to smoke cigarettes and use illicit drugs, and less likely to receive regular prenatal care (Timmermans & others, 2011).

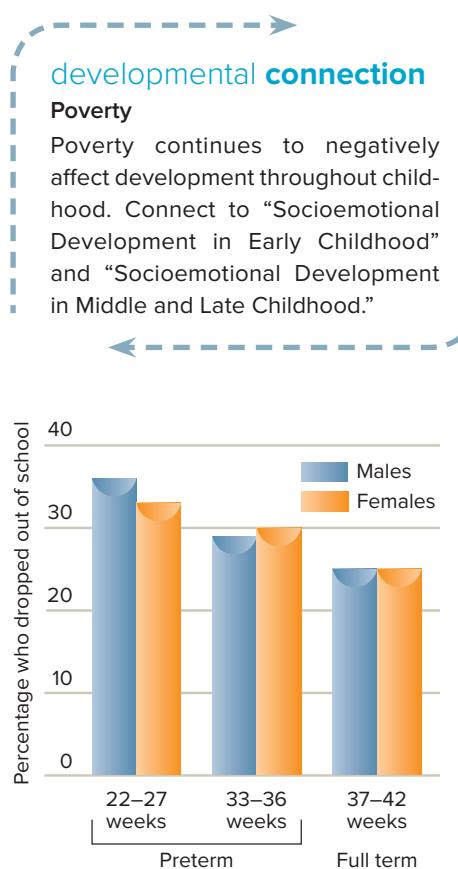

**Consequences of Preterm Birth and Low Birth Weight** Although most preterm and low birth weight infants are healthy, as a group they have more health problems and developmental delays than normal birth weight infants (George & others, 2018; London & others, 2017). For preterm birth, the terms *extremely preterm* and *very preterm* are increasingly used (Ohlin & others, 2015). *Extremely preterm infants* are those born at less than 28 weeks gestation, and *very preterm infants* are those born at less than 33 weeks of gestational age. Figure 8 shows the results of a Norwegian study indicating that the earlier preterm infants are born, the more likely they are to drop out of school (Swamy, Ostbye, & Skjaerven, 2008).

The number and severity of health problems increase when infants are born very early and as their birth weight decreases (Linsell & others, 2017; Pascal & others, 2018). Survival rates for infants who are born very early and very small have risen, but with this improved survival rate have come an increased rate of severe brain damage (Rogers & Hintz, 2018) and lower level of executive function, especially in working memory and planning (Burnett & others, 2018).

One study revealed that very preterm, low birth weight infants had abnormal axon development in their brains and impaired cognitive development at 9 years of age (Iwata & others, 2012). Children born low in birth weight are more likely than their normal birth weight counterparts to develop a learning disability, attention deficit hyperactivity disorder, autism spectrum disorders, or breathing problems such as asthma (Brinskma & others, 2017; Ng & others, 2017). Approximately 50 percent of all low birth weight children are enrolled in special education programs.

**kangaroo care** Treatment for preterm infants that involves skin-to-skin contact.

**Nurturing Low Birth Weight and Preterm Infants** Two increasingly used interventions in the neonatal intensive care unit (NICU) are kangaroo care and massage therapy. **Kangaroo care** involves skin-to-skin contact in which the baby, wearing only a diaper, is held upright against the parent’s bare chest, much as a baby kangaroo is carried by its mother (Raajashri & others, 2018; Stockwell, 2017). Kangaroo care is typically practiced for two to three hours per day, skin-to-skin over an extended time in early infancy.

Why use kangaroo care with preterm infants? Preterm infants often have difficulty coordinating their breathing and heart rate, and the close physical contact with the parent provided by kangaroo care can help to stabilize the preterm infant’s heartbeat, temperature, and breathing (Boundy & others, 2017; Furman, 2017). Preterm infants who experience kangaroo care gain more weight than their counterparts who are not given this care (Sharma, Murki, & Oleti, 2018). Recent research also revealed that kangaroo care decreased pain in newborns (Johnston & others, 2017; Mooney-Leber & Brummelte, 2017). Further, a research review concluded that kangaroo care decreased the risk of mortality in low birth weight infants (Conde-Aguedelo, Belizan, & Diaz-Rosello, 2014).

Also, a research study demonstrated the positive long-term benefits of kangaroo care (Feldman, Rosenthal, & Eidelman, 2014). In this study, maternal-newborn kangaroo care with preterm infants was linked to better respiratory and cardiovascular functioning, sleep patterns, and cognitive functioning from 6 months to 10 years of age. Further, in a longitudinal study, the nurturing positive effects of kangaroo care with preterm and low birth weight infants that were initially found for intelligence and home environment at one year of age were still positive 20 years later in emerging adults’ reduced school absenteeism, reduced hyperactivity, lower aggressiveness, and social skills (Charpak & others, 2017).

A survey conducted in the United States found that mothers were much more likely to have a positive view of kangaroo care and to believe it should be provided daily than were neonatal intensive care nurses (Hendricks-Munoz & others, 2013). There is concern that kangaroo care is not used as often as it could be used in neonatal intensive care units (Smith & others, 2017). Increasingly, kangaroo care is recommended as standard practice for all newborns (Johnston & others, 2017).

Many adults will attest to the therapeutic effects of receiving a massage. In fact, many will pay a premium to receive one at a spa on a regular basis. But can massage play a role in improving the developmental outcomes for preterm infants? A study found that both kangaroo care and massage therapy were equally effective in improving body weight and reducing length of hospital stay for low birth weight infants (Rangey & Sheth, 2014). In another recent study, massage therapy improved the scores of HIV-exposed infants on both physical and mental scales, while also improving their hearing and speech (Perez & others, 2015). ## How Does Massage Therapy Affect the Mood and Behavior of Babies?

Throughout history and in many cultures, caregivers have massaged infants. In Africa and Asia, infants are routinely massaged by parents or other family members for several months after birth. In the United States, interest in using touch and massage to improve the growth, health, and well-being of infants has been stimulated by the research of Tiffany Field, director of the Touch Research Institute at the University of Miami School of Medicine (Field, 2001, 2007, 2010b, 2017; Diego, Field, & Hernandez-Reif, 2008, 2014; Field, Diego, & Hernandez-Reif, 2008, 2010; Field & others, 2006).

In one study, preterm infants in a neonatal intensive care unit (NICU) were randomly assigned to a massage therapy group or a control group (Hernandez-Reif, Diego, & Field, 2007). For five consecutive days, the preterm infants in the massage group were given three 15-minute moderate-pressure massages. Behavioral observations of the following stress behaviors were made on the first and last days of the study: crying, grimacing, yawning, sneezing, jerky arm and leg movements, startles, and finger flaring. The various stress behaviors were summarized in a composite stress behavior

index. As indicated in Figure 9, massage had a stress-reducing effect on the preterm infants, which is especially important because they encounter numerous stressors while they are hospitalized.

In a research review of massage therapy with preterm infants, Field and her colleagues (Field, Hernandez-Reif, & Freedman, 2004) concluded that the most consistent findings involve two positive results: (1) increased weight gain and (2) discharge from the hospital from three to six days earlier.

Infants are not the only ones who may benefit from massage therapy (Field, 2017). In other studies, Field and her colleagues have demonstrated the benefits of massage therapy with women in reducing labor pain (Field, Hernandez-Reif, Taylor, & others, 1997), with children who have asthma (Field, Henteleff, & others, 1998), with autistic children's attentiveness (Field, Lasko, & others, 1997), and with adolescents who have attention deficit hyperactivity disorder (Field, Quintino, & others, 1998).

## 3 The Postpartum Period

LG3

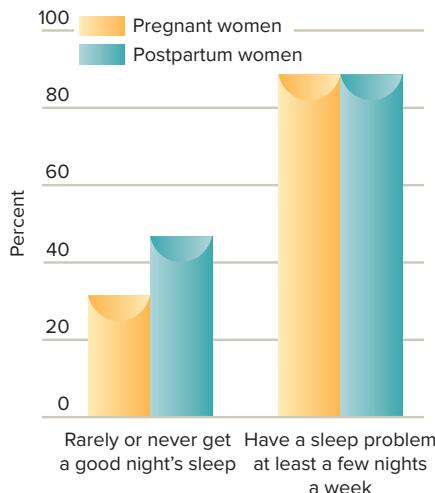

Explain the changes that take place in the postpartum period.

Physical Adjustments

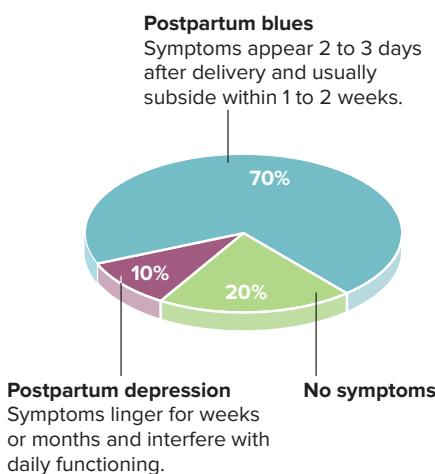

Emotional and Psychological Adjustments

Bonding

The weeks after childbirth present challenges for many new parents and their offspring. This is the **postpartum period**, the period after childbirth or delivery that lasts for about six weeks or until the mother's body has completed its adjustment and has returned to a nearly

**FIGURE 10**  
**SLEEP DEPRIVATION IN PREGNANT AND POSTPARTUM WOMEN**

**FIGURE 11**  
**POSTPARTUM BLUES AND POSTPARTUM DEPRESSION AMONG U.S. WOMEN**

**U.S. WOMEN.** Some health professionals refer to the postpartum period as the “fourth trimester.” Though the time span of the postpartum period does not necessarily cover three months, the term “fourth trimester” suggests the continuity and the importance of the first several months after birth for the mother and baby.

**postpartum period** The period after childbirth when the mother adjusts, both physically and psychologically, to the process of childbirth. This period lasts for about six weeks or until her body has completed its adjustment and returned to a near prepregnant state.

**postpartum depression** A condition experienced by women who have such strong feelings of sadness, anxiety, or despair that they have trouble coping with daily tasks during the postpartum period.

pregnant state. It is a time when the woman adjusts, both physically and psychologically, to the process of childbearing.

The postpartum period involves a great deal of adjustment and adaptation (Doering & others, 2017). The adjustments needed are physical, emotional, and psychological.

## PHYSICAL ADJUSTMENTS

A woman’s body makes numerous physical adjustments in the first days and weeks after childbirth (Neiterman & Fox, 2018). She may have a great deal of energy or feel exhausted and let down. Though these changes are normal, the fatigue can undermine the new mother’s sense of well-being and confidence in her ability to cope with a new baby and a new family life (Doering, Sims, & Miller, 2017).

A concern is the loss of sleep that the primary caregiver experiences in the postpartum period (McBean, Kinsey, & Montgomery-Downs, 2016). In the 2007 Sleep in America survey, a substantial percentage of women reported loss of sleep during pregnancy and in the postpartum period (National Sleep Foundation, 2007) (see Figure 10). The loss of sleep can contribute to stress, marital conflict, and impaired decision making (Meerlo, Sgoifo, & Suchecki, 2008). In a recent study, worsening or minimal improvement in sleep problems from 6 weeks to 7 months postpartum were associated with an increase in depressive symptoms (Lewis & others, 2018).

After delivery, a mother’s body undergoes sudden and dramatic changes in hormone production. When the placenta is delivered, estrogen and progesterone levels drop steeply and remain low until the ovaries start producing hormones again.

## EMOTIONAL AND PSYCHOLOGICAL ADJUSTMENTS

Emotional fluctuations are common for mothers in the postpartum period. For some women, emotional fluctuations decrease within several weeks after the delivery, but other women experience more long-lasting emotional swings (O’Hara & Engeldinger, 2018; Pawluski, Lonstein, & Fleming, 2017).

As shown in Figure 11, about 70 percent of new mothers in the United States have what are called the postpartum blues. About two to three days after birth, they begin to feel depressed, anxious, and upset. These feelings may come and go for several months after the birth, often peaking about three to five days after birth. Even without treatment, these feelings usually go away after one or two weeks.

However, some women develop **postpartum depression**, which involves a major depressive episode that typically occurs about four weeks after delivery. Women with postpartum depression have such strong feelings of sadness, anxiety, or despair that for at least a two-week period they have trouble coping with their daily tasks. Without treatment, postpartum depression may become worse and last for many months (Di Florio & others, 2014). And many women with postpartum depression don’t seek help. For example, one study found that 15 percent of the women surveyed had postpartum depression symptoms but less than half had sought help (McGarry & others, 2009). Estimates indicate that 10 to 14 percent of new mothers experience postpartum depression.

A research review concluded that the following are risk factors for developing postpartum depression: a history of depression, depression and anxiety during pregnancy, neuroticism, low self-esteem, postpartum blues, poor marital relationship, and a low level of social support (O’Hara & McCabe, 2013). And another recent study revealed that women who had a history of depression were 20 times more likely to develop postpartum depression than women who had no history of depression (Silverman & others, 2017).

Several antidepressant drugs are effective in treating postpartum depression and appear to be safe for breast-feeding women (Howard, Mehta, & Powrie, 2017; Latendresse, Elmore, & Deneris, 2017). Psychotherapy, especially cognitive therapy, is effective in easing postpartum depression for many women (Dennis, 2017; O’Hara & Engeldinger, 2018). Also, engaging in regular exercise may help in treating postpartum depression (Gobinath & others, 2018; McCurdy & others, 2017). For example, a recent meta-analysis concluded that physical exercise

### Diane Sanford, Clinical Psychologist and Postpartum Expert

Diane Sanford has a doctorate in clinical psychology, and for many years she had a private practice that focused on marital and family relationships. But after she began collaborating with a psychiatrist whose clients included women with postpartum depression, Dr. Sanford, along with a women's health nurse, founded Women's Healthcare Partnership in St. Louis, Missouri, which specialized in women's adjustment during the postpartum period. Sanford (with Ann Dunnewold) authored *Life Will Never Be the Same: The Real Mom's Postpartum Survival Guide*. She also is a medical expert for BabyCenter.com.

during the postpartum period is a safe strategy to reduce postpartum depressive symptoms (Poyatos-Leon & others, 2017).

A mother's postpartum depression can affect the way she interacts with her infant (Kleinman & Reizer, 2018). A research review concluded that the interaction difficulties of depressed mothers and their infants occur across cultures and socioeconomic status groups, and encompass less sensitivity of the mothers and less responsiveness on the part of their infants (Field, 2010a). Several caregiving activities also are compromised, including feeding (especially breast feeding), sleep routines, and safety practices. In a recent study, postpartum depression was associated with an increase in 4-month-old infants' unintentional injuries (Yamaoka, Fujiwara, & Tamiya, 2016). Further, a recent study revealed that mothers' postpartum depression, but not generalized anxiety, were linked to their children's emotional negativity and behavior problems at 2 years of age (Prenoveau & others, 2017). To read about one individual who specializes in women's adjustment during the postpartum period, see *Connecting with Careers*.

Fathers also undergo considerable adjustment in the postpartum period, even when they work away from home all day (Shorey & others, 2017; Takehara & others, 2017). When the mother develops postpartum depression, many fathers also experience feelings of depression (Cameron & others, 2017; Sundstrom Poromaa & others, 2017). Many fathers feel that the baby comes first and gets all of the mother's attention; some feel that they have been replaced by the baby. A recent study found that 5 percent of fathers had depressive symptoms in the first two weeks following delivery (Anding & others, 2016).

The father's support and caring can play a role in whether the mother develops postpartum depression (Kumar, Oliffe, & Kelly, 2018). One study revealed that higher support by fathers was related to a lower incidence of postpartum depression in women (Smith & Howard, 2008). Also, a recent study found that depressive symptoms in both the mother and father were associated with impaired bonding with their infant during the postpartum period (Kerstis & others, 2016).

The postpartum period is a time of considerable adjustment and adaptation for both the mother and the father. mother to make her delivery less painful can make the mother drowsy, interfering with her ability to respond to and stimulate the newborn. Mothers and newborns are often separated shortly after delivery, and preterm infants are isolated from their mothers even more than full-term infants.

Do these practices do any harm? Some physicians believe that during the period shortly after birth, the parents and newborn need to form an emotional attachment as a foundation for optimal development in years to come (Kennell, 2006; Kennell & McGrath, 1999). Is there evidence that close contact between mothers and babies in the first several days after birth is critical for optimal development later in life? Although some research supports this bonding hypothesis (Klaus & Kennell, 1976), a body of research challenges the significance of the first few days of life as a critical period (Bakeman & Brown, 1980; Rode & others, 1981). Indeed, the extreme form of the bonding hypothesis—that the newborn must have close contact with the mother in the first few days of life to develop optimally—simply is not true.

Nonetheless, the weakness of the bonding hypothesis should not be used as an excuse to keep motivated mothers from interacting with their newborns. Such contact brings pleasure to many mothers. In some mother-infant pairs—including preterm infants, adolescent mothers, and mothers from disadvantaged circumstances—early close contact may establish a climate for improved interaction after the mother and infant leave the hospital.

Many hospitals now offer a *rooming-in* arrangement, in which the baby remains in the mother’s room most of the time during its hospital stay. However, if parents choose not to use this rooming-in arrangement, the weight of the research suggests that this decision will not harm the infant emotionally (Lamb, 1994).

Normal Prenatal Development

**LG1** Describe prenatal development.

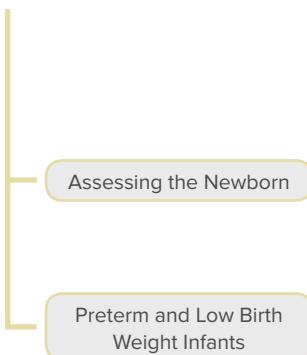

- Prenatal development is divided into three periods: germinal (conception until 10 to 14 days later), which ends when the zygote (a fertilized egg) attaches to the uterine wall; embryonic (two to eight weeks after conception), during which the embryo differentiates into three layers, life-support systems develop, and organ systems form (organogenesis); and fetal (from two months after conception until about nine months, or when the infant is born), a time when organ systems have matured to the point at which life can be sustained outside the womb.
- The growth of the brain during prenatal development is nothing short of remarkable. By the time babies are born, they have approximately 100 billion neurons, or nerve cells. Neurogenesis is the term for the formation of new neurons. The nervous system begins with the formation of a neural tube at 18 to 24 days after conception. Proliferation and migration are two processes that characterize brain development in the prenatal period. The basic architecture of the brain is formed in the first two trimesters of prenatal development.
- Teratology is the field of study that investigates the causes of congenital (birth) defects. Any agent that causes birth defects is called a teratogen. The dose, genetic susceptibility, and time of exposure influence the severity of the damage to an unborn child and the type of defect that occurs.
- Prescription drugs that can be harmful include antibiotics. Nonprescription drugs that can be harmful include diet pills, aspirin, and caffeine. Legal psychoactive drugs that are potentially harmful to prenatal development include alcohol and nicotine.
- Fetal alcohol spectrum disorders are a cluster of abnormalities that appear in offspring of mothers who drink heavily during pregnancy. Even when pregnant women drink moderately (one to two drinks a few days a week), negative effects on their offspring have been found.
- Cigarette smoking by pregnant women has serious adverse effects on prenatal and child development, including low birth weight. Illegal psychoactive drugs that are potentially harmful to offspring include marijuana, cocaine, and heroin. Incompatibility of the mother's and the father's blood types can also be harmful to the fetus.
- Environmental hazards include radiation, environmental pollutants, and toxic wastes. Syphilis, rubella (German measles), genital herpes, and AIDS are infectious diseases that can harm the fetus.
- Other parental factors that affect prenatal development include maternal diet and nutrition, age, emotional states and stress, and paternal factors. A developing fetus depends entirely on its mother for nutrition. Maternal age can negatively affect the offspring's development if the mother is an adolescent or over 35. High stress in the mother is linked with less than optimal prenatal and birth outcomes. Paternal factors that can adversely affect prenatal development include exposure to lead, radiation, certain pesticides, and petrochemicals, as well as smoking.
- Prenatal care varies extensively but usually involves health maintenance services with a defined schedule of visits.
- It is important to remember that, although things can go wrong during pregnancy, most of the time pregnancy and prenatal development go well.

### 2 Birth

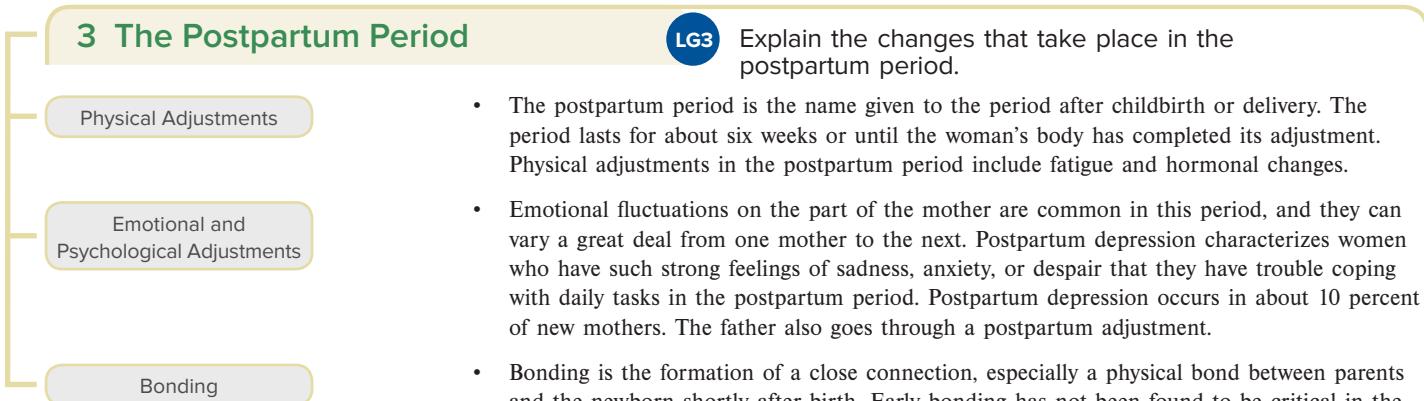

The Birth Process

**LG2** Describe the birth process.

- Childbirth occurs in three stages. The first stage, which lasts about 6 to 12 hours for a woman having her first child, is the longest stage. The cervix dilates to about 10 centimeters (4 inches) by the end of the first stage. The second stage begins when the baby's head starts to move through

- the cervix and ends with the baby's complete emergence. The third stage involves the delivery of the placenta after birth. Childbirth strategies involve the childbirth setting and attendants.
- In many countries, a doula attends a childbearing woman. Methods of delivery include medicated, natural or prepared, and cesarean.
  - For many years, the Apgar Scale has been used to assess the newborn's health. The Brazelton Neonatal Behavioral Assessment Scale examines the newborn's neurological development, reflexes, and reactions to people. Recently, the Neonatal Intensive Care Unit Network Neurobehavioral Scale (NNNS) was created to assess at-risk infants.
  - Low birth weight infants weigh less than 5 pounds 8 ounces, and they may be preterm (born before the completion of 37 weeks of gestation) or small for date (also called small for gestational age, which refers to infants whose birth weight is below normal when the length of pregnancy is considered). Small for date infants may be preterm or full term. Although most low birth weight and preterm infants are normal and healthy, as a group they have more health problems and developmental delays than normal birth weight infants. Kangaroo care and massage therapy have been shown to have benefits for preterm infants.

**LG3**

Explain the changes that take place in the postpartum period.

- The postpartum period is the name given to the period after childbirth or delivery. The period lasts for about six weeks or until the woman's body has completed its adjustment. Physical adjustments in the postpartum period include fatigue and hormonal changes.
- Emotional fluctuations on the part of the mother are common in this period, and they can vary a great deal from one mother to the next. Postpartum depression characterizes women who have such strong feelings of sadness, anxiety, or despair that they have trouble coping with daily tasks in the postpartum period. Postpartum depression occurs in about 10 percent of new mothers. The father also goes through a postpartum adjustment.
- Bonding is the formation of a close connection, especially a physical bond between parents and the newborn shortly after birth. Early bonding has not been found to be critical in the development of a competent infant.

## Infancy

As newborns, we were not empty-headed organisms. We had some basic reflexes, among them crying, kicking, and coughing. We slept a lot, and occasionally we smiled, although the meaning of our first smiles was not entirely clear. We ate and we grew. We crawled and then we walked, a journey of a thousand miles beginning with a single step. Sometimes we conformed; sometimes others conformed to us. Our development was a continuous creation of more complex forms. We needed the meeting eyes of love. We juggled the necessity of curbing our will with becoming what we could will freely. This section contains three chapters: “Physical Development in Infancy,” “Cognitive Development in Infancy,” and “Socioemotional Development in Infancy.”

**L**atonya is a newborn baby in Ghana. During her first days of life, she has been kept apart from her mother and bottle fed.

Manufacturers of infant formula provide the hospital where she was born with free or subsidized milk powder. Her mother has been persuaded to bottle feed rather than breast feed her. When her mother bottle feeds Latonya, she overdilutes the milk formula with unclean water. Latonya's feeding bottles have not been sterilized. Latonya becomes very sick. She dies before her first birthday.

Ramona was born in a Nigerian hospital with a "baby-friendly" program. In this program, babies are not separated from their mothers when they are born, and the mothers are encouraged to breast feed them. The mothers are told of the perils that bottle feeding can bring because of unsafe water and unsterilized bottles. They also are informed about the advantages of breast milk, which include its nutritive and hygienic qualities, its ability to immunize babies against common illnesses, and the role of breast feeding in reducing the mother's risk of breast and ovarian cancer. Ramona's mother is breast feeding her. At 1 year of age, Ramona is very healthy.

For many years, maternity units in hospitals favored bottle feeding and did not give mothers adequate information about the benefits of breast feeding. In recent years, the World Health Organization and UNICEF have tried to reverse the trend toward bottle feeding of infants in many impoverished countries. They instituted "baby-friendly" programs in many countries (Grant, 1993). They also persuaded the International Association of Infant Formula Manufacturers to stop marketing their baby formulas to hospitals in countries where the governments support the baby-friendly initiatives (Grant, 1993). For the hospitals themselves, costs actually were reduced as infant formula, feeding bottles, and separate nurseries became unnecessary. For example, baby-friendly Jose Fabella Memorial Hospital in the Philippines reported saving 8 percent of its annual budget. Still, there are many places in the world where the baby-friendly initiatives have not been implemented.

The advantages of breast feeding in impoverished countries are substantial (UNICEF, 2017). However, these advantages must be balanced against the risk of passing the human immunodeficiency virus (HIV) to babies through breast milk if

## topical connections *looking back* -----

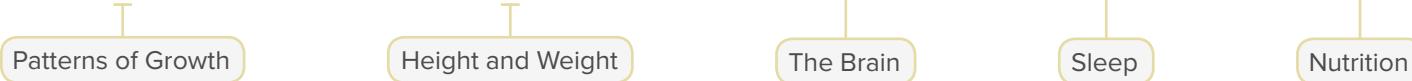

Previously, we followed the physical development that takes place from fertilization through the germinal, embryonic, and fetal periods of prenatal development. We learned that by the time the fetus has reached full gestational age (approximately 40 weeks), it has grown from a fertilized egg, barely visible to the human eye, to a fully formed human weighing approximately 8 pounds and measuring 20 inches in length. Also remarkable is the fact that by the end of the prenatal period the brain has developed approximately 100 billion neurons.

the mothers have the virus (Croffut & others, 2018; Mnyani & others, 2017; Wojcicki, 2017). In some areas of Africa, more than 30 percent of mothers have HIV, but the majority of these mothers don't know that they are infected (Mepham, Bland, and Newell, 2011). Later in the chapter, in the section on nutrition, we will look more closely at recent research on breast feeding in the United States, outlining the benefits for infants and mothers and discussing several life-threatening diseases that infants can contract as a result of malnutrition.

## preview

It is very important for infants to get a healthy start. When they do, their first two years of life are likely to be a time of amazing development. In this chapter, we focus on the biological domain and the infant's physical development, exploring physical growth, motor development, and sensory and perceptual development.

**FIGURE 1**

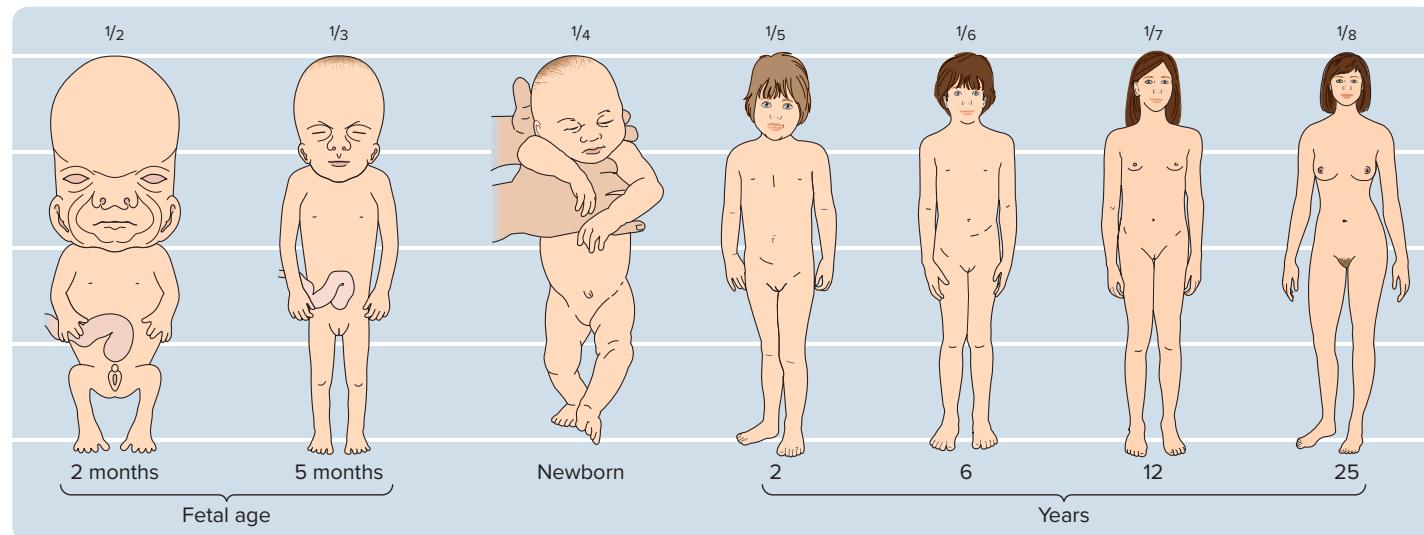

#### CHANGES IN PROPORTIONS OF THE HUMAN BODY DURING GROWTH.

As individuals develop from infancy through adulthood, one of the most noticeable physical changes is that the head becomes smaller in relation to the rest of the body. The fractions listed refer to head size as a proportion of total body length at different ages.

Infants' physical development in the first two years of life is extensive. Newborns' heads are quite large in comparison with the rest of their bodies. They have little strength in their necks and cannot hold their heads up, but they have some basic reflexes. In the span of 12 months, infants become capable of sitting anywhere, standing, stooping, climbing, and usually walking. During the second year, growth decelerates, but rapid increases in such activities as running and climbing take place. Let's now examine in greater detail the sequence of physical development in infancy.

#### PATTERNS OF GROWTH

An extraordinary proportion of the total body is occupied by the head during prenatal development and early infancy (see Figure 1). The **cephalocaudal pattern** is the sequence in which the earliest growth always occurs at the top—the head—with physical growth and differentiation of features gradually working their way down from top to bottom (for example, shoulders,

middle trunk, and so on). This same pattern occurs in the head area, because the top parts of the head—the eyes and brain—grow faster than the lower parts, such as the jaw.

Motor development generally proceeds according to the cephalocaudal principle. For example, infants see objects before they can control their torso, and they can use their hands long before they can crawl or walk. However, development does not follow a rigid blueprint. One study found that infants reached for toys with their feet prior to reaching with their hands (Galloway & Thelen, 2004). On average, infants first touched the toy with their feet when they were 12 weeks old and with their hands when they were 16 weeks old.

Growth also follows the **proximodistal pattern**, the sequence in which growth starts at the center of the body and moves toward the extremities. For example, infants control the muscles of their trunk and arms before they control their hands and fingers, and they use their whole hands before they can control several fingers (Bindler & others, 2017).

## HEIGHT AND WEIGHT

The average North American newborn is 20 inches long and weighs 7.6 pounds. Ninety-five percent of full-term newborns are 18 to 22 inches long and weigh between 5 and 10 pounds.

In the first several days of life, most newborns lose 5 to 7 percent of their body weight before they adjust to feeding by sucking, swallowing, and digesting. Then they grow rapidly, gaining an average of 5 to 6 ounces per week during the first month. They have doubled their birth weight by the age of 4 months and have nearly tripled it by their first birthday. Infants grow about 1 inch per month during the first year, approximately doubling their birth length by their first birthday.

Growth slows considerably in the second year of life (London & others, 2017). By 2 years of age, infants weigh approximately 26 to 32 pounds, having gained a quarter to half a pound per month during the second year to reach about one-fifth of their adult weight. At 2 years of age, infants average 32 to 35 inches in height, which is nearly half of their adult height.

An important point about growth is that it often is not smooth and continuous but rather is *episodic*, occurring in spurts (Adolph, 2018; Adolph & Berger, 2015). In infancy, growth spurts may occur in a single day and alternate with long time frames characterized by little or no growth for days and weeks (Lampl & Johnson, 2011; Lampl & Schoen, 2018). In two analyses, in a single day, infants grew seven-tenths of an inch in length in a single day (Lampl, 1993) and their head circumference increased three-tenths of an inch (Caino & others, 2010).

## THE BRAIN

We have described the amazing growth of the brain from conception to birth. By the time it is born, the infant that began as a single cell is estimated to have a brain that contains approximately 100 billion nerve cells, or neurons. Extensive brain development continues after birth, through infancy and later (Sullivan & Wilson, 2018; Vasa & others, 2018). Because the brain is still developing so rapidly in infancy, the infant's head should be protected from falls or other injuries and the baby should never be shaken. *Shaken baby syndrome*, which includes brain swelling and hemorrhaging, affects hundreds of babies in the United States each year (Hellgren & others, 2017). One analysis found that fathers were the most frequent perpetrators of shaken baby syndrome, followed by child care providers and boyfriends of the victim's mother (National Center on Shaken Baby Syndrome, 2012).

Researchers have been successful in using the electroencephalogram (EEG), a measure of the brain's electrical activity, to learn about the brain's development in infancy (Bell & others, 2018; Hari & Puce, 2017) (see Figure 2). For example, a recent study found that higher-quality mother-infant interaction early in infancy predicted higher-quality frontal lobe functioning that was assessed with EEG later in infancy (Bernier, Calkins, & Bell, 2016).

Researchers also are increasingly using functional near-infrared spectroscopy (fNIRS), which uses very low levels of near-infrared light to monitor changes in blood oxygen, to study infants' brain activity (de Oliveira & others, 2018; Emberson & others, 2017a, b; Taga, Watanabe, & Homae, 2018) (see Figure 3). Unlike fMRI, which uses magnetic fields or electrical activity, fNIRS is portable and allows the infants to be assessed as they explore the world around them. And recently Patricia Kuhl and her colleagues (Ferjan Ramirez & others, 2017) at the Institute for Learning and Brain Sciences at the University of Washington have been using

magnetoencephalography, or MEG, brain-imaging machines to assess infants' brain activity. MEG maps brain activity by recording magnetic fields produced by electrical currents and is being used to assess such perceptual and cognitive activities as vision, hearing, and language in infants (see Figure 4).

Among the researchers who are making strides in finding out more about the brain's development in infancy are:

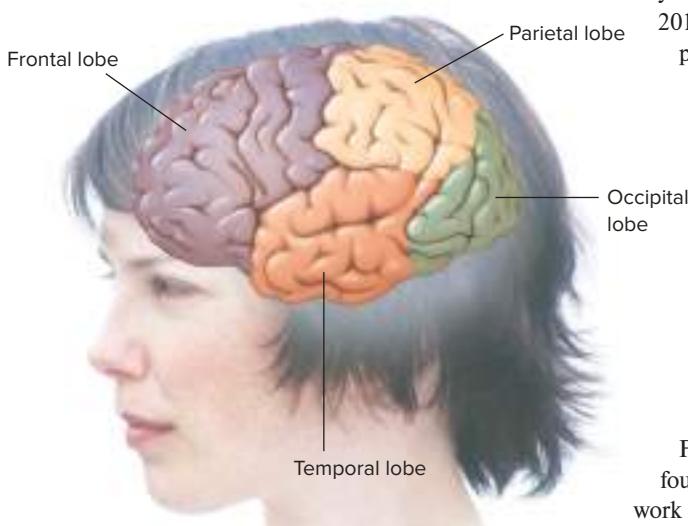

- Charles Nelson and his colleagues (Berens & Nelson, 2015; Bick & Nelson, 2018; Bick & others, 2017; Finch & others, 2017; McLaughlin, Sheridan, & Nelson, 2017; Nelson, 2007, 2012, 2013a, b; Nelson, Fox, & Zeanah, 2014; Vanderwert & others, 2016; Varcin & others, 2016) who are exploring various aspects of memory development, face recognition and facial emotion, and the role of experience in influencing the course of brain development;

- Martha Ann Bell and her colleagues (Bell, 2015; Bell & Cuevas, 2012, 2014, 2015; Bell & others, 2018; Bell, Ross, & Patton, 2018; Broomell & Bell, 2018; Li & others, 2017; MacNeill & others, 2018; Lusby & others, 2016) who are studying brain-behavior links, emotion regulation, inhibitory control, and the integration of cognition and emotion;
- Mark Johnson and his colleagues (Anzures & others, 2016; Gliga & others, 2017; Hakuno & others, 2018; Johnson, Jones, & Gliga, 2015; Johnson, Senju, & Tomalski, 2015; Milosavljevic & others, 2017; Saez de Urabain & others, 2017; Senju & others, 2016), who are examining neuroconstructivist links between the brain, cognitive and perceptual processes, and environmental influences as well as studying the development of the prefrontal cortex and its functions, early identification of autism, face processing, and early social experiences; and
  - John Richards and his colleagues (Emberson & others, 2017a; Lloyd-Fox & others, 2015; Richards, 2009, 2010, 2013; Richards & others, 2015; Richards, Reynolds, & Courage, 2010; Richards & Xie, 2015; Xie, Mallin, & Richards, 2018; Xie & Richards, 2016, 2017) who are examining sustained attention, perception of TV programs, and eye movements.

**THE BRAIN'S FOUR LOBES.** Shown here are the locations of the brain's four lobes: frontal, occipital, temporal, and parietal.

**The Brain's Development** At birth, the newborn's brain is about 25 percent of its adult weight. By the second birthday, the brain is about 75 percent of its adult weight. However, the brain's areas do not mature uniformly.

**Mapping the Brain** Scientists analyze and categorize areas of the brain in numerous ways (Bell & others, 2018; Dean & others, 2018; Ferjan Ramirez & others, 2017). The portion farthest from the spinal cord is known as the forebrain. This region includes the cerebral cortex and several structures beneath it. The cerebral cortex covers the forebrain like a wrinkled cap. The brain has two halves, or hemispheres (see Figure 5). Based on ridges and valleys in the cortex, scientists distinguish four main areas, called lobes, in each hemisphere. Although the lobes usually work together, each has a somewhat different primary function (see Figure 6):

- *Frontal lobes* are involved in voluntary movement, thinking, personality, and intentionality or purpose.
- *Occipital lobes* function in vision.
- *Temporal lobes* have an active role in hearing, language processing, and memory.
- *Parietal lobes* play important roles in registering spatial location, attention, and motor control.

To some extent, the type of information handled by neurons depends on whether they are in the left or right hemisphere of the cortex (Benjamin & others, 2017; Sidtis & others, 2018). Speech and grammar, for example, depend on activity in the left hemisphere in most people; humor and the use of metaphors depend on activity in the right hemisphere (Holler-Wallscheid & others, 2017). This specialization of function in one hemisphere of the cerebral cortex or the other is called **lateralization**. However, most neuroscientists agree that complex functions such as reading or performing music involve both hemispheres. Labeling people as “left-brained” because they are logical thinkers or “right-brained” because they are creative thinkers does not correspond to the way the brain’s hemispheres work. Complex thinking in normal people is the outcome of communication between both hemispheres of the brain (Nora & others, 2017; Raemaekers & others, 2018).

At birth, the hemispheres of the cerebral cortex already have started to specialize: Newborns show greater electrical brain activity in the left hemisphere than the right hemisphere when they are listening to speech sounds (Telkemeyer & others, 2011). How are the areas of the brain different in the newborn and the infant from those in an adult, and why do the differences matter? Important differences have been documented at both the cellular and the structural levels.

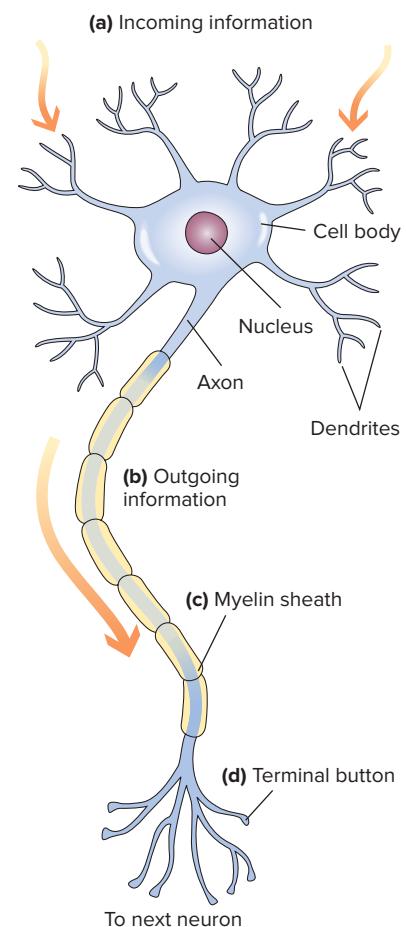

**Changes in Neurons** Within the brain, the type of nerve cells called neurons send electrical and chemical signals, communicating with each other. A *neuron* is a nerve cell that handles information processing (see Figure 7). Extending from the neuron’s cell body are two types of fibers known as axons and dendrites. Generally, the axon carries signals away from the cell body and dendrites carry signals toward it. A *myelin sheath*, which is a layer of fat cells, encases many axons (see Figure 7). The myelin sheath insulates axons and helps electrical signals travel faster down the axon (Cercignani & others, 2017; van Tilborg & others, 2018). Myelination also is involved in providing energy to neurons and in communication (Saab & Nave, 2017). At the end of the axon are terminal buttons, which release chemicals called *neurotransmitters* into *synapses*, which are tiny gaps between neurons’ fibers. Chemical interactions in synapses connect axons and dendrites, allowing information to pass from neuron to neuron (Ismail, Fatemi, & Johnson, 2017; Zhou & others, 2018). Think of the synapse as a river that blocks a road. A grocery truck arrives at one bank of the river, crosses by ferry, and continues its journey to market. Similarly, a message in the brain is “ferried” across the synapse by a neurotransmitter, which pours out information contained in chemicals when it reaches the other side of the river.

Neurons change in two very significant ways during the first years of life. First, *myelination*, the process of encasing axons with fat cells, begins prenatally and continues after birth, even into adolescence and emerging adulthood (Juraska & Willing, 2017). Second, connectivity among neurons increases, creating new neural pathways (Eggebrecht & others, 2017; Zhou & others, 2018). New dendrites grow, connections among dendrites increase, and synaptic connections between axons and dendrites proliferate. Whereas myelination speeds up neural transmissions, the expansion of dendritic connections facilitates the spreading of neural pathways in infant development.

How complex are these neural connections? In a recent analysis, it was estimated that each of the billions of neurons is connected to as many as 1,000 other neurons, producing neural networks with trillions of connections (de Haan, 2015). As we have discussed previously, most of these billions of neurons essentially have been created, have traveled to their correct locations, and are connected to other neurons by the time of full-term birth. Nonetheless, they undergo further differentiation, and neural connectivity patterns continue to change at least into emerging adulthood (Vasa & others, 2018).

Researchers have discovered an intriguing aspect of synaptic connections: nearly twice as many of these connections are made as will ever be used (Huttenlocher & Dabholkar, 1997). The connections that are used survive and become stronger, while the unused ones are replaced by other pathways or disappear. In the language of neuroscience, these connections will be “pruned” (Gould, 2017). For example, the more babies engage in physical activity or use language, the more those pathways will be strengthened.

The age at which “blooming” and subsequent “pruning” of synapses occurs varies by brain region. For example, the peak of synaptic overproduction in the visual cortex occurs at about the fourth postnatal month, followed by a gradual retraction until the middle to end of the preschool years. In areas of the brain involved in hearing and language, a similar, though somewhat later, course is detected. However, in the prefrontal cortex, the area of the brain where higher-level thinking and self-regulation occur, the peak of overproduction takes place at about 1 year of age; it is not until emerging adulthood that adult density of synapses is attained. Both heredity and environment are thought to influence the timing and course of synaptic overproduction and subsequent retraction.

### EARLY DEPRIVATION AND BRAIN

**ACTIVITY.** These two photographs are PET (positron emission tomography) scans, which use radioactive tracers to image and analyze blood flow and metabolic activity in the body's organs. These scans show the brains of (a) a typically developing child and (b) an institutionalized Romanian orphan who experienced substantial deprivation since birth. In PET scans, the highest to lowest brain activity is reflected in the colors of red, yellow, green, blue, and black, respectively. As can be seen, red and yellow show up to a much greater degree in the PET scan of the typically developing child than the deprived Romanian orphan.

Courtesy of Dr. Harry T. Chugani, Children's Hospital of Michigan

**Early Experience and the Brain** Children who grow up in a deprived environment may have depressed brain activity (Bick & Nelson, 2018; Bick & others, 2017; McLaughlin, Sheridan, & Nelson, 2017; Nelson, Fox, & Zeanah, 2014). As shown in Figure 8, a child who grew up in the unresponsive and unstimulating environment of a Romanian orphanage showed considerably depressed brain activity compared with a child who grew up in a normal environment.

Are the effects of deprived environments reversible? There is reason to think that for some individuals the answer is "yes" (Dennis & others, 2014). The brain demonstrates both flexibility and resilience. Consider 14-year-old Michael Rehbein. At age 7, he began to experience uncontrollable seizures—as many as 400 a day. Doctors said the only solution was to remove the left hemisphere of his brain where the seizures were occurring. Recovery was slow, but his right hemisphere began to reorganize and take over functions that normally occur in the brain's left hemisphere, including speech (see Figure 9).

Neuroscientists believe that what wires the brain—or rewires it, in the case of Michael Rehbein—is repeated experience. Each time a baby tries to touch an attractive object or gazes intently at a face, tiny bursts of electricity shoot through the brain, knitting together neurons into circuits. The results are some of the behavioral milestones we discuss in this chapter.

**The Neuroconstructivist View** Not long ago, scientists thought that our genes determined how our brains were "wired" and that the cells in the brain responsible for processing information just maturally unfolded with little or no input from environmental experiences. Whatever brain your heredity had dealt you, you were essentially stuck with. This view, however, turned out to be wrong. Research reveals that the brain has plasticity and its development depends on context (Bick & Nelson, 2018; D'Souza & Karmiloff-Smith, 2018; McLaughlin & Broihier, 2018; Snyder & Smith, 2018).

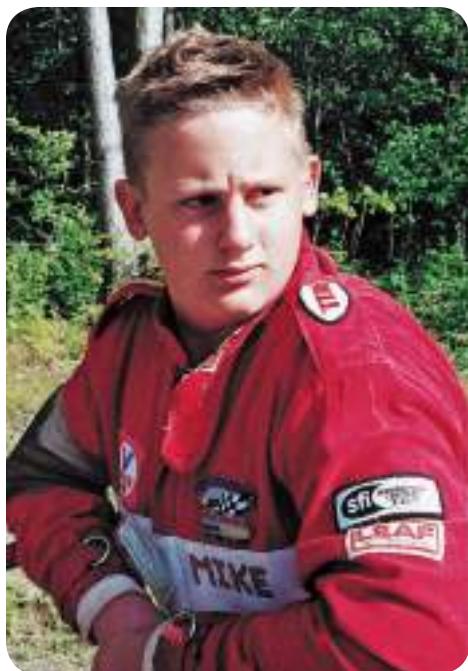

The infant's brain depends on experiences to determine how connections are made. Before birth, it appears that genes mainly direct basic wiring patterns. Neurons grow and travel to distant places awaiting further instructions. After birth, the inflowing stream of sights, sounds, smells, touches, language, and eye contact help shape the brain's neural connections.

In the increasingly popular **neuroconstructivist view**, (a) biological processes (genes, for example) and environmental conditions (enriched or impoverished, for example) influence the brain's development; (b) the brain has plasticity and is context dependent; and (c) the child's cognitive development is closely linked to development of the brain. These factors constrain or advance the construction of cognitive skills (Goldberg, 2017; Mucke & others, 2018; Schreuders & others, 2018; Westermann, Thomas, & Karmiloff-Smith, 2011). The neuroconstructivist view emphasizes the importance of considering interactions between experience and gene expression in the brain's development, much as the epigenetic view proposes (Moore, 2017; Smith & others, 2018; Westermann, 2016).

## SLEEP

Sleep restores, replenishes, and rebuilds our brains and bodies. What function does sleep have in people's lives? How do sleep patterns change in infancy?

**Why Do We Sleep?** A number of theories have been proposed about why we sleep. From an evolutionary perspective, all animals sleep and this sleep likely is necessary for survival. Thus, sleep may have developed because animals needed to protect themselves at night. A second perspective is that sleep replenishes and rebuilds the brain and body, which the day's waking activities can wear out. In support of this restorative function, many of the body's cells show increased production and reduced breakdowns of proteins during sleep (Frank, 2017). Further, a current emphasis is that sleep is essential to clearing out waste in neural tissues, such as metabolites and cerebrospinal fluid (Aguirre, 2016). A third perspective is that sleep is critical for brain plasticity (Sterpenich, Ceravolo, & Schwartz, 2017). For example, neuroscientists recently have argued that sleep increases synaptic connections between neurons (Areal, Warby, & Mongrain, 2017). These increased synaptic connections during sleep have been linked to improved consolidation of memories (Gui & others, 2017). Further, a research review concluded that not only can sleep improve memory, but losing a few hours of sleep a night is related to negative effects on attention, reasoning, and decision making (Diekelmann, 2014).

In sum, sleep likely serves a number of functions with no one theory accounting for all of the functions. Let's now turn our attention to sleep in infancy. In later chapters, we will explore sleep through the remainder of the life span.

**Infant Sleep** When we were infants, sleep consumed more of our time than it does now (Goh & others, 2017). The typical newborn sleeps approximately 18 hours a day, but newborns vary greatly in how much they sleep (Dias & others, 2018; Sadeh, 2008). The range is from about 10 hours to about 21 hours a day.

In a recent study, sleep sessions lasted approximately 3.5 hours during the first few months and increased to about 10.5 hours from 3 to 7 months (Mindell & others, 2016). A previous research review concluded that infants 0 to 2 years of age slept an average of 12.8 hours out of the 24, within a range of 9.7 to 15.9 hours (Galland & others, 2012). Another study revealed that by 6 months of age the majority of infants slept through the night, awakening their parents only once or twice a week (Weinraub & others, 2012).

Sleep problems have been estimated to affect 15 to 25 percent of infants. The most common infant sleep-related problem reported by parents is nighttime waking (Dias & others, 2018;

Hospital for Sick Children & others, 2010). Surveys indicate that 20 to 30 percent of infants have difficulty going to sleep at night and staying asleep until morning (Sadeh, 2008). One study found that nighttime wakings at 1 year of age predicted lower sleep efficiency at 4 years of age (Tikotzky & Shaashua, 2012). Further research found that (1) maternal depression during pregnancy, (2) early introduction of solid foods, (3) infant TV viewing, and (4) child care attendance were related to shorter duration of infant sleep (Nevarez & others, 2010). And a recent study revealed that later bedtime and less sleep across a 24-hour period were linked to infants having more separation distress, greater inhibition, and higher anxiety and depression levels (Mindell & others, 2017).

Research also indicates that parental factors other than maternal depression are linked to infants' sleep patterns (Field, 2017; Volkovich & others, 2018; Yu & others, 2017). A recent study found that maternal sleep when the infant was 3 months of age predicted the infant's sleep patterns at 6 months of age and that increased involvement of the father in caregiving responsibilities improved the infant's sleep (Tikotzky & others, 2015). And other recent research indicated that a higher level of maternal emotional availability at bedtime was associated with a lower level of infant distress at bedtime and longer infant sleep duration (Philbrook & Teti, 2016).

Cultural variations influence infant sleeping patterns (Field, 2017). For example, in the Kipsigis culture in Kenya, infants sleep with their mothers at night and are permitted to nurse on demand (Super & Harkness, 1997). During the day, they are strapped to their mothers' backs, accompanying them on daily rounds of chores and social activities. As a result, the Kipsigis infants do not sleep through the night until much later than American infants do. During the first eight months of postnatal life, Kipsigis infants rarely sleep longer than three hours at a stretch, even at night. This sleep pattern contrasts with that of American infants, many of whom begin to sleep up to eight hours a night by 8 months of age.

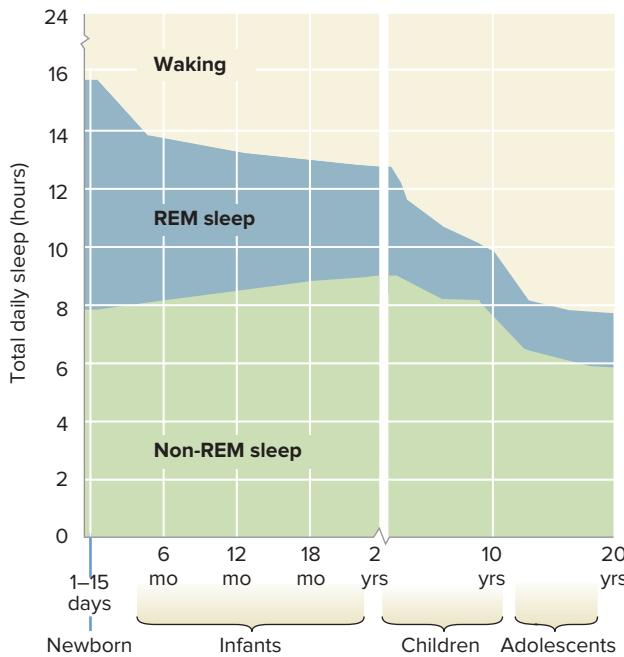

**REM Sleep** In REM sleep, the eyes flutter beneath closed lids; in non-REM sleep, this type of eye movement does not occur and sleep is more quiet (Bathory & Tomopoulos, 2017). Figure 10 shows developmental changes in the average number of total hours spent in REM and non-REM sleep. By the time they reach adulthood, individuals spend about one-fifth of their night in REM sleep, and REM sleep usually appears about one hour after non-REM sleep. However, about half of an infant's sleep is REM sleep, and infants often begin their sleep cycle with REM sleep rather than non-REM sleep. A much greater amount of time is taken up by REM sleep in infancy than at any other point in the life span. By the time infants reach 3 months of age, the percentage of time they spend in REM sleep falls to about 40 percent, and REM sleep no longer begins their sleep cycle.

Why do infants spend so much time in REM sleep? Researchers are not certain. The large amount of REM sleep may provide infants with added self-stimulation, since they spend less time awake than do older children. REM sleep also might promote the brain's development in infancy (Graven, 2006).

When adults are awakened during REM sleep, they frequently report that they have been dreaming, but when they are awakened during non-REM sleep, they are much less likely to report having been dreaming (Cartwright & others, 2006). Since infants spend more time than adults in REM sleep, can we conclude that they dream a lot? We don't know whether infants dream or not, because they don't have any way of reporting dreams.

**Shared Sleeping** Sleeping arrangements for newborns vary from culture to culture (Field, 2017). For example, sharing a bed with a mother is a common practice in many cultures, such as Guatemala and China, whereas in others, such as the United States and Great Britain, newborns usually sleep in a crib, either in the same room as the parents or in a separate room. In some cultures, infants sleep with the mother until they are weaned, after which they sleep with siblings until middle and late childhood (Walker, 2006). Whatever the sleeping arrangements, it is recommended that the infant's bedding provide firm support and that the crib has side rails (Kreth & others, 2018).

In the United States, shared sleeping remains a controversial issue (Burnham, 2014). Some experts recommend it and others argue against it, although recently the recommendation trend has been to avoid infant-parent bed sharing, especially if the infant is younger than 6 months of age (Byard, 2012a, b; Field, 2017; Mitchell & others, 2017; Weber & others, 2012). In a recent study,

**FIGURE 10**  
DEVELOPMENTAL CHANGES IN REM AND NON-REM SLEEP

infant-parent bed sharing was associated with more night waking for mothers as well as infants, and more marital distress (Teti & others, 2016). The American Academy of Pediatrics Task Force on Infant Positioning and SIDS (AAPTFIPS) (2000) recommends against shared sleeping. Its members argue that in some instances bed sharing might lead to sudden infant death syndrome (SIDS), as could be the case if a sleeping mother rolls over on her baby (Moon & others, 2017). Recent studies have found that bed sharing is linked with a higher incidence of SIDS, especially when parents smoke (Adams, Ward, & Garcia, 2015). Further, a recent large-scale study in six countries (including the United States) found that parents of 6- to 12-month-old infants reported earlier bedtimes, shorter time to fall asleep, fewer sleep interruptions, and more total sleep when the infants slept in a separate room compared with infants sleeping in the same room or same bed with their parents (Mindell, Leichman, & Walters, 2018).

**SIDS** Sudden infant death syndrome (SIDS) is a condition that occurs when infants stop breathing, usually during the night, and die suddenly without any apparent reason. SIDS continues to be a leading cause of infant death in the United States, with more than 2,000 infant deaths annually attributed to SIDS (NICHD, 2018). Risk of SIDS is highest at 2 to 4 months of age.

Since 1992, the American Academy of Pediatrics (AAP) has recommended that infants be placed to sleep on their backs (supine position) to reduce the risk of SIDS, and the frequency of prone sleeping (on the stomach) among U.S. infants has dropped dramatically (AAPTFIPS, 2000). Researchers have found that SIDS does indeed decrease when infants sleep on their backs rather than their stomachs or sides (Bombard & others, 2018; Siren, 2017; Sperhake, Jorch, & Bajanowski, 2018). Why? Because sleeping on their backs increases their access to fresh air and reduces their chances of getting overheated.

In addition to sleeping in a prone position, researchers have found that the following factors are linked to SIDS:

- SIDS occurs more often in infants with abnormal brain stem functioning involving the neurotransmitter serotonin (Rognum & others, 2014; Rubens & Sarnat, 2013).
- Heart arrhythmias are estimated to occur in as many as 15 percent of SIDS cases, and two studies found that gene mutations were linked to the occurrence of these arrhythmias (Brion & others, 2012; Van Norstrand & others, 2012).
- Six percent of infants with sleep apnea, a temporary cessation of breathing in which the airway is completely blocked, usually for 10 seconds or longer, die of SIDS (Ednick & others, 2010).
- Breast feeding is linked to a lower incidence of SIDS (Carlin & Moon, 2017).
- Low birth weight infants are 5 to 10 times more likely to die of SIDS than are their normal-weight counterparts (Horne & others, 2002).
- SIDS is more likely to occur in infants who do not use a pacifier when they go to sleep than in those who do use a pacifier (Carlin & Moon, 2017). A recent research review confirmed that pacifier use is linked to a lower incidence of SIDS (Alm & others, 2016).
- Infants whose siblings have died of SIDS are two to four times as likely to die of it (Lenoir, Mallet, & Calenda, 2000).
- African American and Eskimo infants are four to six times as likely as all others to die of SIDS (Kitsantas & Gaffney, 2010; Moon & others, 2017).
- SIDS is more common in lower socioeconomic groups (Hogan, 2014).
- SIDS is more common in infants who are passively exposed to cigarette smoke (Horne, 2018; Salm Ward & Balfour, 2016).
- SIDS is more common when infants and parents share the same bed (Carlin & Moon, 2017; Moon & others, 2017). A recent Swedish study confirmed that bed sharing was more common in SIDS cases than in other types of infant deaths (Mollborg & others, 2015).
- SIDS is more common if infants sleep in soft bedding (McGarvey & others, 2006).
- SIDS is less common when infants sleep in a bedroom with a fan. One study revealed that sleeping in a bedroom with a fan lowers the risk of SIDS by 70 percent (Coleman-Phox, Odouli, & Li, 2008).

It is generally accepted that the most critical factor in predicting whether an infant will develop SIDS is prone sleeping. As public awareness has grown regarding the importance of not letting infants sleep in a prone position, the number of infant deaths in the United States has decreased,

although SIDS still is one of the leading causes of infant death (Bombard & others, 2018). In a recent research review, it was concluded that the two other factors that place infants at the highest risk for SIDS are (1) maternal smoking and (2) bed sharing (Mitchell & Krous, 2015).

One concern raised by critics of the “back to sleep movement” (ensuring that young infants sleep on their back rather than their stomach) is a decline in prone skills. To prevent this decline, many mothers provide their young infants with “tummy time” by periodically placing them on their stomachs when they are awake.

**Sleep and Cognitive Development** Might infant sleep be linked to children’s cognitive development? A recent research review indicated that there is a positive link between infant sleep and cognitive functioning, including memory, language, and executive function (Tham, Schneider, & Broekman, 2017). A study also revealed that a lower quality of sleep at 1 year of age was linked to lower attention regulation and more behavior problems at 3 to 4 years of age (Sadeh & others, 2015). And in another study, infants with poorer sleep patterns showed more distractibility during an attention task (Geva, Yaron, & Kuint, 2016). The link between infant sleep and children’s cognitive functioning likely occurs because of sleep’s role in brain maturation and memory consolidation, which may improve daytime alertness and learning.

## NUTRITION

From birth to 1 year of age, human infants nearly triple their weight and increase their length by 50 percent. What do they need to sustain this growth?

**Nutritional Needs and Eating Behavior** Individual differences among infants in terms of their nutrient reserves, body composition, growth rates, and activity patterns make defining actual nutrient needs difficult (Borowitz & Borowitz, 2018; Rolfs & Pinna, 2018). However, because parents need guidelines, nutritionists recommend that infants consume approximately 50 calories per day for each pound they weigh—more than twice an adult’s caloric requirement per pound.

A number of developmental changes involving eating characterize the infant’s first year (Leow & others, 2017). As infants’ motor skills improve, they change from using suck-and-swallow movements with breast milk or formula to chew-and-swallow movements with semisolid and then more complex foods. As their fine motor control improves in the first year, they transition from being fed by others toward self-feeding. “By the end of the first year of life, children can sit independently, can chew and swallow a range of textures, are learning to feed themselves, and are making the transition to the family diet and meal patterns” (Black & Hurley, 2007, p. 1). At this point, infants need to have a diet that includes a variety of foods—especially fruits and vegetables.

Caregivers play very important roles in infants’ early development of eating patterns (Baye, Tariku, & Mouquet-Rivier, 2018; Brown, 2017). Caregivers who are not sensitive to developmental changes in infants’ nutritional needs, caregivers who are negligent, and conditions of poverty can contribute to the development of eating problems in infants (Black & Hurley, 2017; Perez-Escamilla & Moran, 2017). One study found that low maternal sensitivity when infants were 15 and 24 months of age was linked to a higher risk of obesity in adolescence (Anderson & others, 2012). And in a recent study, infants who were introduced to vegetables at 4 to 5 months of age showed less fussy eating behavior at 4 years of age than their counterparts who were introduced to vegetables after 6 months (de Barse & others, 2017).

A national study of more than 3,000 randomly selected 4- to 24-month-olds documented that many U.S. parents were feeding their babies too much junk food and not giving them enough fruits and vegetables (Fox & others, 2004). Up to one-third of the babies ate no vegetables and fruit but frequently ate French fries, and almost half of the 7- to 8-month-old babies were fed desserts, sweets, or sweetened drinks. By 15 months, French fries were the most common vegetable the babies ate.

Such poor dietary patterns early in development can result in more infants being overweight (Black & Hurley, 2017; Blake, 2017; Feldman-Winter & others, 2018). In addition to consuming too many French fries, sweetened drinks, and desserts, are there other factors that might explain increased numbers of overweight U.S. infants? A mother’s weight gain during pregnancy and a mother’s own high weight before pregnancy may be factors (Catalano & Shankar, 2017). Also, an important factor likely is whether an infant is breast fed or bottle fed (Uwaezuoke, Eneh, & Ndu, 2017). Breast-fed infants have lower rates of weight gain than bottle-fed infants in childhood and adolescence, and it is estimated that breast feeding reduces

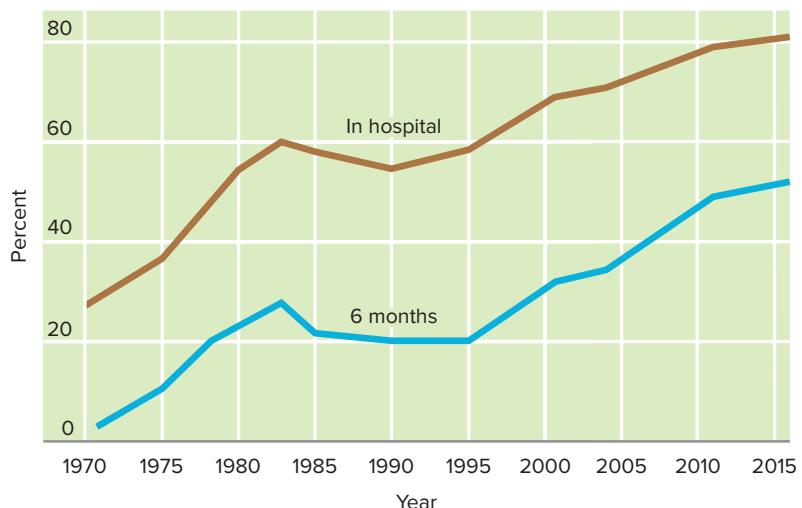

the risk of obesity by approximately 20 percent (Uwaezuoke, Eneh, & Ndu, 2017).

**Breast versus Bottle Feeding** For the first four to six months of life, human milk or an alternative formula is the baby's source of nutrients and energy. For years, debate has focused on whether breast feeding is better for the infant than bottle feeding. The growing consensus is that breast feeding is better for the baby's health (Blake, Munoz, & Volpe, 2019; DeBruyne & Pinna, 2017; Thompson & Manore, 2018). Since the 1970s, breast feeding by U.S. mothers has soared (see Figure 11). In 2016, 81 percent of U.S. mothers breast fed their newborns, and 52 percent breast fed their 6-month-olds (Centers for Disease Control and Prevention, 2016). The American Academy of Pediatrics Section on Breastfeeding (2012) reconfirmed its recommendation of exclusive breast feeding in the first six months followed by continued breast feeding as complementary foods are introduced, and further breast feeding for one year or longer as mutually desired by the mother and infant.

What are some of the benefits of breast feeding? The following conclusions have been supported by research.

### Outcomes for the Child

- *Gastrointestinal infections.* Breast-fed infants have fewer gastrointestinal infections (Bartick & others, 2017, 2018).
- *Respiratory tract infections.* Breast-fed infants have fewer infections of the lower respiratory tract (Bartick & others, 2018).
- *Allergies.* A recent research review found no support for breast feeding reducing the risk of allergies in young children (Heinrich, 2017).
- *Asthma.* Exclusive breast feeding for three months protects against wheezing in babies, but whether it prevents asthma in older children is unclear (Wang & others, 2018). However, a recent Japanese study found that breast feeding was linked to a lower incidence of asthma from 6 to 42 months of age (Yamakawa & others, 2015).
- *Ear, throat, and sinus infections.* One study found that infants who had been breast fed for 9 months or longer were less likely to have developed ear, throat, and sinus infections in the past year when they were 6 years old than their counterparts who had been breast fed for 3 months or less (Li & others, 2014). Breast-fed infants also are less likely to develop otitis media, a middle ear infection (Pelton & Leibovitz, 2009).
- *Overweight and obesity.* Consistent evidence indicates that breast-fed infants are less likely to become overweight or obese in childhood, adolescence, and adulthood (Catalano & Shankar, 2017; Uwaezuoke, Eneh, & Ndu, 2018).
- *Diabetes.* Breast-fed infants are less likely to develop type 1 diabetes in childhood (Lund-Blix & others, 2015) and type 2 diabetes in adulthood (Minniti & others, 2014).
- *SIDS.* Breast-fed infants have lower rates of SIDS (Bartick & others, 2017b; Wennergren & others, 2015).
- *Hospitalization.* A recent study of more than 500,000 Scottish children found that those who were breast fed exclusively at 6 to 8 weeks of age were less likely to have ever been hospitalized through early childhood than their formula-fed counterparts (Ajetunmobi & others, 2015). Other recent research has found that breast-fed infants had lower rates of hospitalization for a number of conditions, including gastrointestinal problems and lower respiratory tract infection, and breast-feeding mothers had lower rates of hospitalization for cardiovascular problems and diabetes (Bartick & others, 2018).

In large-scale research reviews, no conclusive evidence for the benefits of breast feeding was found for children's cognitive development and cardiovascular health (Agency for Healthcare Research and Quality, 2007; Ip & others, 2009).

### Outcomes for the Mother

- *Breast cancer.* Consistent evidence indicates a lower incidence of breast cancer in women who breast feed their infants (Bartick & others, 2017b; Mayor, 2015).
- *Ovarian cancer.* Evidence also reveals a reduction in ovarian cancer in women who breast feed their infants (Stuebe & Schwartz, 2010).
- *Type 2 diabetes.* Some evidence suggests that there is a reduction in type 2 diabetes in women who breast feed their infants (Bartick & others, 2017b).

In large-scale research reviews, no conclusive evidence could be found for maternal benefits of breast feeding involving return to prepregnancy weight, reduced rates of osteoporosis, and decreased risk of postpartum depression (Agency for Healthcare Research and Quality, 2007; Ip & others, 2009). However, one study revealed that women who breast fed their infants had a lower incidence of metabolic syndrome (a disorder characterized by obesity, hypertension, and insulin resistance) in midlife (Ram & others, 2008).

Many health professionals have argued that breast feeding facilitates the development of an attachment bond between the mother and infant (Britton, Britton, & Gronwaldt, 2006; Wittig & Spatz, 2008). However, a research review found that the positive role of breast feeding on the mother-infant relationship is not supported by research (Jansen, de Weerth, & Riksen-Walraven, 2008). The review concluded that recommending breast feeding should not be based on its role in improving the mother-infant relationship but rather on its positive effects on infant and maternal health. Also, researchers have not consistently found links between breast feeding and higher intelligence in children, although in two recent studies, breast feeding was associated with a small increase in children's intelligence (Bernard & others, 2017; Kanazawa, 2015).

Which women are least likely to breast feed? They include mothers who work full-time outside the home, mothers under age 25, mothers without a high school diploma, African American mothers, and mothers in low-income circumstances (Merewood & others, 2007). In one study of low-income mothers in Georgia, interventions (such as counseling focused on the benefits of breast feeding and the free loan of a breast pump) increased the incidence of breast feeding (Ahluwalia & others, 2000). Increasingly, mothers who return to work during the infant's first year of life use a breast pump to extract breast milk that can be stored for later feeding of the infant when the mother is not present.

As mentioned earlier, the American Academy of Pediatrics Section on Breastfeeding (2012) strongly endorses exclusive breast feeding for the first 6 months and further recommends breast feeding for another year. Are there circumstances when mothers should not breast feed? Yes, a mother should not breast feed (1) when she is infected with HIV or some other infectious disease that can be transmitted through her milk, (2) if she has active tuberculosis, or (3) if she is taking any drug that may not be safe for the infant (Brown & others, 2017; Schultz, Kostic, & Kharasch, 2018; Williams & others, 2016).

Some women cannot breast feed their infants because of physical difficulties; others feel guilty if they terminate breast feeding early. Mothers may also worry that they are depriving their infants of important emotional and psychological benefits if they bottle feed rather than breast feed. Some researchers have found, however, that there are no psychological differences between breast-fed and bottle-fed infants (Ferguson, Harwood, & Shannon, 1987; Young, 1990).

A further issue in interpreting the benefits of breast feeding was underscored in large-scale research reviews (Agency for Healthcare Research and Quality, 2007; Ip & others, 2009). While highlighting a number of breast feeding benefits for children and mothers, the report issued a caution about breast feeding research: None of the findings imply causality. Breast versus bottle feeding studies are correlational rather than experimental, and women who breast feed are wealthier, older, more educated, and likely more health-conscious than their bottle feeding counterparts, which could explain why breast-fed children are healthier.

**Malnutrition in Infancy** Many infants around the world are malnourished (UNICEF, 2018). Early weaning of infants from breast milk to inadequate sources of nutrients, such as unsuitable and unsanitary cow's milk formula, can cause protein deficiency and malnutrition in infants. However, as we saw in the discussion following the chapter opening story, a concern

## Improving the Nutrition of Infants and Young Children Living in Low-Income Families

Poor nutrition is a special concern in the lives of infants from low-income families. To address this problem in the United States, the WIC (Women, Infants, and Children) program provides federal grants to states for healthy supplemental foods, health care referrals, and nutrition education for women from low-income families beginning in pregnancy, and to infants and young children up to 5 years of age who are at nutritional risk (Chang, Brown, & Nitzke, 2017; Gilmore & others, 2017). WIC serves approximately 7,500,000 participants in the United States.

Positive influences on infants' and young children's nutrition and health have been found for participants in WIC (Chen & others, 2018; Gross & others, 2017; Lee & others, 2017; Martinez-Brockman & others, 2018; McCoy & others, 2018). One study revealed that a WIC program that introduced peer counseling services for pregnant women increased breast feeding initiation by 27 percent (Olson & others, 2010a, b). Another study found that entry during the first trimester of pregnancy to the WIC program in Rhode Island reduced rates of maternal cigarette smoking (Brodsky, Viner-Brown, & Handler, 2009). Also, a multiple-year literacy intervention with Spanish-speaking families in the WIC program in Los Angeles increased literacy resources and activities at home, which in turn led to a higher level of school readiness in children (Whaley & others, 2011). And in recent longitudinal studies, when

in developing countries is the increasing number of women who are HIV-positive and the fear that they will transmit this virus to their offspring (Croffut & others, 2018). Breast feeding is more optimal for mothers and infants in developing countries, except for mothers who have or are suspected of having HIV/AIDS.

A large-scale study that examined feeding practices in 28 developing countries found that the practices were far from optimal (Arabi & others, 2012). In this study, only 25 percent of infants 5 months of age and younger were breast fed. Also, feeding guidelines call for introducing complementary foods (solid and semisolid foods) beginning at 6 months. However, in this study, only 50 percent of the caregivers reported feeding their 6- to 8-month-olds complementary foods.

Even if it is not fatal, severe and lengthy malnutrition is detrimental to physical, cognitive, and social development (Donatelle & Ketcham, 2018; UNICEF, 2018; Wardlaw, Smith, & Collene, 2018). One study found that Asian Indian children who had a history of chronic malnutrition performed more poorly on tests of attention and memory than their counterparts who were not malnourished (Kar, Rao, & Chandramouli, 2008). And a longitudinal study revealed that Barbadians who had experienced moderate to severe protein/energy malnutrition during infancy had persisting attention deficits when they were 40 years old (Galler & others, 2012). Researchers also have found that interventions can benefit individuals who have experienced malnutrition in infancy. For example, in one study standard nutritional care combined with a psychosocial intervention (group meetings with mothers and play sessions with infants, as well as six months of home visits) reduced the negative effects of malnutrition on severely malnourished Bangladeshi 6- to 24-month-olds' cognitive development (Najar & others, 2008).

## Faize Mustafa-Infante

Dr. Mustafa-Infante grew up in Colombia, South America. Her initial profession was as an elementary school teacher in Colombia and then she obtained her medical degree with a specialty in pediatrics. Once she finished her medical training, she moved to San Bernardino, California, working as a health educator with a focus on preventing and treating child obesity in low-income communities. Dr. Mustafa-Infante currently works at Mission Pediatrics in Riverside, California, where she mainly treats infants. She continues her effort to prevent obesity in children and also serves as a volunteer for Ayacucho Mission, a nonprofit organization that provides culturally sensitive medical care for people living in poverty in Ayacucho, Peru. With regard to her cultural background, Dr. Mustafa-Infante describes herself as a Latino doctor with a middle-eastern name that reflects her strong family commitments to both heritages. Dr. Mustafa says that hard work and education have been the keys to her success and personal satisfaction.

For more information about what pediatricians do, see the *Careers in Life-Span Development* appendix.

Adequate early nutrition is an important aspect of healthy development (Rolfes & Pinna, 2018). In addition to sound nutrition, children need a nurturing, supportive environment (Black & Hurley, 2017; Blake, 2017). One individual who has stood out as an advocate of caring for children and who has been especially passionate about preventing child obesity is pediatrician Faize Mustafa-Infante, who is featured in *Connecting with Careers*.

As a newborn, Ramona, whom you read about in the chapter opening story, could suck, fling her arms, and tightly grip a finger placed in her tiny hand. Within just two years, she would be toddling around on her own, opening doors and jars as she explored her little world. Are her accomplishments inevitable? How do infants develop their motor skills, and which skills do they develop at specific ages?

## THE DYNAMIC SYSTEMS VIEW

Developmentalist Arnold Gesell (1934) thought his painstaking observations had revealed how people develop their motor skills. He had discovered that infants and children develop rolling, sitting, standing, and other motor skills in a fixed order and within specific time frames. These observations, said Gesell, show that motor development comes about through the unfolding of a genetic plan, or *maturational*.

Later studies, however, demonstrated that the sequence of developmental milestones is not as fixed as Gesell indicated and not due as much to heredity as Gesell argued (Adolph, 2018; Adolph & Robinson, 2015). Beginning in the 1980s, the study of motor development experienced a renaissance as psychologists developed new insights about *how* motor skills develop (Adolph, 2018; Kretch & Adolph, 2018). One increasingly influential perspective is dynamic systems theory, proposed by Esther Thelen (Thelen & Smith, 1998, 2006).

According to **dynamic systems theory**, infants assemble motor skills for perceiving and acting. Notice that perception and action are coupled, according to this theory. To develop motor skills, infants must perceive something in their environment that motivates them to act and use their perceptions to fine-tune their movements. Motor skills assist infants in reaching their goals (Adolph, 2018).

How is a motor skill developed, according to this theory? When infants are motivated to do something, they might create a new motor behavior. The new behavior is the result of many converging factors: the development of the nervous system, the body's physical properties and its possibilities for movement, the goal the child is motivated to reach, and availability of environmental support for the skill. For example, babies learn to walk only when maturation of the nervous system allows them to control certain leg muscles, when they want to move, when their legs have grown strong enough to support their weight, and when they have sufficient balance control to support their body on one leg.

Mastering a motor skill requires the infant's active efforts to coordinate several components of the skill. Infants explore and select possible solutions to the demands of a new task; they assemble adaptive patterns by modifying their current movement patterns (Adolph, 2018). The first step occurs when the infant is motivated by a new challenge—such as the desire to cross a room—and gets into the “ballpark” of the task demands by taking a couple of stumbling steps. Then, the infant “tunes” these movements to make them smoother and more effective. The tuning is achieved through repeated cycles of action and perception of the consequences of that action. According to the dynamic systems view, even universal milestones, such as crawling, reaching, and walking, are learned through this process of adaptation: Infants modulate their movement patterns to fit a new task by exploring and selecting possible configurations (Adolph, 2018; Comalli, Persand, & Adolph, 2017).

To see how dynamic systems theory explains motor behavior, imagine that you offer a new toy to a baby named Gabriel (Thelen & others, 1993). There is no exact program that can tell Gabriel ahead of time how to move his arm and hand and fingers to grasp the toy. Gabriel must adapt to his goal—grasping the toy—and the context. From his sitting position, he must make split-second adjustments to extend his arm, holding his body steady so that his arm and torso don't plow into the toy. Muscles in his arm and shoulder contract and stretch in a host of combinations, exerting a variety of forces. He improvises a way to reach out with one arm and wrap his fingers around the toy.

Thus, according to dynamic systems theory, motor development is not a passive process in which genes dictate the unfolding of a sequence of skills over time. Rather, the infant actively puts together a skill to achieve a goal within the constraints set by the infant's body and environment. Nature and nurture, the infant and the environment, are all working together as part of an ever-changing system.

As we examine the course of motor development, we will describe how dynamic systems theory applies to some specific skills. First, though, let's examine the beginning of motor development: the infant's reflexes.

## REFLEXES

The newborn is not completely helpless. Among other things, it has some basic reflexes. For example, when submerged in water, the newborn automatically holds its breath and contracts its throat to keep water out.

Esther Thelen is shown conducting an experiment to discover how infants learn to control their arm movements to reach and grasp for objects. A computer device is used to monitor the infant's arm movements and to track muscle patterns. Thelen's research is conducted from a dynamic systems perspective. *What is the nature of this perspective?*

**reflexes** Built-in reactions to stimuli that govern the newborn's movements, which are automatic and beyond the newborn's control.

**rooting reflex** A newborn's built-in reaction that occurs when the infant's cheek is stroked or the side of the mouth is touched. In response, the infant turns his or her head toward the side that was touched, in an apparent effort to find something to suck.

**sucking reflex** A newborn's built-in reaction to automatically suck an object placed in its mouth. The sucking reflex enables the infant to get nourishment before he or she has associated a nipple with food and also serves as a self-soothing or self-regulating mechanism.

**Moro reflex** A neonatal startle response in which the newborn arches its back, throws its head back, flings out its arms and legs, and then pulls its arms and legs close to the center of the body.

**Reflexes** are built-in reactions to stimuli; they govern the newborn's movements, which are automatic and beyond the newborn's control. Reflexes are genetically carried survival mechanisms. They allow infants to respond adaptively to their environment before they have had the opportunity to learn. The rooting and sucking reflexes are important examples. Both have survival value for newborn mammals, who must find a mother's breast to obtain nourishment. The **rooting reflex** occurs when the infant's cheek is stroked or the side of the mouth is touched. In response, the infant turns its head toward the side that was touched in an apparent effort to find something to suck. The **sucking reflex** occurs when newborns automatically suck an object placed in their mouth. This reflex enables newborns to get nourishment before they have associated a nipple with food and also serves as a self-soothing or self-regulating mechanism.

Another example is the **Moro reflex**, which occurs in response to a sudden, intense noise or movement (see Figure 12). When startled, the newborn arches its back, throws back its head, and flings out its arms and legs. Then the newborn rapidly draws in its arms and legs. The Moro reflex is believed to be a way of grabbing for support while falling; it would have had survival value for our primate ancestors.

Some reflexes—coughing, sneezing, blinking, shivering, and yawning, for example—persist throughout life. They are as important for the adult as they are for the infant. Other reflexes, though, disappear several months following birth, as the infant's brain matures and voluntary control over many behaviors develops. The rooting and Moro reflexes, for example, tend to disappear when the infant is 3 to 4 months old.

The movements of some reflexes eventually become incorporated into more complex, voluntary actions. One important example is the **grasping reflex**, which occurs when something touches the infant's palms (see Figure 12). The infant responds by grasping tightly. By the end of the third month, the grasping reflex diminishes and the infant shows a more voluntary grasp. As its motor coordination becomes smoother, the infant will grasp objects, carefully manipulate them, and explore their qualities.

The old view of reflexes is that they were exclusively genetic, built-in mechanisms that governed the infant's movements. The new perspective on infant reflexes is that they are not automatic or completely beyond the infant's control. For example, infants can alternate the movement of their legs to make a mobile jiggle or change their sucking rate to listen to a recording (Adolph & Robinson, 2015).

## GROSS MOTOR SKILLS

Ask any parents about their baby, and sooner or later you are likely to hear about one or more motor milestones, such as "Cassandra just learned to crawl," "Jesse is finally sitting alone," or "Angela took her first step last week." Parents proudly announce such milestones as their children transform themselves from babies unable to lift their heads to toddlers who grab things off the grocery store shelf, chase a cat, and participate actively in the family's social life (Thelen, 2000). These milestones are examples of **gross motor skills**, which involve large-muscle activities such as moving one's arms and walking.

**The Development of Posture** How do gross motor skills develop? As a foundation, these skills require postural control. For example, to track moving objects, you must be able to control the movement of your head in order to stabilize your gaze; before you can walk, you must be able to balance on one leg.

Posture is more than just holding still and straight. Posture is a dynamic process that is linked with sensory information in the skin, joints, and muscles, which tell us where we are in space; in vestibular organs in the inner ear that regulate balance and equilibrium; and in vision and hearing (Soska, Robinson, & Adolph, 2015).

Newborn infants cannot voluntarily control their posture. Within a few weeks, though, they can hold their heads erect, and soon they can lift their heads while prone. By 2 months of age, babies can sit while supported on a lap or an infant seat, but they cannot sit independently until they are 6 or 7 months of age. Standing also develops gradually during the first year of life. By about 8 to 9 months of age, infants usually learn to pull themselves up and hold on to a chair, and they often can stand alone by about 10 to 12 months of age.

Newly crawling infant

Experienced walker

## FIGURE 13

### THE ROLE OF EXPERIENCE IN CRAWLING AND WALKING INFANTS' JUDGMENTS OF WHETHER TO GO DOWN A SLOPE

**Karen Adolph (1997)** found that locomotor experience rather than age was the primary predictor of adaptive responding on slopes of varying steepness. Newly crawling and walking infants could not judge the safety of the various slopes. With experience, they learned to avoid slopes where they would fall. When expert crawlers began to walk, they again made mistakes and fell, even though they had judged the same slope accurately when crawling. Adolph referred to this as the specificity of learning because it does not transfer across crawling and walking.

**Learning to Walk** Locomotion and postural control are closely linked, especially in walking upright (Kretch & Adolph, 2018). To walk upright, the baby must be able both to balance on one leg as the other is swung forward and to shift weight from one leg to the other.

Even young infants can make the alternating leg movements that are needed for walking. The neural pathways that control leg alternation are in place from a very early age, even at birth or before. Indeed, researchers have found that alternating leg movements occur during the *fetal period and at birth* (Adolph & Robinson, 2015). Both alternating leg movements and forward stepping movements occur early in development and are precursors to walking.

If infants can produce forward stepping movements so early, why does it take them so long to learn to walk? The key skills in learning to walk appear to be stabilizing balance on one leg long enough to swing the other forward and shifting weight without falling. These are difficult biomechanical problems to solve, and it takes infants about a year to do it.

In learning to locomote, infants learn what kinds of places and surfaces are safe for locomotion (Adolph, 2018; Karasik, Tamis-LeMonda, & Adolph, 2016). Karen Adolph (1997) investigated how experienced and inexperienced crawling infants and walking infants go down steep slopes (see Figure 13). Newly crawling infants, who averaged about 8½ months in age, rather indiscriminately went down the steep slopes, often falling in the process (with their mothers next to the slope to catch them). After weeks of practice, the crawling babies became more adept at judging which slopes were too steep to crawl down and which ones they could navigate safely. New walkers also could not judge the safety of the slopes, but experienced walkers accurately matched their skills with the steepness of the slopes. They rarely fell downhill, either refusing to go down the steep slopes or going down backward in a cautious manner. Experienced walkers perceptually assessed the situation—looking, swaying, touching, and thinking before they moved down the slope. With experience, both the crawlers and the walkers learned to avoid the risky slopes where they would fall, integrating perceptual information with the development of a new motor behavior. In this research, we again see the importance of perceptual-motor coupling in the development of motor skills. Thus, practice is very important in the development of new motor skills (Adolph & Berger, 2015).

Practice is especially important in learning to walk (Adolph, 2018; Adolph & Robinson, 2015). “Thousands of daily walking steps, each step slightly different from the last because of variations in the terrain and the continually varying biomechanical constraints on the body, may help infants to identify the relevant” combination of strength and balance required to improve their walking skills (Adolph, Vereijken, & Shrout, 2003, p. 495). In one study, Adolph and her colleagues (2012) observed 12- to 19-month-olds during free play. Locomotor experience was extensive, with the infants averaging 2,368 steps and 17 falls per hour.

A recent study explored how infants plan and guide their locomotion in the challenging context of navigating a series of bridges varying in width (Kretch & Adolph, 2018). Infants' visual exploration (direction of their gaze) was assessed using a head-mounted eye-tracking device, and their locomotor actions were captured using video. The 14-month-olds engaged in

**gross motor skills** Motor skills that involve large-muscle activities, such as walking.

visual exploration from a distance as an initial assessment before they crossed almost every bridge. The visual information led to modifications in their gait when approaching narrow bridges, and they used haptic (touch) information at the edge of the bridges. As they gained more walking experience, their exploratory behaviors became more efficient and they became more adept at deciding which bridges were safe to walk across.

Might the development of walking be linked to advances in other aspects of development? Walking allows the infant to gain contact with objects that were previously out of reach and to initiate interaction with parents and other adults, thereby promoting language development (Adolph & Robinson, 2015; He, Walle, & Campos, 2015). Thus, just as with advances in postural skills, walking skills can produce a cascade of changes in the infant's development (Marrus & others, 2018).

**The First Year: Motor Development Milestones and Variations** Figure 14 summarizes the range of ages at which infants accomplish various gross motor skills during the first year, culminating in the ability to walk easily. After studying Figure 14, you should be able to order the milestones and describe the typical ages at which babies reach these milestones.

A recent study found a number of factors that are linked to motor development in the first year of life (Flensborg-Madsen & Mortensen, 2017). Twelve developmental milestones were assessed, including grasping, rolling, sitting, crawling; standing and walking; and overall mean of milestones. A larger size at birth (such as birth weight, birth length, and head circumference) was the aspect of pregnancy and delivery that showed the strongest link to reaching motor milestones earlier. Mother's smoking in the last trimester of prenatal development was associated with reaching the motor milestones later. Also, increase in size (weight increase, length increase, and head increase) in the first year were related to reaching the motor milestones earlier. Breast feeding also was linked to reaching the milestones earlier.

However, the timing of these milestones, especially the later ones, may vary by as much as two to four months, and experiences can modify the onset of these accomplishments (Adolph, 2018). For example, since 1992, when pediatricians began recommending that parents place their babies on their backs to sleep, fewer babies crawled, and those who crawled did so later (Davis & others, 1998). Also, some infants do not follow the standard sequence of motor accomplishments. For example, many American infants never crawl on their belly or on their hands and knees. They may discover an idiosyncratic form of locomotion before walking, such as rolling or scooting, or they might never locomote until they are upright (Adolph & Robinson, 2015). In the African Mali tribe, most infants do not crawl (Bril, 1999). And in Jamaica, approximately one-fourth of babies skip crawling (Hopkins, 1991).

According to Karen Adolph and Sarah Berger (2005), “the old-fashioned view that growth and motor development reflect merely the age-related output of maturation is, at best, incomplete. Rather, infants acquire new skills with the help of their caregivers in a real-world environment of objects, surfaces, and planes.”

**Development in the Second Year** The motor accomplishments of the first year bring increasing independence, allowing infants to explore their environment more extensively and to initiate interaction with others more readily. In the second year of life, toddlers become more motorically skilled and mobile. Motor activity during the second year is vital to the child’s competent development, and few restrictions, except for safety, should be placed on their adventures.

By 13 to 18 months, toddlers can pull a toy attached to a string and use their hands and legs to climb a number of steps. By 18 to 24 months, toddlers can walk quickly or run stiffly for a short distance, balance on their feet in a squatting position while playing with objects on the floor, walk backward without losing their balance, stand and kick a ball without falling, stand and throw a ball, and jump in place.

Can parents give their babies a head start on becoming physically fit and physically talented through structured exercise classes? Most infancy experts recommend against structured exercise classes for babies. But there are other ways to guide infants’ motor development.

Mothers in developing countries tend to stimulate their infants’ motor skills more than mothers in more developed countries (Hopkins, 1991; Karasik & others, 2015). In many African, Indian, and Caribbean cultures, mothers massage and stretch their infants during daily baths (Adolph, Karasik, & Tamis-LeMonda, 2010). Mothers in the Gusii culture of Kenya also encourage vigorous movement in their babies.

Do these cultural variations make a difference in the infant’s motor development? When caregivers provide babies with physical guidance by physically handling them in special ways (such as stroking, massaging, or stretching) or by giving them opportunities for exercise, the infants often reach motor milestones earlier than infants whose caregivers have not provided these activities (Adolph, 2018; Adolph, Karasik, & Tamis-LeMonda, 2010; Karasik & others, 2015). For example, Jamaican mothers expect their infants to sit and walk alone two to three months earlier than English mothers do (Hopkins & Westra, 1990). And in sub-Saharan Africa, traditional practices in many villages involve mothers and siblings engaging babies in exercises, such as frequent exercise for trunk and pelvic muscles (Super & Harkness, 1997).

Many forms of restricted movement—such as Chinese sandbags, orphanage restrictions, and failure of caregivers to encourage movement in Budapest—have been found to produce substantial delays in motor development (Adolph, Karasik, & Tamis-LeMonda, 2010). In some rural Chinese provinces, for example, babies are placed in a bag of fine sand, which acts as a diaper and is changed once a day. The baby is left alone, face up, and is visited only when being fed by the mother (Xie & Young, 1999).

Some studies of *swaddling* (wrapping an infant tightly in a blanket) show slight delays in motor development, but other studies show no delays. Cultures that do swaddle infants usually do so early in the infant’s development when the infant is not yet mobile; when the infant becomes more mobile, swaddling decreases.

## FINE MOTOR SKILLS

Whereas gross motor skills involve large muscle activity, **fine motor skills** involve finely tuned movements. Grasping a toy, using a spoon, buttoning a shirt, or any activity that requires finger dexterity demonstrates fine motor skills. Infants have hardly any control over fine motor

skills at birth, but newborns do have many components of what will become finely coordinated arm, hand, and finger movements (McCormack, Hoerl, & Butterfill, 2012).

The onset of reaching and grasping marks a significant achievement in infants' ability to interact with their surroundings (Rachwani & others, 2015). During the first two years of life, infants refine how they reach and grasp (Dosso, Herrera, & Boudreau, 2017; Needham, 2009). Initially, infants reach by moving their shoulders and elbows crudely, swinging their arms toward an object. Later, when infants reach for an object they move their wrists, rotate their hands, and coordinate their thumb and forefinger. Infants do not have to see their own hands in order to reach for an object (Clifton & others, 1993). Cues from muscles, tendons, and joints, not sight of the limb, guide reaching by 4-month-old infants. Recent research studies found that short-term training involving practice of reaching movements increased both pre-term and full-term infants' reaching for and touching objects (Cunha & others, 2016; Guimaraes & Tudelia, 2015).

Infants refine their ability to grasp objects by developing two types of grasps. Initially, infants grip with the whole hand, which is called the *palmar grasp*. Later, toward the end of the first year, infants also grasp small objects with their thumb and forefinger, which is called the *pincer grip*. Their grasping system is very flexible. They vary their grip on an object depending on its size, shape, and texture, as well as the size of their own hands relative to the object's size. Infants grip small objects with their thumb and forefinger (and sometimes their middle finger too), but they grip large objects with all of the fingers of one hand or both hands.

*Perceptual-motor coupling* is necessary for the infant to coordinate grasping (Barrett, Traupman, & Needham, 2008). At different stages of development, infants use different perceptual systems to coordinate grasping. Four-month-old infants rely greatly on touch to determine how they will grip an object; 8-month-olds are more likely to use vision as a guide (Newell & others, 1989). This developmental change is efficient because vision lets infants preshape their hands as they reach for an object.

Experience plays a role in reaching and grasping. In a recent study, 3-month-olds who were not yet engaging in reaching behavior were provided with reaching experiences. These experiences were linked to increased object exploration and attention focusing skills at 15 months of age (Libertus, Joh, & Needham, 2016). In another study, 3-month-old infants participated in play sessions wearing "sticky mittens"—mittens with palms that stuck to the edges of toys and allowed the infants to pick up the toys" (Needham, Barrett, & Peterman, 2002, p. 279) (see Figure 15). Infants who participated in sessions with the mittens grasped and manipulated objects earlier in their development than a control group of infants who did not receive the "mittens" experience. The infants who had worn the sticky mittens looked at the objects longer, swatted at them more during visual contact, and were more likely to mouth the objects. In a later study, 5-month-old infants whose parents trained them to use the sticky mittens for 10 minutes a day over a two-week period showed advances in their reaching behavior at the end of the two weeks (Libertus & Needham, 2010). Also, in a recent study, 3-month-old infants participated in active motor training using sticky mittens that allowed them to pick up toys, and these infants engaged in more sophisticated object exploration at 5.5 months of age (Wiesen, Watkins, & Needham, 2016).

Just as infants need to exercise their gross motor skills, they also need to exercise their fine motor skills (Needham, 2009). Especially when they can manage a pincer grip, infants delight in picking up small objects. Many develop the pincer grip and begin to crawl at about the same time, and infants at this time pick up virtually everything in sight, especially on the floor, and put the objects in their mouth. Thus, parents need to be vigilant in regularly monitoring what objects are within the infant's reach (Keen, 2005).

Rachel Keen (2011; Keen, Lee, & Adolph, 2014) emphasizes that tool use is an excellent context for studying problem solving in infants because tool use provides information about how infants plan to reach a goal. Researchers in this area have studied infants' intentional actions, which range from picking up a spoon in different orientations to retrieving rakes from inside tubes. One study explored motor origins of tool use by assessing developmental changes in banging movements in 6- to 15-month-olds (Kahrs, Jung, & Lockman, 2013). In this study, younger infants were inefficient and variable when banging an object but by one year of age infants showed consistent straight up-and-down hand movements that resulted in precise aiming and consistent levels of force.

## 3 Sensory and Perceptual Development

**LG3**

Summarize the course of sensory and perceptual development in infancy.

What Are Sensation and Perception?

The Ecological View

Visual Perception

Other Senses

Intermodal Perception

Nature, Nurture, and Perceptual Development

Perceptual-Motor Coupling

How do sensations and perceptions develop? Can a newborn see? If so, what can it perceive? What about the other senses—hearing, smell, taste, and touch? What are they like in the newborn, and how do they develop? Can an infant put together information from two modalities, such as sight and sound? These are among the intriguing questions that we will explore in this section.

### WHAT ARE SENSATION AND PERCEPTION?

How does a newborn know that her mother's skin is soft rather than rough? How does a 5-year-old know what color his hair is? Infants and children "know" these things as a result of information that comes through the senses. Without vision, hearing, touch, taste, and smell, we would be isolated from the world; we would live in dark silence, a tasteless, colorless, feelingless void.

**Sensation** occurs when information interacts with sensory *receptors*—the eyes, ears, tongue, nostrils, and skin. The sensation of hearing occurs when waves of pulsating air are collected by the outer ear and transmitted through the bones of the inner ear to the auditory nerve. The sensation of vision occurs as rays of light contact the eyes, become focused on the retina, and are transmitted by the optic nerve to the visual centers of the brain.

**Perception** is the interpretation of what is sensed. The air waves that contact the ears might be interpreted as noise or as musical sounds, for example. The physical energy transmitted to the retina of the eye might be interpreted as a particular color, pattern, or shape, depending on how it is perceived.

The experiences of the first three years of life are almost entirely lost to us, and when we attempt to enter into a small child's world, we come as foreigners who have forgotten the landscape and no longer speak the native tongue.

### THE ECOLOGICAL VIEW

For the past several decades, much of the research on perceptual development in infancy has been guided by the ecological view of Eleanor and James J. Gibson (E. J. Gibson, 1969, 1989, 2001; J. J. Gibson, 1966, 1979). They argue that we do not have to take bits and pieces of data from sensations and build up representations of the world in our minds. Instead, our perceptual system can select from the rich information that the environment itself provides.

**sensation** The product of the interaction between information and the sensory receptors—the eyes, ears, tongue, nostrils, and skin.

**perception** The interpretation of what is sensed.

How would you use the Gibsons' ecological theory of perception and the concept of affordance to explain the role that perception is playing in this baby's activity?

©Ryan KC Wong/Getty Images

According to the Gibsons' **ecological view**, we directly perceive information that exists in the world around us. This view is called *ecological* "because it connects perceptual capabilities to information available in the world of the perceiver" (Kellman & Arterberry, 2006, p. 112). Thus, perception brings us into contact with the environment so we can interact with and adapt to it (Kretch & Adolph, 2017). Perception is designed for action. Perception gives people information such as when to duck, when to turn their bodies as they move through a narrow passageway, and when to put their hands up to catch something.

In the Gibsons' view, objects have **affordances**, which are opportunities for interaction offered by objects that fit within our capabilities to perform activities. A pot may afford you something to cook with, and it may afford a toddler something to bang. Adults typically know when a chair is appropriate for sitting, when a surface is safe for walking, or when an object is within reach. An infant who runs down a steep slope or crawls across a narrow beam is determining the affordances of the slope or beam. We directly and accurately perceive these affordances by sensing information from the environment—the light or sound reflecting from the surfaces of the world—and from our own bodies through muscle receptors, joint receptors, and skin receptors, for example (Adolph & Kretch, 2015).

An important developmental question is: What affordances can infants or children detect and use? In one study, for example, when babies who could walk were faced with a squishy waterbed, they stopped and explored it, then chose to crawl rather than walk across it (Gibson & others, 1987). They combined perception and action to adapt to the demands of the task.

Similarly, as we described earlier in the section on motor development, infants who were just learning to crawl or just learning to walk were less cautious when confronted with a steep slope than experienced crawlers or walkers were (Adolph, 1997). The more experienced crawlers and walkers perceived that a slope *affords* the possibility for not only faster locomotion but also for falling. Again, infants coupled perception and action to make a decision about what to do in their environment. Through perceptual development, children become more efficient at discovering and using affordances (Kretch & Adolph, 2017).

Studying infants' perceptions has not been an easy task. For instance, if newborns have limited communication abilities and are unable to verbalize what they are seeing, hearing, smelling, and so on, how can we study their perception? *Connecting Through Research* describes some of the ingenious ways researchers study infants' perceptions.

## VISUAL PERCEPTION

What do newborns see? How does visual perception develop in infancy?

**Visual Acuity and Human Faces** Psychologist William James (1890/1950) called the newborn's perceptual world a "blooming, buzzing confusion." More than a century later, we can safely say that he was wrong (Bremner & others, 2017; Damon & others, 2018; Singarajah & others, 2017; Weatherhead & White, 2017). Even the newborn perceives a world with some order. That world, however, is far different from the one perceived by the toddler or the adult.

Just how well can infants see? At birth, the nerves and muscles and lens of the eye are still developing. As a result, newborns cannot see small things that are far away. The newborn's vision is estimated to be 20/240 on the well-known Snellen chart used for eye examinations, which means that a newborn can see at 20 feet what an adult with normal vision can see at 240 feet (Aslin & Lathrop, 2008). In other words, an object 20 feet away is only as clear to the newborn as it would be if it were 240 feet away from an adult with normal vision (20/20). By 6 months of age, though, on average vision is 20/40 (Aslin & Lathrop, 2008).

Faces are possibly the most important visual stimuli in children's social environment, and it is important that they extract key information from others' faces (Singarajah & others, 2017; Sugden & Moulson, 2017). Infants show an interest in human faces soon after birth (Johnson & Hannon, 2015). Research shows that within hours after infants are born, they prefer to look at faces rather than other objects and to look at attractive faces more than at unattractive ones (Lee & others, 2013).

**ecological view** The view that perception functions to bring organisms in contact with the environment and to increase adaptation.

**affordances** Opportunities for interaction offered by objects that fit within our capabilities to perform functional activities.

## How Can Newborns' Perception Be Studied?

The creature has poor motor coordination and can move itself only with great difficulty. Although it cries when uncomfortable, it uses few other vocalizations. In fact, it sleeps most of the time, about 16 to 17 hours a day. You are curious about this creature and want to know more about what it can do. You think to yourself, "I wonder if it can see. How could I find out?"

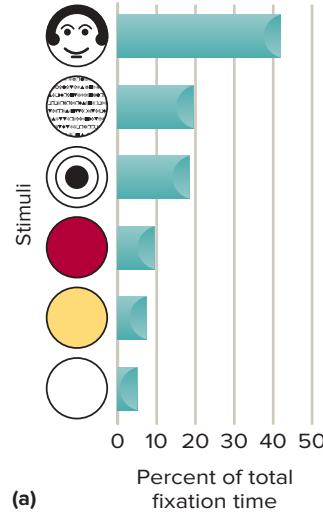

You obviously have a communication problem with the creature. You must devise a way that will allow the creature to "tell" you that it can see. While examining the creature one day, you make an interesting discovery. When you move an object horizontally in front of the creature, its eyes follow the object's movement.

The creature's eye movement suggests that it has at least some vision. In case you haven't already guessed, the creature you have been reading about is the human infant, and the role you played is that of a researcher interested in devising techniques to learn about the infant's visual perception. After years of work, scientists have developed research methods and tools sophisticated enough to examine the subtle abilities of infants and to interpret their complex actions (Bendersky & Sullivan, 2007).

Following are six research techniques that are used to study sensory and perceptual development: (1) visual preference method, (2) habituation/dishabituation, (3) high-amplitude sucking, (4) orienting response, (5) eye tracking, and (6) equipment.

### Visual Preference Method

Robert Fantz (1963) was a pioneer in this effort. Fantz made an important discovery that advanced the ability of researchers to investigate infants' visual perception: Infants look at different things for different lengths of time. Fantz placed an infant in a "looking chamber," which had two visual displays on the ceiling above the infant's head. An experimenter viewed the infant's eyes by looking through a peephole. If the infant was fixating on one of the displays, the experimenter could see the display's reflection in the infant's eyes. This allowed

**FIGURE 16**

**FANTZ'S EXPERIMENT ON INFANTS' VISUAL PERCEPTION.** (a) Infants 2 to 3 weeks old preferred to look at some stimuli more than others. In Fantz's experiment, infants preferred to look at patterns rather than at color or brightness. For example, they looked longer at a face, a piece of printed matter, or a bull's-eye than at red, yellow, or white discs. (b) Fantz used a "looking chamber" to study infants' perception of stimuli.

the experimenter to determine how long the infant looked at each display. Fantz (1963) found that infants only 2 days old looked longer at patterned stimuli, such as faces and concentric circles, than at red, white, or yellow discs. Infants 2 to 3 weeks old also preferred to look at patterns—a face, a piece of printed matter, or a bull's-eye—longer than at red, yellow, or white discs (see Figure 16). Fantz's research method—studying whether infants can distinguish one stimulus from another by measuring the length of time they attend to different stimuli—is referred to as the **visual preference method**.

### Habituation and Dishabituation

Another way that researchers have studied infant perception is to present a stimulus (such as a sight or a sound) a number of times. If the infant decreases its response to the stimulus after several presentations, it indicates that the infant is no longer interested in looking at the stimulus. If the researcher now presents a new stimulus, the infant's response will recover—indicating the infant can discriminate between the old and new stimulus (Messinger & others, 2017).

**Habituation** is the name given to decreased responsiveness to a stimulus after repeated presentations of the stimulus. **Dishabituation** is the recovery of a habituated response after a change in stimulation. Newborn infants can habituate to repeated sights, sounds, smells, or

**HABITUATION AND DISHABITUATION.** In the first part of one study, (a) 7-hour-old newborns were shown a stimulus. As indicated, the newborns looked at it an average of 41 seconds when it was first presented to them (Slater, Morison, & Somers, 1988). Over seven more presentations of the stimulus, they looked at it less and less. In the second part of the study, (b) infants were presented with both the familiar stimulus to which they had just become habituated and a new stimulus (which was rotated 90 degrees). The newborns looked at the new stimulus three times as long as the familiar stimulus.

touches (Rovee-Collier, 2004). Among the measures researchers use in habituation studies are sucking behavior (sucking stops when the young infant attends to a novel object), heart and respiration rates, and the length of time the infant looks at an object. Figure 17 shows the results of one study of habituation and dishabituation with newborns (Slater, Morison, & Somers, 1988).

### High-Amplitude Sucking

To assess an infant's attention to sound, researchers often use a method called high-amplitude sucking. In this method, infants are given a nonnutritive nipple to suck, and the nipple is connected to a sound-generating system. The researcher computes a baseline high-amplitude sucking rate in a one-minute silent period. Following the baseline, presentation of a sound is made contingent on the rate of high-amplitude sucking. Initially babies suck frequently so the sound occurs often. Gradually they lose interest in hearing the same sound, so they begin to suck less often. Then the researcher changes the sound that is being presented. If the babies renew their vigorous sucking, the inference is that they

have noticed the sound change and are sucking more because they want to hear the interesting new sound (Menn & Stoel-Gammon, 2009).

### The Orienting Response and Eye-Tracking

A technique that can be used to determine whether an infant can see or hear is the orienting response, which involves turning one's head toward a sight or sound. However, the most important recent advance in measuring infant perception is the development of sophisticated eye-tracking equipment (Boardman & Fletcher-Watson, 2017; Kretch & Adolph, 2017; van Renswoude & others, 2018). Eye-tracking consists of measuring eye movements that follow (track) a moving object and can be used to evaluate an infant's early visual ability, or a startle response can determine an infant's reaction to a noise (Bendersky & Sullivan, 2007). Figure 18 shows an infant wearing an eye-tracking headgear in a recent study on visually guided motor behavior and social interaction. Most studies of infant development use remote optics eye trackers that have a camera that is not attached to the infant's head.

(continued)

One of the main reasons that infant perception researchers are so enthusiastic about the availability of sophisticated eye-tracking equipment is that looking time is among the most important measures of infant perceptual and cognitive development (Aslin, 2012). The new eye-tracking equipment allows for far greater precision in assessing various aspects of infant looking and gaze than is possible with human observation (Boardman & Fletcher-Watson, 2017; Law & others, 2018). Among the areas of infant perception in which eye-tracking equipment is being used are attention (Jia & others, 2017; Meng, Uto, & Hashiya, 2017), memory (Kingo & Krogaard, 2015), and face processing (Chhaya & others, 2018). Further, eye-tracking equipment is improving our understanding of atypically developing infants, such as those who have autism or who were born preterm (Falck-Ytter & others, 2018; Finke, Wilkinson, & Hickerson, 2017; Liberati & others, 2017).

One eye-tracking study shed light on the effectiveness of TV programs and DVDs that claim to educate infants (Kirkorian, Anderson, & Keen, 2012). In this study, 1-year-olds, 4-year-olds, and adults watched *Sesame Street* and the eye-tracking equipment recorded precisely what they looked at on the screen. The 1-year-olds were far less likely to consistently look at the same part of the screen as their older counterparts, suggesting that the 1-year-olds showed little understanding

of the *Sesame Street* video but instead were more likely to be attracted by what was salient than by what was relevant.

### Equipment

Technology can facilitate the use of most methods for investigating the infant's perceptual abilities. Video-recording equipment allows researchers to investigate elusive behaviors. High-speed computers make it possible to perform complex data analysis in minutes. Other equipment records respiration, heart rate, body movement, visual fixation, and sucking behavior, which provide clues to what the infant is perceiving. For example, some researchers use equipment that detects whether a change in infants' respiration follows a change in the pitch of a sound. If so, it suggests that the infants heard the pitch change.

*Scientists have had to be very creative when assessing the development of infants, discovering ways to "interview" them even though they cannot yet talk. Other segments of the population, such as adults who have suffered from a stroke, have difficulty communicating verbally. What kinds of methods or equipment do you think researchers might use to evaluate their perceptual abilities?*

Figure 19 shows a computer estimation of what a picture of a face looks like to an infant at different ages from a distance of about 6 inches. Infants spend more time looking at their mother's face than a stranger's face as early as 12 hours after being born (Bushnell, 2003). By 3 months of age, infants (1) match voices to faces, (2) distinguish between male and female faces, and (3) discriminate between faces of their own ethnic group and those of other ethnic groups (Gaither, Pauker, & Johnson, 2012; Kelly & others, 2005, 2007; Lee & others, 2013; Liu & others, 2011, 2015).

Experience plays an important role in face processing in infancy and later in development. One aspect of this experience involves the concept of *perceptual narrowing*, in which infants are more likely to distinguish between faces to which they have been exposed than faces that they have never seen before (Kobayashi & others, 2018; Minar & Lewkowicz, 2018; Tham, Bremner, & Hayes, 2017).

**Color Vision** The infant's color vision also improves (Yang & others, 2015). By 8 weeks, and possibly as early as 4 weeks, infants can discriminate between some colors (Kelly, Borchert, &

**size constancy** The recognition that an object remains the same even though the retinal image of the object changes as the observer moves toward or away from the object.

**shape constancy** The recognition that an object's shape remains the same even though its orientation to the observer changes.

**FIGURE 20**

**INFANTS' PREDICTIVE TRACKING OF A BRIEFLY OCCLUDED MOVING BALL.** The top picture shows the visual scene that infants experienced. At the beginning of each event, a multicolored ball bounced up and down with an accompanying bouncing sound, and then rolled across the floor until it disappeared behind the partition. The other three pictures show the three stimulus events that the 5- to 9-month-old infants experienced: (a) Gradual occlusion—the ball gradually disappears behind the right side of the occluding partition located in the center of the display. (b) Abrupt occlusion—the ball abruptly disappears when it reaches the location of the white circle and then abruptly reappears two seconds later at the location of the second white circle on the other side of the occluding partition. (c) Implosion—the rolling ball quickly decreases in size as it approaches the occluding partition and rapidly increases in size as it reappears on the other side of the occluding partition.

Teller, 1997). By 4 months of age, they have color preferences that mirror adults' in some cases, preferring saturated colors such as royal blue over pale blue, for example (Bornstein, 1975). In part, the changes in vision described here reflect biological origins and maturation (Skelton & others, 2017). Experience, however, is also necessary for color vision to develop normally (Sugita, 2004).

**Perceptual Constancy** Some perceptual accomplishments are especially intriguing because they indicate that the infant's perception goes beyond the information provided by the senses (Bremner & others, 2017). This is the case in perceptual constancy, in which sensory stimulation is changing but perception of the physical world remains constant. If infants did not develop perceptual constancy, each time they saw an object at a different distance or in a different orientation, they would perceive it as a different object. Thus, the development of perceptual constancy allows infants to perceive their world as stable. Two types of perceptual constancy are size constancy and shape constancy.

**Size constancy** is the recognition that an object remains the same even though the retinal image of the object changes as you move toward or away from the object. The farther away from us an object is, the smaller its image is on our eyes. Thus, the size of an object on the retina is not sufficient to tell us its actual size. For example, you perceive a bicycle standing right in front of you as smaller than the car parked across the street, even though the bicycle casts a larger image on your eyes than the car does. When you move away from the bicycle, you do not perceive it to be shrinking even though its image on your retinas shrinks; you perceive its size as constant.

But what about babies? Do they have size constancy? Researchers have found that babies as young as 3 months of age show size constancy (Bower, 1966; Day & McKenzie, 1973). However, at 3 months of age, this ability is not full-blown. It continues to develop until 10 or 11 years of age (Kellman & Banks, 1998).

**Shape constancy** is the recognition that an object remains the same shape even though its orientation to us changes. Look around the room you are in right now. You likely see objects of varying shapes, such as tables and chairs. If you get up and walk around the room, you will see these objects from different sides and angles. Even though your retinal image of the objects changes as you walk and look, you will still perceive the objects as having the same shape.

Do babies have shape constancy? As with size constancy, researchers have found that babies as young as 3 months of age have shape constancy (Bower, 1966; Day & McKenzie, 1973). Three-month-old infants, however, do not have shape constancy for irregularly shaped objects such as tilted planes (Cook & Birch, 1984).

**Perception of Occluded Objects** Look around where you are now. You likely see that some objects are partly occluded by other objects that are in front of them—possibly a desk behind a chair, some books behind a computer, or a car parked behind a tree. Do infants perceive an object as complete when it is occluded by an object in front of it?

In the first two months of postnatal development, infants don't perceive occluded objects as complete; instead, they perceive only what is visible (Johnson & Hannon, 2015). Beginning at about 2 months of age, infants develop the ability to perceive that occluded objects are whole (Slater, Field, & Hernandez-Reif, 2007). How does perceptual completion develop? In Scott Johnson's research (2010, 2011, 2013), learning, experience, and self-directed exploration via eye movements play key roles in the development of perceptual completion in young infants.

Many objects that are occluded appear and disappear behind closer objects, as when you are walking down the street and see cars appear and disappear behind buildings as they move or you move. Infants develop the ability to track briefly occluded moving objects at about 3 to 5 months of age (Bertenthal, 2008). One study explored the ability of 5- to 9-month-old infants to track moving objects that disappeared gradually behind an occluded partition, disappeared abruptly, or imploded (shrank quickly in size) (Bertenthal, Longo, & Kenny, 2007) (see Figure 20). In this study, the infants were more likely to accurately predict the reappearance of the moving object when it disappeared gradually than when it vanished abruptly or exploded.

**Depth Perception** Might infants even perceive depth? To investigate this question, Eleanor Gibson and Richard Walk (1960) constructed a miniature cliff with a drop-off covered by glass in their laboratory. They placed infants on the edge of this visual cliff and had their mothers coax them to crawl onto the glass (see Figure 21). Most infants would not crawl out on the glass, choosing instead to remain on the shallow side, an indication that they could perceive depth.

## OTHER SENSES

Other sensory systems besides vision also develop during infancy. We will explore development in hearing, touch and pain, smell, and taste.

**Hearing** During the last two months of pregnancy, as the fetus nestles in its mother's womb, it can hear sounds such as the mother's voice, music, and so on (Kisilevsky & others, 2009). Two psychologists wanted to find out if a fetus who heard Dr. Seuss' classic story *The Cat in the Hat* while still in the mother's womb would prefer hearing the story after birth (DeCasper & Spence, 1986). During the last months of pregnancy, 16 women read *The Cat in the Hat* to their fetuses. Then shortly after the babies were born, they listened to recordings of their mothers reading either *The Cat in the Hat* or a story with a different rhyme and pace, *The King, the Mice and the Cheese* (which was not read to them during prenatal development). The infants sucked on a nipple in a different way when they listened to the recordings of the two stories, suggesting that the infants recognized the pattern and tone of *The Cat in the Hat* (see Figure 22). This study illustrates not only that a fetus can hear but also that it has a remarkable ability to learn and remember even before birth. An fMRI study confirmed capacity of the fetus to hear at 33 to 34 weeks into the prenatal period by assessing fetal brain response to auditory stimuli (Jardri & others, 2012).

The fetus can also recognize the mother's voice, as one study demonstrated (Kisilevsky & others, 2003). Sixty term fetuses (mean gestational age, 38.4 weeks) were exposed to a tape recording either of their mother or of a female stranger reading a passage. The sounds of the tape were delivered through a loudspeaker held just above the mother's abdomen. Fetal heart rate increased in response to the mother's voice but decreased in response to the stranger's voice.

What kind of changes in hearing take place during infancy? They involve perception of a sound's loudness, pitch, and localization:

- **Loudness.** Immediately after birth, infants cannot hear soft sounds quite as well as adults can; a stimulus must be louder to be heard by a newborn than by an adult (Trehub & others, 1991). For example, an adult can hear a whisper from about 4 to 5 feet away, but a newborn requires that sounds be closer to a normal conversational level to be heard at that distance. By three months of age, infants' perception of sounds improves, although some aspects of loudness perception do not reach adult levels until 5 to 10 years of age (Trainor & He, 2013).
- **Pitch.** Infants are also less sensitive to the pitch of a sound than adults are. *Pitch* is the perception of the frequency of a sound. A soprano voice sounds high-pitched, a bass voice low-pitched. Infants are less sensitive to low-pitched sounds and are more likely to hear high-pitched sounds (Aslin, Jusczyk, & Pisoni, 1998). One study revealed that by 7 months of age, infants can process simultaneous pitches when they hear voices but they are more likely to encode the higher-pitched voice (Marie & Trainor, 2013). By 2 years of age, infants have considerably improved their ability to distinguish sounds of different pitch.
- **Localization.** Even newborns can determine the general location from which a sound is coming, but by 6 months of age, they are more proficient at *localizing* sounds or detecting their origins. Their ability to localize sounds continues to improve during the second year (Burnham & Mattock, 2010).

Although infants can process variations in sound loudness, pitch, and localization, these aspects of hearing continue to improve during the childhood years (Trainor & He, 2013).

### Touch and Pain

Do newborns respond to touch? Can they feel pain?

Newborns do respond to touch. A touch to the cheek produces a turning of the head; a touch to the lips produces sucking movements.

Regular gentle tactile stimulation prenatally may have positive developmental outcomes. For example, a recent study found that 3-month-olds who had regular gentle tactile stimulation as fetuses were more likely to have an easy temperament than their counterparts who had irregular gentle or no tactile stimulation as fetuses (Wang, Hua, & Xu, 2015).

**FIGURE 21**

### EXAMINING INFANTS' DEPTH PERCEPTION ON THE VISUAL CLIFF.

Eleanor Gibson and Richard Walk (1960) found that most infants would not crawl out on the glass, which, according to Gibson and Walk, indicated that they had depth perception. However, some critics point out that the visual cliff is a better indication of the infant's social referencing and fear of heights than of the infant's perception of depth.

### Sensation and Perception

Kangaroo care and massage therapy are associated with many positive outcomes in preterm and low birth weight infants. Connect to “Prenatal Development and Birth.”

Newborns can also feel pain (Bellieni & others, 2016). If you have a son and consider whether he should be circumcised, the issue of an infant’s pain perception probably will become important to you. Circumcision is usually performed on infant boys about the third day after birth. Will your son experience pain if he is circumcised when he is 3 days old? An investigation by Megan Gunnar and her colleagues (1987) found that newborn infant males cried intensely during circumcision. Circumcised infants also display amazing resiliency. Within several minutes after the surgery, they can nurse and interact in a normal manner with their mothers. And, if allowed to, the newly circumcised newborn drifts into a deep sleep, which seems to serve as a coping mechanism.

For many years, doctors performed operations on newborns without anesthesia. This practice was accepted because of the dangers of anesthesia and because of the supposition that newborns do not feel pain. As researchers demonstrated that newborns can feel pain, the practice of operating on newborns without anesthesia has been challenged. Anesthesia now is used in some circumcisions (Morris & others, 2012).

Recent neuroimaging studies indicate that newborn infants likely experience some aspects of pain similarly to adults (Ranger & Grunau, 2015). Magnetic resonance imaging (MRI) studies of adults have found that there is a complex brain activity network that underlies pain, which is called the “pain matrix.” The pain matrix brain regions consist of areas located in the thalamus, somatosensory cortex, and amygdala (Denk, McMahon, & Tracey, 2014). In a recent study, researchers discovered that 18 of the 20 regions in the adult pain matrix also are present in the newborn’s pain matrix (Goksan & others, 2015). However, a major brain region in the adult’s pain matrix that was not present in the infant’s was the amygdala, which involves emotional responses. Also in this study, the MRI information revealed that the pain threshold in newborns occurs at a lower level of stimulation than for adults, confirming newborns’ heightened pain sensitivity that has been found in earlier behavioral studies. And in a recent study, kangaroo care was effective in reducing neonatal pain, especially indicated by the significantly lower level of crying when the care was instituted after the newborn’s blood had been drawn by a heel stick (Seo, Lee, & Ahn, 2016).

**FIGURE 23**

### NEWBORNS’ PREFERENCE FOR THE SMELL OF THEIR MOTHER’S BREAST PAD.

**PAD.** In the experiment by MacFarlane (1975), 6-day-old infants preferred to smell their mother’s breast pad rather than a clean one that had never been used, but 2-day-old infants did not show this preference, indicating that odor preference requires several days of experience to develop.

©Jean Guichard

**Smell** Newborns can differentiate odors (Doty & Shah, 2008). The expressions on their faces seem to indicate that they like the way vanilla and strawberries smell but do not like the way rotten eggs and fish smell (Steiner, 1979). In one investigation, 6-day-old infants who were breast fed showed a clear preference for smelling their mother’s breast pad rather than a clean breast pad (MacFarlane, 1975) (see Figure 23). However, when they were 2 days old they did not show this preference, indicating that they require several days of experience to recognize this odor.

**Taste** Sensitivity to taste is present even before birth (Doty & Shah, 2008). Human newborns learn tastes prenatally through the amniotic fluid and in breast milk after birth (Beauchamp & Mennella, 2009). In one study, even at only 2 hours of age, babies made different facial expressions when they tasted sweet, sour, and bitter solutions (Rosenstein & Oster, 1988). At about 4 months of age, infants begin to prefer salty tastes, which as newborns they had found to be aversive (Doty & Shah, 2008).

## INTERMODAL PERCEPTION

Imagine yourself playing basketball or tennis. You are experiencing many visual inputs: the ball coming and going, other players moving around, and so on. However, you are experiencing many auditory inputs as well: the sound of the ball bouncing or being hit, the grunts and groans of other players, and so on. There is good correspondence between much of the visual and auditory information: When you see the ball bounce, you hear a bouncing sound; when a player stretches to hit a ball, you hear a groan. When you look at and listen to what is going on, you do not experience just the sounds or just the sights—you put all these things together. You experience a unitary episode. This is **intermodal perception**, which involves integrating information from two or more sensory modalities, such as vision and hearing (Bremner & Spence, 2017; Hannon, Schachner, & Nave-Blodgett, 2017; Nomikou, Koke, & Rohlfing, 2017). Most perception is intermodal (Bahrick, 2010).

Early, exploratory forms of intermodal perception exist even in newborns (Bahrick & Hollich, 2008; Bremner, 2017; Guellai & others, 2016). For example, newborns turn their

**intermodal perception** The ability to relate and integrate information from two or more sensory modalities, such as vision and hearing.

eyes and their head toward the sound of a voice or rattle when the sound is maintained for several seconds (Clifton & others, 1981), but the newborn can localize a sound and look at an object only in a crude way (Bechtold, Bushnell, & Salapatek, 1979). These early forms of intermodal perception become sharpened with experience in the first year of life (Bremner & Spence, 2017; Kirkham & others, 2012). In one study, infants as young as 3 months old looked longer at their parents when they also heard their voices (Spelke & Owsley, 1979). Thus, even young infants can coordinate visual-auditory information involving people.

Can young infants put vision and sound together as precisely as adults do? In the first six months, infants have difficulty connecting sensory input from different modes, but in the second half of the first year they show an increased ability to make this connection mentally (Hannon, Schachner, & Nave-Blodgett, 2017).

What is intermodal perception? Which two senses is this infant using to integrate information about the blocks?

## NATURE, NURTURE, AND PERCEPTUAL DEVELOPMENT

Now that we have discussed many aspects of perceptual development, let's explore one of developmental psychology's key issues in relation to perceptual development: the nature-nurture issue. There has been a longstanding interest in how strongly infants' perception is influenced by nature or nurture (Bremner, 2017; Chen & others, 2017; Johnson & Hannon, 2015). In the field of perceptual development, nature proponents are referred to as *nativists* and those who emphasize learning and experience are called *empiricists*.

In the nativist view, the ability to perceive the world in a competent, organized way is inborn or innate. A completely nativist view of perceptual development no longer is accepted in developmental psychology.

The Gibsons argued that a key question in infant perception is what information is available in the environment and how infants learn to generate, differentiate, and discriminate the information—certainly not a nativist view. The Gibsons' ecological view also is quite different from Piaget's constructivist view. According to Piaget, much of perceptual development in infancy must await the development of a sequence of cognitive stages for infants to construct more complex perceptual tasks. Thus, in Piaget's view the ability to perceive size and shape constancy, a three-dimensional world, intermodal perception, and so on, develops later in infancy than the Gibsons envision.

The longitudinal research of Daphne Maurer and her colleagues (Chen & others, 2017; Lewis & Maurer, 2005, 2009; Maurer, 2016; Maurer & Lewis, 2013; Maurer & others, 1999) has focused on infants born with cataracts—a thickening of the lens of the eye that causes vision to become cloudy, opaque, and distorted and thus severely restricts infants' ability to experience their visual world. Studying infants whose cataracts were removed at different points in development, they discovered that those whose cataracts were removed and new lenses placed in their eyes in the first several months after birth showed a normal pattern of visual development. However, the longer the delay in removing the cataracts, the more their visual development was impaired. In their research, Maurer and her colleagues (2007) have found that experiencing patterned visual input early in infancy is important for holistic and detailed face processing after infancy. Maurer's research program illustrates how deprivation and experience influence visual development, revealing an early sensitive period when visual input is necessary for normal visual development (Chen & others, 2017; Maurer & Lewis, 2013).

Today, it is clear that just as an extreme nativist position on perceptual development is unwarranted, an extreme empiricist position also is unwarranted. Much of very early perception develops from innate (nature) foundations, and the basic foundation of many perceptual abilities can be detected in newborns (Bornstein, Arterberry, & Mash, 2015). However, as infants develop, environmental experiences (nurture) refine or calibrate many perceptual functions, and they may be the driving force behind some functions (Amso & Johnson, 2010). The accumulation of experience with and knowledge about their perceptual world contributes to infants' ability to process coherent perceptions of people and things (Bremner & others, 2016; Johnson & Hannon, 2015). Thus, a full portrait of perceptual development includes the influence of nature, nurture, and a developing sensitivity to information (Bremner & others, 2016; Chen & others, 2017; Maurer, 2016).

## PERCEPTUAL-MOTOR COUPLING

As we come to the end of this chapter, we return to the important theme of perceptual-motor coupling. The distinction between perceiving and doing has been a time-honored tradition in psychology. However, a number of experts on perceptual and motor development question whether this distinction makes sense (Adolph, 2018; Thelen & Smith, 2006). The main thrust of research in Esther Thelen's dynamic systems approach is to explore how people assemble motor behaviors for perceiving and acting. The main theme of the ecological approach of Eleanor and James J. Gibson is to discover how perception guides action. Action can guide perception, and perception can guide action. Only by moving one's eyes, head, hands, and arms and by moving from one location to another can an individual fully experience his or her environment and learn how to adapt to it. Perception and action are coupled (Kretch & Adolph, 2018).

Babies, for example, continually coordinate their movements with perceptual information to learn how to maintain balance, reach for objects in space, and move across various surfaces and terrains (Bremner & others, 2017). They are motivated to move by what they perceive. Consider the sight of an attractive toy across the room. In this situation, infants must perceive the current state of their bodies and learn how to use their limbs to reach the toy. Although their movements at first are awkward and uncoordinated, babies soon learn to select patterns that are appropriate for reaching their goals.

Equally important is the other part of the perception-action coupling. That is, action educates perception (Adolph, 2018). For example, watching an object while exploring it manually helps infants to determine its texture, size, and hardness. Locomoting in the environment teaches babies about how objects and people look from different perspectives, or whether various surfaces will support their weight.

How do infants develop new perceptual-motor couplings? Recall from our discussion earlier in this chapter that in the traditional view of Gesell, infants' perceptual-motor development is prescribed by a genetic plan to follow a fixed and sequential progression of stages in development. The genetic determination view has been replaced by the dynamic systems view that infants learn new perceptual-motor couplings by assembling skills for perceiving and acting. New perceptual-motor coupling is not passively accomplished; rather, the infant actively develops a skill to achieve a goal within the constraints set by the infant's body and the environment (Kretch & Adolph, 2018).

Children perceive in order to move and move in order to perceive. Perceptual and motor development do not occur in isolation from each other but instead are coupled.

In the next chapter, you will read about the remarkable cognitive changes that characterize infant development and how soon infants are able to competently process information about their world. Advances in infants' cognitive development—together with the development of the brain and perceptual-motor advances discussed in this chapter—allow infants to adapt more effectively to their environment. Later in this text, we will further explore physical development when we examine how children progress through early childhood (ages 3 to 5). Young children's physical development continues to change and to become more coordinated in early childhood, although gains in height and weight are not as dramatic in early childhood as in infancy.

# Physical Development in Infancy

## 1 Physical Growth and Development in Infancy

LG1

Discuss physical growth and development in infancy.

Patterns of Growth

- The cephalocaudal pattern is the sequence in which growth proceeds from top to bottom. The proximodistal pattern is the sequence in which growth starts at the center of the body and moves toward the extremities.

Height and Weight

- The average North American newborn is 20 inches long and weighs 7.6 pounds. Infants grow about 1 inch per month in the first year and nearly triple their weight by their first birthday. The rate of growth slows in the second year.

The Brain

- One of the most dramatic changes in the brain in the first two years of life is dendritic spreading, which increases the connections between neurons. Myelination, which speeds the conduction of nerve impulses, continues through infancy and even into adolescence.

- The cerebral cortex has two hemispheres (left and right). Lateralization refers to specialization of function in one hemisphere or the other. Early experiences play an important role in brain development.

- Neural connections are formed early in an infant's life. Before birth, genes mainly direct neurons to different locations. After birth, the inflowing stream of sights, sounds, smells, touches, language, and eye contact helps to shape the brain's neural connections, as does stimulation from caregivers and others. The neuroconstructivist view, in which brain development is influenced by a person's environment and experiences, is an increasingly popular perspective.

Sleep

- Newborns usually sleep about 18 hours a day. By 6 months of age, many American infants approach adult-like sleeping patterns. REM sleep—during which dreaming occurs—is present more in early infancy than in childhood and adulthood.

- Sleeping arrangements for infants vary across cultures. In America, infants are more likely to sleep alone than in many other cultures. Some experts believe shared sleeping can lead to sudden infant death syndrome (SIDS), a condition that occurs when a sleeping infant suddenly stops breathing and dies without an apparent cause. However, it is generally accepted that the most critical factor in predicting whether an infant will develop SIDS is prone sleeping.

- Infants need to consume about 50 calories per day for each pound they weigh. The growing consensus is that in most instances breast feeding is superior to bottle feeding for both the infant and the mother, although the correlational nature of studies must be considered.

Nutrition

- Severe infant malnutrition is still prevalent in many parts of the world. A special concern in impoverished countries is early weaning from breast milk and the misuse and hygiene problems associated with bottle feeding in these countries. The Women, Infants, and Children (WIC) program has produced positive benefits in low-income families in the United States.

## 2 Motor Development

The Dynamic Systems View

Reflexes

Gross Motor Skills

Fine Motor Skills

**LG2**

Describe infants' motor development.

- Thelen's dynamic systems theory seeks to explain how motor behaviors are assembled for perceiving and acting. Perception and action are coupled. According to this theory, motor skills are the result of many converging factors, such as the development of the nervous system, the body's physical properties and its movement possibilities, the goal the child is motivated to reach, and environmental support for the skill. In the dynamic systems view, motor development is far more complex than the result of a genetic blueprint.
- Reflexes—automatic movements—govern the newborn's behavior. They include the sucking, rooting, and Moro reflexes. The rooting and Moro reflexes disappear after three to four months. Permanent reflexes include coughing and blinking. For infants, sucking is an especially important reflex because it provides a means of obtaining nutrition.
- Gross motor skills involve large-muscle activities. Key skills developed during infancy include control of posture and walking. Although infants usually learn to walk by their first birthday, the neural pathways that allow walking begin forming earlier. The age at which infants reach milestones in the development of gross motor skills may vary by as much as two to four months, especially for milestones in late infancy.
- Fine motor skills involve finely tuned movements. The onset of reaching and grasping marks a significant accomplishment, and this skill becomes more refined during the first two years of life.

## 3 Sensory and Perceptual Development

What Are Sensation and Perception?

The Ecological View

Visual Perception

Other Senses

Intermodal Perception

**LG3**

Summarize the course of sensory and perceptual development in infancy.

- Sensation occurs when information interacts with sensory receptors. Perception is the interpretation of sensation.
- Created by the Gibsons, the ecological view states that we directly perceive information that exists in the world around us. Perception brings people in contact with the environment to interact with and adapt to it. Affordances provide opportunities for interaction offered by objects that fit within our capabilities to perform activities.
- Researchers have developed a number of methods to assess the infant's perception, including the visual preference method (which Fantz used to determine young infants' preference for looking at patterned over nonpatterned displays), habituation and dishabituation, and tracking.
- The infant's visual acuity increases dramatically in the first year of life. Infants' color vision improves as they develop. Young infants systematically scan human faces. As early as 3 months of age, infants show size and shape constancy. At approximately 2 months of age, infants develop the ability to perceive that occluded objects are complete. In Gibson and Walk's classic study, infants as young as 6 months of age indicated they could perceive depth.
- The fetus can hear during the last two months of pregnancy. Immediately after birth, newborns can hear, but their sensory threshold is higher than that of adults. Developmental changes in the perception of loudness, pitch, and localization of sound occur during infancy. Newborns can respond to touch and feel pain. Newborns can differentiate odors, and sensitivity to taste may be present before birth.
- Early, exploratory forms of intermodal perception—the ability to relate and integrate information from two or more sensory modalities—are present in newborns and become sharper over the first year of life.

Nature, Nurture, and  
Perceptual Development

Perceptual-Motor Coupling

- In describing the sources of perceptual development, nature advocates are referred to as nativists and nurture proponents are called empiricists. The Gibsons' ecological view that has guided much of perceptual development research leans toward a nativist approach but still allows for developmental changes in distinctive features. Piaget's constructivist view leans toward an empiricist approach, emphasizing that many perceptual accomplishments must await the development of cognitive stages in infancy. A strong empiricist approach is unwarranted. A full account of perceptual development includes the roles of nature, nurture, and the developing sensitivity to information.
- Perception and action are often not isolated but rather are coupled. Individuals perceive in order to move and move in order to perceive.

Jean Piaget, the famous Swiss psychologist, was a meticulous observer of his three children—Laurent, Lucienne, and Jacqueline. His books on cognitive development are filled with these observations. Here are a few of Piaget's observations of his children in infancy (Piaget, 1952):

- At 21 days of age, “Laurent found his thumb after three attempts: prolonged sucking begins each time. But, once he has been placed on his back, he does not know how to coordinate the movement of the arms with that of the mouth and his hands draw back even when his lips are seeking them” (p. 27).
- During the third month, thumb sucking becomes less important to Laurent because of new visual and auditory interests. But, when he cries, his thumb goes to the rescue.
- Toward the end of Lucienne’s fourth month, while she is lying in her crib, Piaget hangs a doll above her feet. Lucienne thrusts her feet at the doll and makes it move. “Afterward, she looks at her motionless foot for a second, then recommences. There is no visual control of her foot, for the movements are the same when Lucienne only looks at the doll or when I place the doll over her head. On the other hand, the tactile control of the foot is apparent: after the first shakes, Lucienne makes slow foot movements as though to grasp and explore” (p. 159).
- At 11 months, “Jacqueline is seated and shakes a little bell. She then pauses abruptly in order to delicately place the bell in front of her right foot; then she kicks hard. Unable to recapture it, she grasps a ball which she then places at the same spot in order to give it another kick” (p. 225).
- At 1 year, 2 months, “Jacqueline holds in her hands an object which is new to her: a round, flat box which she turns all over, shakes, [and] rubs against the bassinet. . . . She lets it go and tries to pick it up. But she only succeeds in touching it with her index finger, without grasping it. She nevertheless makes an attempt and presses on the edge. The box then tilts up and falls again” (p. 273). Jacqueline shows an interest in this result and studies the fallen box.

For Piaget, these observations reflect important changes in the infant’s cognitive development. Piaget maintained that infants go through a series of cognitive substages as they progress in less than two short years.

## topical connections *looking back*

We have discussed that impressive advances occur in the development of the brain during infancy. Engaging in various physical, cognitive, and socioemotional activities strengthens the baby's neural connections. Motor and perceptual development also are key aspects of the infant's development. An important part of this development is the coupling of perceptions and actions. The nature-nurture issue continues to be debated with regard to the infant's perceptual development. In this chapter, you will expand your understanding of the infant's brain, motor, and perceptual development by further examining how infants develop their competencies, focusing on how advances in their cognitive development help them adapt to their world, and how the nature-nurture issue is a key aspect of the infant's cognitive and language development.

## preview

Piaget's descriptions of infants are just the starting point for our exploration of cognitive development. Excitement and enthusiasm about the study of infant cognition have been fueled by an interest in what newborns and infants know, by continued fascination about innate and learned factors in the infant's cognitive development, and by controversies about whether infants construct their knowledge (Piaget's view) or know their world more directly. In this chapter, you will not only study Piaget's theory of infant development but also explore how infants learn, remember, and conceptualize; learn about some of their individual differences; and trace their language development.

Cognitive Processes

The Sensorimotor Stage

Evaluating Piaget's Sensorimotor Stage

We are born capable of learning.

—JEAN-JACQUES ROUSSEAU  
*Swiss-born French Philosopher, 18th Century*

Poet Nora Perry asks, "Who knows the thoughts of a child?" As much as anyone, Piaget knew. Through careful observations of his own three children—Laurent, Lucienne, and Jacqueline—and observations of and interviews with other children, Piaget changed perceptions of the way children think about the world.

Piaget's theory is a general, unifying story of how biology and experience sculpt cognitive development. Piaget thought that, just as our physical bodies have structures that enable us to adapt to the world, we build mental structures that help us adjust to new environmental demands. Piaget stressed that children actively construct their own cognitive worlds; information is not just poured into their minds from the environment. He sought to discover how children at different points in their development think about the world and how systematic changes in their thinking occur.

### COGNITIVE PROCESSES

What processes do children use as they construct their knowledge of the world? Piaget developed several concepts to answer this question; especially important are schemes, assimilation, accommodation, organization, equilibrium, and equilibration.

**Schemes** As the infant or child seeks to construct an understanding of the world, said Piaget (1954), the developing brain creates **schemes**. These are actions or mental representations that organize knowledge. In Piaget's theory, a baby's schemes are structured by simple actions that can be performed on objects, such as sucking, looking, and grasping. Older children have schemes that include strategies and plans for solving problems. For example, in the

**schemes** In Piaget's theory, actions or mental representations that organize knowledge.

descriptions at the opening of this chapter, Laurent displayed a scheme for sucking. By the time we have reached adulthood, we have constructed an enormous number of diverse schemes, ranging from driving a car to balancing a budget to understanding the concept of fairness.

**Assimilation and Accommodation** To explain how children use and adapt their schemes, Piaget offered two concepts: assimilation and accommodation. **Assimilation** occurs when children use their existing schemes to deal with new information or experiences. **Accommodation** occurs when children adjust their schemes to take new information and experiences into account.

Think about a toddler who has learned the word *car* to identify the family vehicle. The toddler might call all moving vehicles on roads “cars,” including motorcycles and trucks; the child has assimilated these objects to his or her existing scheme. But the child soon learns that motorcycles and trucks are not cars and fine-tunes the category to exclude motorcycles and trucks, accommodating the scheme.

Assimilation and accommodation operate even in very young infants. Newborns reflexively suck everything that touches their lips; they assimilate all sorts of objects into their sucking scheme. By sucking different objects, they learn about their taste, texture, shape, and so on. After several months of experience, though, they construct their understanding of the world differently. Some objects, such as fingers and the mother’s breast, can be sucked, and others, such as fuzzy blankets, should not be sucked. In other words, they accommodate their sucking scheme.

**Organization** To make sense out of their world, said Piaget, children cognitively organize their experiences. **Organization** in Piaget’s theory is the grouping of isolated behaviors and thoughts into a higher-order system. Continual refinement of this organization is an inherent part of development. A boy who has only a vague idea about how to use a hammer may also have a vague idea about how to use other tools. After learning how to use each one, he relates these uses, organizing his knowledge.

**Equilibration and Stages of Development** Assimilation and accommodation always take the child to a higher ground, according to Piaget. In trying to understand the world, the child inevitably experiences cognitive conflict, or *disequilibrium*. That is, the child is constantly faced with counterexamples to his or her existing schemes and with inconsistencies. For example, if a child believes that pouring water from a short and wide container into a tall and narrow container changes the amount of water, then the child might be puzzled by where the “extra” water came from and whether there is actually more water to drink. The puzzle creates disequilibrium; for Piaget, an internal search for equilibrium creates motivation for change. The child assimilates and accommodates, adjusting old schemes, developing new schemes, and organizing and reorganizing the old and new schemes. Eventually, the new organization has become fundamentally different from the old organization; it is a new way of thinking.

In short, according to Piaget, children constantly assimilate and accommodate as they seek equilibrium. There is considerable movement between states of cognitive equilibrium and disequilibrium as assimilation and accommodation work in concert to produce cognitive change. **Equilibration** is the name Piaget gave to this mechanism by which children shift from one stage of thought to the next.

The result of these processes, according to Piaget, is that individuals go through four stages of development. A different way of understanding the world makes one stage more advanced than another. Cognition is *qualitatively* different in one stage compared with another. In other words, the way children reason at one stage is different from the way they reason at another stage. In this chapter we will focus on Piaget’s stage of infant cognitive development. In later chapters we will explore Piaget’s other three stages when we study cognitive development in early childhood, middle and late childhood, and adolescence.

## THE SENSORIMOTOR STAGE

The **sensorimotor stage** lasts from birth to about 2 years of age. During this stage of cognitive development, infants construct an understanding of the world by coordinating sensory experiences (such as seeing and hearing) with physical, motoric actions—hence the term

#### Cognitive Theory

Recall the main characteristics of Piaget’s four stages of cognitive development. Connect to “Introduction.”

**assimilation** Piagetian concept of using existing schemes to deal with new information or experiences.

**accommodation** Piagetian concept of adjusting schemes to fit new information and experiences.

**organization** Piaget’s concept of grouping isolated behaviors and thoughts into a higher-order, more smoothly functioning cognitive system.

**equilibration** A mechanism that Piaget proposed to explain how children shift from one stage of thought to the next.

**sensorimotor stage** The first of Piaget’s stages, which lasts from birth to about 2 years of age; infants construct an understanding of the world by coordinating sensory experiences with motoric actions.

Substage	Age	Description	Example
<b>1 Simple reflexes</b>	Birth to 1 month	Coordination of sensation and action through reflexive behaviors.	Rooting, sucking, and grasping reflexes; newborns suck reflexively when their lips are touched.
<b>2 First habits and primary circular reactions</b>	1 to 4 months	Coordination of sensation and two types of schemes: habits (reflex) and primary circular reactions (reproduction of an event that initially occurred by chance). Main focus is still on the infant's body.	Repeating a body sensation first experienced by chance (sucking thumb, for example); then infants might accommodate actions by sucking their thumb differently from how they suck on a nipple.
<b>3 Secondary circular reactions</b>	4 to 8 months	Infants become more object-oriented, moving beyond self-preoccupation; repeat actions that bring interesting or pleasurable results.	An infant coos to make a person stay near; as the person starts to leave, the infant coos again.
<b>4 Coordination of secondary circular reactions</b>	8 to 12 months	Coordination of vision and touch—hand-eye coordination; coordination of schemes and intentionality.	Infant manipulates a stick in order to bring an attractive toy within reach.
<b>5 Tertiary circular reactions, novelty, and curiosity</b>	12 to 18 months	Infants become intrigued by the many properties of objects and by the many things they can make happen to objects; they experiment with new behavior.	A block can be made to fall, spin, hit another object, and slide across the ground.
<b>6 Internalization of schemes</b>	18 to 24 months	Infants develop the ability to use primitive symbols and form enduring mental representations.	An infant who has never thrown a temper tantrum before sees a playmate throw a tantrum; the infant retains a memory of the event, then throws one himself the next day.

**FIGURE 1**

**PIAGET'S SIX SUBSTAGES OF SENSORIMOTOR DEVELOPMENT**

"sensorimotor." At the beginning of this stage, newborns have little more than reflexes with which to work. At the end of the sensorimotor stage, 2-year-olds can produce complex sensorimotor patterns and use primitive symbols. We first will summarize Piaget's descriptions of how infants develop. Later we will consider criticisms of his view.

**Substages** Piaget divided the sensorimotor stage into six substages: (1) simple reflexes; (2) first habits and primary circular reactions; (3) secondary circular reactions; (4) coordination of secondary circular reactions; (5) tertiary circular reactions, novelty, and curiosity; and (6) internalization of schemes (see Figure 1). Piaget argued that each substage builds on the previous one.

**Simple reflexes**, the first sensorimotor substage, corresponds to the first month after birth. In this substage, sensation and action are coordinated primarily through reflexive behaviors such as rooting and sucking. Soon the infant produces behaviors that resemble reflexes in the absence of the usual stimulus for the reflex. For example, a newborn will suck a nipple or bottle only when it is placed directly in the baby's mouth or touched to the lips. But soon the infant might suck when a bottle or nipple is only nearby. Even in the first month of life, the infant is initiating action and actively structuring experiences.

**First habits and primary circular reactions** is the second sensorimotor substage, which develops between 1 and 4 months of age. In this substage, the infant coordinates sensation and two types of schemes: habits and primary circular reactions. A *habit* is a scheme based on a reflex that has become completely separated from its eliciting stimulus. For example, infants in substage 1 suck when bottles are put to their lips or when they see a bottle. Infants in substage 2 might suck even when no bottle is present. A *circular reaction* is a repetitive action.

**A primary circular reaction** is a scheme based on the attempt to reproduce an event that initially occurred by chance. For example, suppose an infant accidentally sucks his fingers when they are placed near his mouth. Later, he searches for his fingers to suck them again, but the fingers do not cooperate because the infant cannot coordinate visual and manual actions.

Habits and circular reactions are stereotyped—that is, the infant repeats them the same way each time. During this substage, the infant's own body continues to be the center of attention. There is no outward pull by environmental events.

**simple reflexes** Piaget's first sensorimotor substage, which corresponds to the first month after birth. In this substage, sensation and action are coordinated primarily through reflexive behaviors.

**first habits and primary circular reactions** Piaget's second sensorimotor substage, which develops between 1 and 4 months of age. In this substage, the infant coordinates sensation and two types of schemes: habits and primary circular reactions.

**primary circular reaction** A scheme based on the attempt to reproduce an event that initially occurred by chance.

**secondary circular reactions** Piaget's third sensorimotor substage, which develops between 4 and 8 months of age. In this substage, the infant becomes more object-oriented, moving beyond preoccupation with the self.

**Secondary circular reactions** is the third sensorimotor substage, which develops between 4 and 8 months of age. In this substage, the infant becomes more object-oriented, moving beyond preoccupation with the self. The infant's schemes are not intentional or goal-directed, but they are repeated because of their consequences. By chance, an infant might shake a rattle. The infant repeats this action for the sake of its fascination. This is a *secondary circular reaction*: an action repeated because of its consequences. The infant also imitates some simple actions, such as the baby talk or burbling of adults, and some physical gestures. However, the baby imitates only actions that he or she is already able to produce.

**Coordination of secondary circular reactions** is Piaget's fourth sensorimotor substage, which develops between 8 and 12 months of age. To progress into this substage the infant must coordinate vision and touch, eye and hand. Actions become more outwardly directed. Significant changes during this substage involve the coordination of schemes and intentionality. Infants readily combine and recombine previously learned schemes in a coordinated way. They might look at an object and grasp it simultaneously, or they might visually inspect a toy, such as a rattle, and finger it simultaneously, exploring it tactilely. Actions are even more outwardly directed than before. Related to this coordination is the second achievement—the presence of intentionality. For example, infants might manipulate a stick in order to bring a desired toy within reach, or they might knock over one block to reach and play with another one. Similarly, when 11-month-old Jacqueline, as described in the chapter opening, placed the ball in front of her and kicked it, she was demonstrating intentionality.

**Tertiary circular reactions, novelty, and curiosity** is Piaget's fifth sensorimotor substage, which develops between 12 and 18 months of age. In this substage, infants become intrigued by the many properties of objects and by the many things that they can make happen to objects. A block can be made to fall, spin, hit another object, and slide across the ground. *Tertiary circular reactions* are schemes in which the infant purposely explores new possibilities with objects, continually doing new things to them and exploring the results. Piaget says that this stage marks the starting point for human curiosity and interest in novelty.

**Internalization of schemes** is Piaget's sixth and final sensorimotor substage, which develops between 18 and 24 months of age. In this substage, the infant develops the ability to use primitive symbols. For Piaget, a *symbol* is an internalized sensory image or word that represents an event. Primitive symbols permit the infant to think about concrete events without directly acting them out or perceiving them. Moreover, symbols allow the infant to manipulate and transform the represented events in simple ways. In a favorite Piagetian example, Piaget's young daughter saw a matchbox being opened and closed. Later, she mimicked the event by opening and closing her mouth. This was an obvious expression of her image of the event.

**Object Permanence** Imagine how chaotic and unpredictable your life would be if you could not distinguish between yourself and your world. This is what the life of a newborn must be like, according to Piaget. There is no differentiation between the self and world; objects have no separate, permanent existence.

By the end of the sensorimotor period, objects are both separate from the self and permanent. **Object permanence** is the understanding that objects continue to exist even when they cannot be seen, heard, or touched. Acquiring the sense of object permanence is one of the infant's most important accomplishments, according to Piaget.

## FIGURE 2

**OBJECT PERMANENCE.** Piaget argued that object permanence is one of infancy's landmark cognitive accomplishments. For this 5-month-old boy, "out of sight" is literally out of mind. The infant looks at the toy monkey (left), but, when his view of the toy is blocked (right), he does not search for it. Several months later, he will search for the hidden toy monkey, an action reflecting the presence of object permanence.

©Doug Goodman/Science Source

How could anyone know whether an infant had a sense of object permanence or not? The principal way that object permanence is studied is by watching an infant's reaction when an interesting object disappears (see Figure 2). If infants search for the object, it is assumed that they believe it continues to exist.

## EVALUATING PIAGET'S SENSORIMOTOR STAGE

Piaget opened up a new way of looking at infants with his view that their main task is to coordinate their sensory impressions with their motor activity. However, the infant's cognitive world is not as neatly packaged as Piaget portrayed it, and some of Piaget's explanations of change are debated. In the past several decades, sophisticated experimental techniques have been devised to study infants, and a large number of research studies have focused on infant development. Much of the new research suggests that Piaget's view of sensorimotor development needs to be modified (Adolph, 2018; Bell & others, 2018; Bremner & others, 2017; Van de Vondervoort & Hamlin, 2018).

**The A-not-B Error** One modification concerns Piaget's claim that certain processes are crucial in transitions from one stage to the next. The data do not always support his explanations. For example, in Piaget's theory, an important feature in the progression into substage 4, *coordination of secondary circular reactions*, is an infant's inclination to search for a hidden object in a familiar location rather than to look for the object in a new location. If a toy is hidden twice, initially at location A and subsequently at location B, 8- to 12-month-old infants search correctly at location A initially. But, when the toy is subsequently hidden at location B, while the child watches, they make the mistake of continuing to search for it at location A. **A-not-B error** is the term used to describe this common mistake. Older infants are less likely to make the A-not-B error because their concept of object permanence is more complete.

Researchers have found, however, that the A-not-B error does not show up consistently (MacNeill & others, 2018; Sophian, 1985). The evidence indicates that A-not-B errors are sensitive to the delay between hiding the object at B and the infant's attempt to find it (Diamond, 1985). Thus, the A-not-B error might be due to a failure in memory. And A-not-B performance may be linked to attention as well. For example, in a recent study, 5-month-olds' more focused attention on a separate task involving a puppet was linked to better performance on an A-not-B task that involved locating an object after it was hidden from view (Marcovitch & others, 2016). Another explanation is that infants tend to repeat a previous motor behavior (Clearfield & others, 2006).

#### Perceptual Development

Eleanor Gibson was a pioneer in crafting the ecological perception view of development. Connect to "Physical Development in Infancy."

**A-not-B error** Error that occurs when infants make the mistake of selecting the familiar hiding place (A) rather than the new hiding place (B) of an object.

**Perceptual Development and Expectations** A number of theorists, such as Eleanor Gibson (2001) and Elizabeth Spelke (1991, 2011, 2013), argue that infants' perceptual abilities are highly developed at a very early stage. Spelke concludes that young infants interpret the world as having predictable occurrences. For example, we have discussed research that demonstrated the presence of intermodal perception—the ability to coordinate information from two or more sensory modalities, such as vision and

hearing—by 3½ months of age, much earlier than Piaget would have predicted (Spelke & Owsley, 1979).

Research also suggests that infants develop the ability to understand how the world works at a very early age (Aslin, 2017; Baillargeon & DeJong, 2017; Liu & Spelke, 2017; Van de Vondervoort & Hamlin, 2018). For example, by the time they are 3 months of age, infants develop expectations about future events. What kinds of expectations do infants form? Experiments by Elizabeth Spelke (Liu & Spelke, 2017; Spelke, 1991, 2000, 2016a, b) have addressed this question. In one study, she placed babies before a puppet stage and showed them a series of actions that are unexpected if you know how the physical world works—for example, one ball seemed to roll through a solid barrier, another seemed to leap between two platforms, and a third appeared to hang in midair (Spelke, 1979). Spelke measured and compared the babies' looking times for unexpected and expected actions. She concluded that by 4 months of age, even though infants do not yet have the ability to talk about objects, move around objects, manipulate objects, or even see objects with high resolution, they expect objects to be solid and continuous. However, at 4 months of age, infants do not expect an object to obey laws of gravity (Spelke & others, 1992). Similarly, research by Renee Baillargeon and her colleagues (Baillargeon, 1995, 2004, 2014, 2016) documents that infants as young as 3 to 4 months expect objects to be substantial (in the sense that other objects cannot move through them) and permanent (in the sense that objects continue to exist when they are hidden).

In sum, researchers conclude that infants see objects as bounded, unitary, solid, and separate from their background, possibly at birth or shortly thereafter, but definitely by 3 to 4 months of age—much earlier than Piaget envisioned. Young infants still have much to learn about objects, but the world appears both stable and orderly to them (Bremner, 2017; Liu & Spelke, 2017; Stavans & Baillargeon, 2018).

By 6 to 8 months, infants have learned to perceive gravity and support—that an object hanging on the end of a table should fall, that ball bearings will travel farther when rolled down a longer rather than a shorter ramp, and that cup handles will not fall when attached to a cup (Slater, Field, & Hernandez-Reif, 2007). As infants develop, their experiences and actions on objects help them to understand physical laws (Baillargeon & DeJong, 2017; Bremner, 2017).

**The Nature-Nurture Issue** In considering the big issue of whether nature or nurture plays the more important role in infant development, Elizabeth Spelke (Spelke, 2003, 2011, 2013, 2016a, b) comes down clearly on the side of nature, a position often referred to as *nativist*. Spelke endorses a **core knowledge approach**, which states that infants are born with domain-specific innate knowledge systems. Among these domain-specific knowledge systems are those involving space, number sense, object permanence, and language (which we will discuss later in this chapter). Strongly influenced by evolution, the core knowledge domains are theorized to be prewired to allow infants to make sense of their world (Strickland & Chemla, 2018). After all, Spelke concludes, how could infants possibly grasp the complex world in which they live if they didn't come into the world equipped with core sets of knowledge? In this approach, the innate core knowledge domains form a foundation around which more mature cognitive functioning and learning develop (Baillargeon & DeJong, 2017). The core knowledge approach argues that Piaget greatly underestimated the cognitive abilities of infants, especially young infants (Baillargeon, 2016; Liu & Spelke, 2017; Spelke, 2016a, b).

Some critics argue that the Spelke experiments mainly demonstrate perceptual competencies or detection of regularities in the environment (Heyes, 2014; Ruffman, 2014). These critics stress that the infants in their studies reflect a very rudimentary understanding that likely differs greatly from the understanding of older children.

An intriguing domain of core knowledge that has been investigated in young infants is whether they have a sense of number. Spelke (2016a, b) concludes that they do (Spelke, 2016a, b). She has found that infants can distinguish between different numbers of objects, actions, and sounds (Spelke, 2016a, b). Of course, not everyone agrees with Spelke's conclusions about young infants' math skills (Cohen, 2002). One criticism is that infants in the number experiments are merely responding to changes in the display that violated their expectations.

Recently, researchers also have explored whether preverbal infants might have a built-in, innate sense of morality (Van de Vondervoort & Hamlin, 2016, 2018). In this research, infants as young as 4 months of age are more likely to make visually guided reaches toward a puppet who has acted as a helper (such as helping someone get up a hill, assisting in opening a box, or giving a ball back) rather than toward a puppet who has acted as a hinderer to others' efforts to achieve such goals (Hamlin, 2013, 2014). Recently, the view that the emergence of morality in infancy is innate was described as problematic (Carpendale & Hammond, 2016). Instead it was argued that morality may emerge through infants' early interaction with others and later transformation through language and reflective thought.

In criticizing the core knowledge approach, British developmental psychologist Mark Johnson (2008) says that the infants studied by Spelke and other advocates of core knowledge already have accumulated hundreds, and in some cases even thousands, of hours of experience in grasping what the world is about, which gives considerable room for the environment's role in the development of infant cognition (Highfield, 2008). According to Johnson (2008), infants likely come into the world with "soft biases to perceive and attend to different aspects of the environment, and to learn about the world in particular ways." A major criticism is that nativists completely neglect the infant's social immersion in the world and instead focus only on what happens inside the infant's head, apart from the environment (de Haan & Johnson, 2016; Hakuno & others, 2018).

Although debate about the cause and course of infant cognitive development continues, most developmentalists today agree that Piaget underestimated the early cognitive accomplishments of infants and that both nature and nurture are involved in infants' cognitive development (Bell & others, 2018; Bremner & others, 2017; Gomez, 2017).

**Conclusions** In sum, many researchers conclude that Piaget wasn't specific enough about how infants learn about their world and that infants, especially young infants, are more competent than Piaget thought (Adolph, 2018; Aslin, 2017; Baillargeon & De Jong, 2017; Bell & others, 2018; Bremner & others, 2017). As researchers have examined the specific ways that infants learn, the field of infant cognition has become very specialized. There are many researchers working on different questions, with no general theory emerging that can connect all of the different findings (Nelson, 1999). These theories often are local theories, focused on specific research questions, rather than grand theories like Piaget's (Kuhn, 1998). Among the unifying themes in the study of infant cognition are seeking to understand more precisely how developmental changes in cognition take place, to examine the big issue of nature and nurture, and to study the brain's role in cognitive development (Aslin, 2017; Bauer, 2015a, b, 2018; Bell & others, 2018; Van de Vondervoort & Hamlin, 2018; Xie, Mallin, & Richards, 2018). Recall that exploring connections between brain, cognition, and development involves the recently emerging field of *developmental cognitive neuroscience* (Bick & Nelson, 2018; Meltzoff & others, 2018a, b; Saez de Urabain, Nuthmann, & Johnson, 2017).

Concept Formation and Categorization

When Piaget hung a doll above 4-month-old Lucienne's feet, as described in the chapter opening, did she remember the doll? If Piaget had rewarded her for moving the doll with her foot, would that have affected Lucienne's behavior? If he had shown her how to shake the doll's hand, could she have imitated him? If he had shown her a different doll, could she have formed the concept of a "doll"?

Questions like these might be examined by researchers taking the behavioral and social cognitive or information-processing approaches introduced earlier. In contrast with Piaget's theory, these approaches do not describe infant development in terms of stages. Instead, they document gradual changes in the infant's ability to understand and process information about the world (Hakuno & others, 2018; Reynolds & Richards, 2018). In this section, we explore what researchers using these approaches can tell us about how infants learn, remember, and conceptualize.

### CONDITIONING

According to Skinner's theory of operant conditioning, the consequences of a behavior produce changes in the probability of the behavior's occurrence. For example, if an infant's behavior is followed by a rewarding stimulus, the behavior is likely to recur.

Operant conditioning has been especially helpful to researchers in their efforts to determine what infants perceive (Rovee-Collier & Barr, 2010). For example, infants will suck faster on a nipple when the sucking behavior is *followed by* a visual display, music, or a human voice (Rovee-Collier, 1987, 2009).

Carolyn Rovee-Collier (1987) has also demonstrated how infants can retain information from the experience of being conditioned. In a characteristic experiment, she places a 2½-month-old baby in a crib under an elaborate mobile (see Figure 3). She then ties one end of a ribbon to the baby's ankle and the other end to the mobile. Subsequently, she observes that the baby kicks and makes the mobile move. The movement of the mobile is the reinforcing stimulus (which increases the baby's kicking behavior) in this experiment. Weeks later, the baby is returned to the crib, but its foot is not tied to the mobile. The baby kicks, which suggests it has retained the information that if it kicks a leg, the mobile will move.

### ATTENTION

**Attention**, the focusing of mental resources on select information, improves cognitive processing on many tasks (Posner, 2018a, b; Wu & Scerif, 2018; Yu & Smith, 2017). At any one time, though, people can pay attention to only a limited amount of information. Even newborns can detect a contour and fix their attention on it. Older infants scan patterns more thoroughly. By 4 months, infants can selectively attend to an object.

In adults, when individuals orient their attention to an object or event, the parietal lobes in the cerebral cortex are involved (Kulke, Atkinson, & Braddick, 2017). It is likely that the parietal lobes are active when infants orient their attention, although research has not yet documented this. (Figure 5 in the chapter on "Physical Development in Infancy" illustrates the location of the parietal lobes in the brain.)

Attention in the first year of life is dominated by an *orienting/investigative process* (Falck-Ytter & others, 2018). This process involves directing attention to potentially important locations in the environment (that is, *where*) and recognizing objects and their features (such as color and form) (that is, *what*). From 3 to 9 months of age, infants can deploy their attention more flexibly and quickly. Another important type of attention is *sustained attention*, also referred to as *focused attention* (Ito-Jager & others, 2017; Xie, Mallin, & Richards, 2018). New stimuli typically elicit an orienting response followed by sustained attention. It is sustained attention that allows infants to learn about and remember characteristics of a stimulus as it

##### Attention

In early childhood, children make significant advances in sustained attention. Connect to "Physical and Cognitive Development in Early Childhood."

becomes familiar. Researchers have found that infants as young as 3 months of age engage in 5 to 10 seconds of sustained attention. From this age through the second year, the length of sustained attention increases (Courage & Richards, 2008). In a recent study, sustained attention at 10 months of age was linked to better self-regulation at 18 months of age, even when infants had insensitive mothers (Frick & others, 2018).

**Habituation and Dishabituation** Closely linked with attention are the processes of habituation and dishabituation (Christodoulou, Leland, & Moore, 2018; Jones & others, 2017). If you say the same word or show the same toy to a baby several times in a row, the baby usually pays less attention to it each time. This is *habituation*—decreased responsiveness to a stimulus after repeated presentations of the stimulus. *Dishabituation* is the increase in responsiveness after a change in stimulation. The chapter on “Physical Development in Infancy” described some of the measures that researchers use to study whether habituation is occurring, such as sucking behavior, heart rate, and the length of time the infant looks at an object.

Infants' attention is strongly governed by novelty and habituation (Messinger & others, 2017). When an object becomes familiar, attention becomes shorter, and infants become more vulnerable to distraction.

Habituation provides a useful tool for assessing what infants can see, hear, smell, taste, and experience touch. When infants habituate to one object, and thus it becomes familiar, they will then tend to look at an unfamiliar object, which shows they can tell the objects apart.

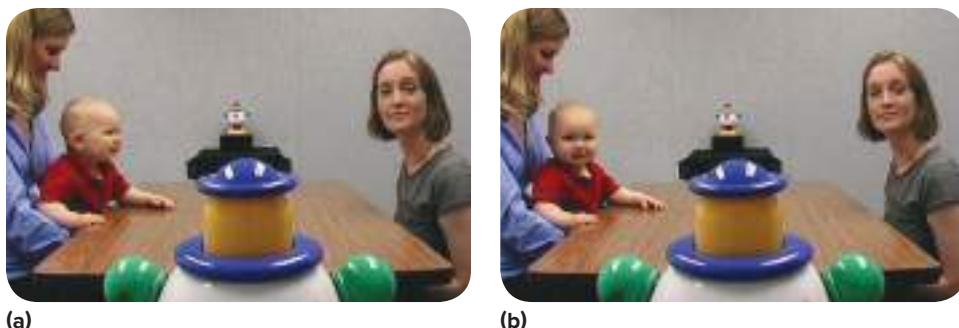

Knowing about habituation and dishabituation can help parents interact effectively with infants. Infants respond to changes in stimulation. Wise parents sense when an infant shows an interest and realize that they may have to repeat something many times for the infant to process information. But if the stimulation is repeated often, the infant stops responding to the parent. In parent-infant interaction, it is important for parents to do novel things and to repeat them often until the infant stops responding. The parent stops or changes behaviors when the infant redirects his or her attention (Rosenblith, 1992).

**Joint Attention** Another type of attention that is an important aspect of infant development is joint attention, in which two or more individuals focus on the same object or event (Mateus & others, 2018; Urqueta Alfaro & others, 2018). Joint attention requires (1) an ability to track another's behavior, such as following the gaze of another person; (2) one person's directing another's attention; and (3) reciprocal interaction. Early in infancy, joint attention involves a caregiver pointing, turning the infant's head, snapping fingers, or using words to direct the infant's attention. Emerging forms of joint attention occur at about 7 to 8 months, but it is not until toward the end of the first year that joint attention skills are frequently observed (Niedzwiecka & Tomalski, 2015). In a study conducted by Andrew Meltzoff and Rechele Brooks (2006), at 10 to 11 months of age infants first began engaging in “gaze following,” looking where another person has just looked (see Figure 4). And by their first

**joint attention** Process that occurs when individuals focus on the same object and are able to track another's behavior, one individual directs another's attention, and reciprocal interaction takes place.

**GAZE FOLLOWING IN INFANCY.** Researcher Rechele Brooks shifts her eyes from the infant to a toy in the foreground (a). The infant then follows her eye movement to the toy (b). Brooks and colleague Andrew Meltzoff (2005) found that infants begin to engage in this kind of behavior, called “gaze following,” at 10 to 11 months of age. *Why might gaze following be an important accomplishment for an infant?* ©2005 University of Washington, Institute for Learning & Brain Sciences

birthday, infants have begun to direct adults' attention to objects that capture their interest (Heimann & others, 2006). One study found that problems in joint attention as early as 8 months of age were linked to the child being diagnosed with autism by 7 years of age (Veness & others, 2014). Also, a recent study involving the use of eye-tracking equipment with 11- to 24-month-olds revealed that infants' hand-eye coordination rather than gaze following alone predicted joint attention (Yu & Smith, 2017).

Joint attention plays important roles in many aspects of infant development and considerably increases infants' ability to learn from other people (McClure & others, 2018). Nowhere is this more apparent than in observations of interchanges between caregivers and infants as infants are learning language (Mason-Apps & others, 2018; Tomasello, 2014). When caregivers and infants frequently engage in joint attention, infants say their first word earlier and develop a larger vocabulary (Mastin & Vogt, 2016). Later in this chapter in our discussion of language, we further discuss joint attention as an early predictor of language development in older infants and toddlers (Mastin & Vogt, 2016). Researchers have found that joint attention is linked to better sustained attention (Yu & Smith, 2016), memory (Kopp & Lindenberger, 2011), self-regulation (Van Hecke & others, 2012), and executive function (Gueron-Sela & others, 2018).

## MEMORY

**Memory** involves the retention of information over time. Attention plays an important role in memory as part of *encoding*, a process in which information is transferred to memory. What can infants remember, and when?

Some researchers, such as Carolyn Rovee-Collier (2009), have concluded that infants as young as 2 to 6 months of age can remember some experiences through 1½ to 2 years of age. However, critics such as Jean Mandler (2004), a leading expert on infant cognition, argue that the infants in Rovee-Collier's experiments were displaying only implicit memory. **Implicit memory** refers to memory without conscious recollection—memories of skills and routine procedures that are performed automatically. In contrast, **explicit memory** refers to conscious remembering of facts and experiences.

When people think about memory, they are usually referring to explicit memory. Most researchers find that babies do not show explicit memory until the second half of the first year (Bauer, 2013, 2015a, b, 2018; Bauer & Fivush, 2014). Explicit memory improves substantially during the second year of life (Bauer, 2013, 2015a, b, 2018; Bauer & Leventon, 2015). In one longitudinal study, infants were assessed several times during their second year (Bauer & others, 2000). Older infants showed more accurate memory and required fewer prompts to demonstrate their memory than younger infants did. Figure 5 summarizes the lengths of time that infants of different ages can remember information (Bauer, 2009a, b). As indicated in Figure 5, researchers have documented that 6-month-olds can retain information for 24 hours, but by 20 months of age infants can remember information they encountered 12 months earlier.

What changes in the brain are linked to infants' memory development? From about 6 to 12 months of age, the maturation of the hippocampus and the surrounding cerebral cortex, especially the frontal lobes, makes explicit memory possible (see Figure 6). Explicit memory continues to improve during the second year as these brain structures further mature and connections between them increase. Less is known about the areas of the brain involved in implicit memory in infancy.

Let's examine another aspect of memory. Do you remember your third birthday party? Probably not. Most adults can remember little if anything from their first three years of life. This is called *infantile* or *childhood amnesia*.

Patricia Bauer and her colleagues (Bauer, 2015a, 2018; Bauer & Larkina, 2014, 2016; Pathman, Doydum, & Bauer, 2013) have been recently studying when infantile amnesia begins to occur. In one study, children's memory for events that occurred at 3 years of age was periodically assessed through age 9 (Bauer & Larkina, 2014). By 8 to 9 years of age, children's memory of events that occurred at 3 years of age began to fade away significantly.

In Bauer's (2015a, 2018) view, the processes that account for these developmental changes are early, gradual development of the ability to form, retain, and later retrieve memories of personally relevant past events followed by an accelerated rate of forgetting in childhood.

**deferred imitation** Imitation that occurs after a delay of hours or days.

**concepts** Cognitive groupings of similar objects, events, people, or ideas.

In sum, most of young infants' conscious memories appear to be rather fragile and short-lived, although their implicit memory of perceptual-motor actions can be substantial (Bauer, 2015, 2018; Mandler, 2004). By the end of the second year, long-term memory is more substantial and reliable (Bauer, 2015a, b, 2018; Hayne & Gross, 2017).

## IMITATION

Can infants imitate someone else's emotional expressions? If an adult smiles, for example, will the baby respond with a smile? If an adult sticks out her tongue, wrinkles her forehead, and frowns, will the baby show a sad face?

Infant development researcher Andrew Meltzoff (2004, 2005, 2011, 2017; Meltzoff & Moore, 1999; Meltzoff & others, 2018a, b; Meltzoff & Williamson, 2010, 2013; Meltzoff, Williamson, & Marshall, 2013; Waismeyer & Meltzoff, 2017) has conducted numerous studies of infants' imitative abilities. He sees infants' imitative abilities as biologically based, because infants can imitate a facial expression within the first few days after birth. He also emphasizes that the infant's imitative abilities do not resemble a hardwired response but rather involve flexibility and adaptability. Meltzoff (2017) also emphasizes that infants' imitation informs us about their processing of social events and contributes to rapid social learning. In Meltzoff's observations of infants throughout their first 72 hours of life, the infants gradually displayed more complete imitation of an adult's facial expression, such as protruding the tongue or opening the mouth wide (see Figure 7).

Meltzoff (2007) concludes that infants don't blindly imitate everything they see and often make creative errors. He also argues that beginning at birth there is an interplay between learning by observing and learning by doing (Piaget emphasized learning by doing).

Meltzoff (2005, 2011, 2017) also has studied **deferred imitation**, which occurs after a time delay of hours or days. Piaget held that deferred imitation doesn't occur until about 18 months of age. Meltzoff's research suggested that it occurs much earlier. In one study, Meltzoff (1988) demonstrated that 9-month-old infants could imitate actions—such as pushing a recessed button in a box, which produced a beeping sound—that they had seen performed 24 hours earlier.

## CONCEPT FORMATION AND CATEGORIZATION

Along with attention, memory, and imitation, concepts are key aspects of infants' cognitive development (Quinn, 2016). **Concepts** are cognitive groupings of similar objects, events, people, or ideas. Without concepts, you would see each object and event as unique; you would not be able to make any generalizations.

Do infants have concepts? Yes, they do, although we do not know precisely how early concept formation begins (Quinn & Bhatt, 2016).

Using habituation experiments like those described earlier in the chapter, some researchers have found that infants as young as 3 to 4 months of age can group together objects with similar appearances, such as animals (Quinn, 2016). This research capitalizes on the knowledge that infants are more likely to look at a novel object than a familiar object. Jean Mandler (2004, 2009) argues that these early categorizations are best described as *perceptual categorization*. That is, the categorizations are based on similar perceptual features of objects, such as size, color, and movement, as well as parts of objects, such as legs for animals (Quinn & Bhatt, 2016). Mandler (2004) concludes that it is not until about 7 to 9 months of age that infants form *conceptual categories* rather than just making perceptual discriminations between different categories. In one study of 9- to 11-month-olds, infants classified birds as animals

and airplanes as vehicles even though the objects were perceptually similar—airplanes and birds with their wings spread (Mandler & McDonough, 1993) (see Figure 8).

In addition to infants categorizing items on the basis of external, perceptual features such as shape, color, and parts, they also may categorize items on the basis of prototypes, or averages, that they extract from the structural regularities of items (Rakison & Lawson, 2013).

Further advances in categorization occur in the second year of life (Booth, 2006; Rakison & Lawson, 2013). Many infants' "first concepts are broad and global in nature, such as 'animal' or 'indoor thing.' Gradually, over the first two years these broad concepts become more differentiated into concepts such as 'land animal,' then 'dog,' or to 'furniture,' then 'chair'" (Mandler, 2009, p. 1). Also in the second year, infants often categorize objects on the basis of their shape (Landau, Smith, & Jones, 1998).

Learning to put things into the correct categories—what makes something one kind of thing rather than another kind of thing, such as what makes a bird a bird, or a fish a fish—is an important aspect of learning (Quinn, 2016). As infant development researcher Alison Gopnik (2010, p. 159) pointed out, "If you can sort the world into the right categories—put things in the right boxes—then you've got a big advance on understanding the world."

Do some very young children develop an intense, passionate interest in a particular category of objects or activities? One study confirmed that they do (DeLoache, Simcock, & Macari, 2007). A striking finding was the large gender difference in categories, with an intense interest in particular categories stronger for boys than girls. Categorization of boys' intense interests focused on vehicles, trains, machines, dinosaurs, and balls; girls' intense interests were more likely to involve dress-ups and books/reading (see Figure 9). When your author's grandson Alex was 18 to 24 months old, he already had developed an intense, passionate interest in the category of vehicles. For example, at this age, he categorized vehicles into such subcategories as cars, trucks, earth-moving equipment, and buses. In addition to common classifications of cars into police cars, jeeps, taxis, and such, and trucks into fire trucks, dump trucks, and the like, his categorical knowledge of earth-moving equipment included bulldozers and excavators, and he categorized buses into school buses, London buses, and funky Malta buses (retro buses on the island of Malta). Later, at 3 years of age, Alex developed an intense, passionate interest in categorizing dinosaurs.

In sum, the infant's advances in processing information—through attention, memory, imitation, and concept formation—is much richer, more gradual and less stage-like, and occurs earlier than was envisioned by earlier theorists, such as Piaget (Bauer, 2018; Bell & others, 2018; Bremner & others, 2017; Gomez, 2017; Xie, Mallin, & Richards, 2018). As leading infant researcher Jean Mandler (2004) concluded, “The human infant shows a remarkable degree of learning power and complexity in what is being learned and in the way it is represented” (p. 304).

### Review

- How do infants learn through conditioning?
- What is attention? What characterizes attention in infants?
- To what extent can infants remember?
- How is imitation involved in infant learning?
- When do infants develop concepts, and how does concept formation change during infancy?

### Connect

- In this section, we learned that explicit memory improves in the second year as

the hippocampus and frontal lobes mature and as connections between them increase. What did you learn in the text associated with Figure 6 in the chapter on “Physical Development in Infancy” that might also contribute to improvements in a mental process such as memory during this same time frame?

How Language Develops

Biological and Environmental Influences

An Interactionist View

In 1799, a nude boy was observed running through the woods in France. The boy was captured when he was 11 years old. He was called the Wild Boy of Aveyron and was believed to have lived in the woods alone for six years (Lane, 1976). When found, he made no effort to communicate. He never learned to communicate effectively. Sadly, a modern-day wild child named Genie was discovered in Los Angeles in 1970. Despite intensive intervention, Genie has never acquired more than a primitive form of language. Both cases—the Wild Boy of Aveyron and Genie—raise questions about the biological and environmental determinants of language, topics that we also will examine later in this chapter. First, though, we need to define language.

## DEFINING LANGUAGE

**Language** is a form of communication—whether spoken, written, or signed—that is based on a system of symbols. Language consists of the words used by a community and the rules for varying and combining them.

Think how important language is in our everyday lives. We need language to speak with others, listen to others, read, and write. Our language enables us to describe past events in detail and to plan for the future. Language lets us pass down information from one generation to the next and create a rich cultural heritage. Language learning involves comprehending a sound system (or sign system for individuals who are deaf), the world of objects, actions, and events, and how units such as words and grammar connect sound and world (Nathan, 2017; Hoffman, 2017; van der Hulst, 2017; Wilcox & Occhino, 2017).

All human languages have some common characteristics (Clark, 2017). These include infinite generativity and organizational rules. **Infinite generativity** is the ability to produce and comprehend an endless number of meaningful sentences using a finite set of words and rules. Rules describe the way language works. Let's explore what these rules involve.

## LANGUAGE'S RULE SYSTEMS

When nineteenth-century American writer Ralph Waldo Emerson said, “The world was built in order, and the atoms march in tune,” he must have had language in mind. Language is highly ordered and organized. The organization involves five systems of rules: phonology, morphology, syntax, semantics, and pragmatics.

**Phonology** Every language is made up of basic sounds. **Phonology** is the sound system of the language, including the sounds that are used and how they may be combined (Goswami & Bryant, 2016). For example, English has the initial consonant cluster *spr* as in *spring*, but no words begin with the cluster *rsp*.

Phonology provides a basis for constructing a large and expandable set of words out of two or three dozen phonemes (Nathan, 2017). A **phoneme** is the basic unit of sound in a language; it is the smallest unit of sound that affects meaning. For example, in English the sound represented by the letter *p*, as in the words *pot* and *spot*, is a phoneme. The /*p*/ sound is slightly different in the two words, but this variation is not distinguished in English, and therefore the /*p*/ sound is a single phoneme. In some languages, such as Hindi, the variations of the /*p*/ sound represent separate phonemes.

**Morphology** **Morphology** refers to the units of meaning involved in word formation. A **morpheme** is a minimal unit of meaning; it is a word or a part of a word that cannot be broken into smaller meaningful parts (Lems, Miller, & Soro, 2017; Payne, 2017). Every word in the English language is made up of one or more morphemes. Some words consist of a single morpheme (for example, *help*), whereas others are made up of more than one morpheme (for example, *helper* has two morphemes, *help* and *er*, with the morpheme *-er* meaning “one who”—in this case, “one who helps”). Thus, not all morphemes are words by themselves; for example, *pre-*, *-tion*, and *-ing* are morphemes.

Just as the rules that govern phonology describe the sound sequences that can occur in a language, the rules of morphology describe the way meaningful units (morphemes) can be combined in words (Beck, 2017; Deevy, Leonard, & Marchman, 2017). Morphemes have many jobs in grammar, such as marking tense (for example, “she walks” versus “she walked”) and number (“she walks” versus “they walk”).

**Syntax** **Syntax** involves the way words are combined to form acceptable phrases and sentences (Langacker, 2017; Narrog, 2017). If someone says to you, “Bob slugged Tom” or “Bob was slugged by Tom,” you know who did the slugging and who was slugged in each case because you have a syntactic understanding of these sentence structures. You also understand that the sentence, “You didn’t stay, did you?” is a grammatical sentence, but that “You didn’t stay, didn’t you?” is unacceptable and ambiguous.

If you learn another language, English syntax will not get you very far. For example, in English an adjective usually precedes a noun (as in *blue sky*), whereas in Spanish the adjective usually follows the noun (*cielo azul*). Despite the differences in their syntactic structures, however, syntactic

**language** A form of communication, whether spoken, written, or signed, that is based on a system of symbols. Language consists of the words used by a community and the rules for varying and combining them.

**infinite generativity** The ability to produce and comprehend an endless number of meaningful sentences using a finite set of words and rules.

**phonology** The sound system of the language, including the sounds that are used and how they may be combined.

**morphology** Units of meaning involved in word formation.

**syntax** The ways words are combined to form acceptable phrases and sentences.

Rule System	Description	Examples
Phonology	The sound system of a language. A phoneme is the smallest sound unit in a language.	The word <i>chat</i> has three phonemes or sounds: /ch/ /ă/ /t/. An example of phonological rule in the English language is while the phoneme /r/ can follow the phonemes /t/ or /d/ in an English consonant cluster (such as <i>track</i> or <i>drab</i> ), the phoneme /l/ cannot follow these letters.
Morphology	The system of meaningful units involved in word formation.	The smallest sound units that have a meaning are called morphemes, or meaning units. The word <i>girl</i> is one morpheme, or meaning unit; it cannot be broken down any further and still have meaning. When the suffix <i>s</i> is added, the word becomes <i>girls</i> and has two morphemes because the <i>s</i> changed the meaning of the word, indicating that there is more than one girl.
Syntax	The system that involves the way words are combined to form acceptable phrases and sentences.	Word order is very important in determining meaning in the English language. For example, the sentence “Sebastian pushed the bike” has a different meaning than “The bike pushed Sebastian.”
Semantics	The system that involves the meaning of words and sentences.	Knowing the meaning of individual words—that is, vocabulary. For example, semantics includes knowing the meaning of such words as <i>orange</i> , <i>transportation</i> , and <i>intelligent</i> .
Pragmatics	The system of using appropriate conversation and knowledge of how to effectively use language in context.	An example is using polite language in appropriate situations, such as being mannerly when talking with one’s teacher. Taking turns in a conversation involves pragmatics.

**FIGURE 10**

**THE RULE SYSTEMS OF LANGUAGE**

systems in all of the world’s languages have some common ground (Hoffman, 2017; Koeneman & Zeijstra, 2017). For example, no language we know of permits sentences like the following one:

*The mouse the cat the farmer chased killed ate the cheese.*

It appears that language users cannot process subjects and objects arranged in too complex a fashion in a sentence.

**Semantics** Semantics refers to the meaning of words and sentences. Every word has a set of semantic features, which are required attributes related to meaning (McKeown & others, 2017). *Girl* and *woman*, for example, share many semantic features, but they differ semantically in regard to age.

Words have semantic restrictions on how they can be used in sentences (Taylor, 2017). The sentence *The bicycle talked the boy into buying a candy bar* is syntactically correct but semantically incorrect. The sentence violates our semantic knowledge that bicycles don’t talk.

**Pragmatics** A final set of language rules involves pragmatics, the appropriate use of language in different contexts. Pragmatics covers a lot of territory (Clark, 2017; Fischer, 2017; Wilce, 2017). When you take turns speaking in a discussion or use a question to convey a command (“Why is it so noisy in here? What is this, Grand Central Station?”), you are demonstrating knowledge of pragmatics. You also apply the pragmatics of English when you use polite language in appropriate situations (for example, when talking to your teacher) or tell stories that are interesting, jokes that are funny, and lies that convince. In each of these cases, you are demonstrating that you understand the rules of your culture for adjusting language to suit the context.

At this point, we have discussed five important rule systems involved in language. An overview of these rule systems is presented in Figure 10.

## HOW LANGUAGE DEVELOPS

According to an ancient historian, in the thirteenth century the emperor of Germany, Frederick II, had a cruel idea. He wanted to know what language children would speak if no one talked to them. He selected several newborns and threatened their caregivers with death if they ever talked to the infants. Frederick never found out what language the children spoke because they all died. Today, we are still curious about infants’ development of language, although our experiments and observations are, to say the least, far more humane than the evil Frederick’s.

Whatever language they learn, infants all over the world follow a similar path in language development. What are some key milestones in this development?

**semantics** The meaning of words and sentences.

**pragmatics** The appropriate use of language in different contexts.

**Recognizing Language Sounds** Long before they begin to learn words, infants can make fine distinctions among the sounds of the language. In Patricia Kuhl's (1993, 2000, 2007, 2009, 2011, 2015) research, phonemes from languages all over the world are piped through a speaker for infants to hear (see Figure 11). A box with a toy bear in it is placed where the infant can see it. A string of identical syllables is played; then the syllables are changed (for example, *ba ba ba ba*, and then *pa pa pa pa*). If the infant turns its head when the syllables change, the box lights up and the bear dances and drums, rewarding the infant for noticing the change.

Kuhl's (2007, 2009, 2011, 2015) research has demonstrated that from birth up to about 6 months of age, infants are "citizens of the world": They recognize when sounds change most of the time, no matter what language the syllables come from. But over the next six months, infants get even better at perceiving the changes in sounds from their "own" language (the one their parents speak) and gradually lose the ability to recognize differences in sounds that are not important in their own language (Kuhl, 2015; Kuhl & Damasio, 2012). Kuhl (2015) has found that a baby's brain becomes most open to learning the sounds of a native language at 6 months for vowels and at 9 months for consonants.

Also, in the second half of the first year, infants begin to segment the continuous stream of speech they encounter into words (Ota & Skarabela, 2018; Polka & others, 2018). Initially, they likely rely on statistical information such as the co-occurrence patterns of phonemes and syllables, which allows them to extract potential word forms (Aslin, 2017; Lany & others, 2018; Richtsmeier & Goffman, 2017; Saffran & Kirkham, 2018). For example, discovering that the sequence *br* occurs more often at the beginning of words while *nt* is more common at the end of words helps infants detect word boundaries. And as infants extract an increasing number of potential word forms from the speech stream they hear, they begin to associate these with concrete, perceptually available objects in their world (Saffran & Kirkham, 2018). For example, infants might detect that the spoken word "monkey" has a reliable statistical regularity of occurring in the visual presence of an observed monkey but not in the presence of other animals, such as bears (Pace & others, 2016). Thus, statistical learning involves extracting information from the world to learn about the environment.

Richard Aslin (2017) recently emphasized that statistical learning—which involves no instruction, reinforcement, or feedback—is a powerful learning mechanism in infant development. In statistical learning, infants soak up statistical regularities in the world merely through exposure to them (Lany & others, 2018; Monroy & others, 2018; Saffran & Kirkham, 2018).

**Babbling and Other Vocalizations** Long before infants speak recognizable words, they produce a number of vocalizations. The functions of these early vocalizations are to practice making sounds, to communicate, and to attract attention (Lee & others, 2017). Babies' sounds go through the following sequence during the first year:

- *Crying.* Babies cry even at birth. Crying can signal distress, but, as we will discuss in the chapter on "Socioemotional Development in Infancy," different types of cries signal different things.

**FIGURE 11**

**FROM UNIVERSAL LINGUIST TO LANGUAGE-SPECIFIC LISTENER.** In Patricia Kuhl's research laboratory babies listen to tape-recorded voices that repeat syllables. When the sounds of the syllables change, the babies quickly learn to look at the bear. Using this technique, Kuhl has demonstrated that babies are universal linguists until about 6 months of age, but in their next six months they become language-specific listeners. *Does Kuhl's research give support to the view that either "nature" or "nurture" is the source of language acquisition?*

Courtesy of Dr. Patricia Kuhl, Institute for Learning and Brain Sciences, University of Washington

- *Cooing.* Babies first coo at about 2 to 4 months (Menn & Stoel-Gammon, 2009). These are gurgling sounds that are made in the back of the throat and usually express pleasure during interaction with the caregiver.
- *Babbling.* In the middle of the first year, babies babble—that is, they produce strings of consonant-vowel combinations, such as “ba, ba, ba, ba.” Infants’ babbling influences the behavior of their caregivers, creating social interaction that facilitates their own communicative development (Albert, Schwade, & Goldstein, 2018). In a recent study, babbling onset predicted when infants would say their first words (McGillion & others, 2017a).

Long before infants speak recognizable words, they communicate by producing a number of vocalizations and gestures. At approximately what ages do infants begin to produce different types of vocalizations and gestures?

©Don Hammond/Design Pics

**Gestures** Infants start using gestures, such as showing and pointing, at about 7 to 15 months of age with a mean age of approximately 11 to 12 months. They may wave bye-bye, nod to mean “yes,” show an empty cup to ask for more milk, and point to a dog to draw attention to it. Some early gestures are symbolic, as when an infant smacks her lips to indicate food or drink. Pointing is regarded by language experts as an important index of the *social aspects of language*, and it follows this developmental sequence: from pointing without checking on adult gaze to pointing while looking back and forth between an object and the adult (Goldin-Meadow, 2017a, b). Lack of pointing is a significant indicator of problems in the infant’s communication system (Brentari & Goldin-Meadow, 2017; Cooperrider & Goldin-Meadow, 2018; Novack & others, 2018). For example, failure to engage in pointing characterizes many autistic children. Use of the pointing gesture becomes more effective in the second year of life alongside advances in other aspects of language communication.

Why might gestures such as pointing promote further language development? Infants’ gestures advance their language development since caregivers often talk to them about what they are pointing to. Also, babies’ first words often are for things they have previously pointed to.

**First Words** Infants understand their first words earlier than they speak them (Pace & others, 2016). As early as 5 months of age, infants recognize their name when someone says it. On average, infants understand about 50 words at about 13 months, but they can’t say this many words until about 18 months (Menyuk, Liebergott, & Schultz, 1995). Thus, in infancy *receptive vocabulary* (words the child understands) considerably exceeds *spoken* (or *expressive*) *vocabulary* (words the child uses).

A child’s first words include those that name important people (*dada*), familiar animals (*kitty*), vehicles (*car*), toys (*ball*), food (*milk*), body parts (*eye*), clothes (*hat*), household items (*clock*), and greeting terms (*bye*). These were the first words of babies 50 years ago, and they are the first words of babies today. Children often express various intentions with their single words, so that “cookie” might mean, “That’s a cookie” or “I want a cookie.” Nouns are easier to learn because the majority of words in this class are more perceptually accessible than words not in this class (Parish-Morris, Golinkoff, & Hirsh-Pasek, 2013). Think how the noun “car” is so much more concrete and imaginable than the verb “goes,” making the word “car” much easier to acquire than the word “goes.”

The infant’s spoken vocabulary rapidly increases after the first word is spoken (Werker & Gervain, 2013). The average 18-month-old can speak about 50 words, but most 2-year-olds can speak about 200 words. This rapid increase in vocabulary that begins at approximately 18 months is called the *vocabulary spurt* (Bloom, Lifter, & Broughton, 1985).

Like the timing of a child’s first word, the timing of the vocabulary spurt varies (Lieven, 2008). Figure 12 shows the range for these two language milestones in 14 children. On average, these children said their first word at 13 months and had a vocabulary spurt at 19 months. However, the ages for the first spoken word of individual children varied from 10 to 17 months and for their vocabulary spurt from 13 to 25 months. Also, the spurt actually involves the increase in the rate at which words are learned. That is, early on, a few words are learned every few days, then later on, a few words are learned each day, and eventually many words each day.

Does early vocabulary development predict later language development? One study found that infant vocabulary development at 16 to 24 months of age was linked to vocabulary, phonological awareness, reading accuracy, and reading comprehension five years later (Duff & others, 2015).

What characterizes the infant’s early word learning?

©JGI/Jamie Grill/Blend Images LLC

Cross-linguistic differences occur in word learning (Waxman & others, 2013). Children learning Mandarin Chinese, Korean, and Japanese acquire more verbs earlier in their development than do children learning English. This cross-linguistic difference reflects the greater use of verbs in the language input to children in these Asian languages. Indeed, the language of Korean children is often described as verb friendly and the language of English as noun friendly (Waxman & others, 2013).

Children sometimes overextend or underextend the meanings of the words they use (Woodward & Markman, 1998). *Overextension* is the tendency to apply a word to objects that are inappropriate for the word's meaning by going beyond the set of referents an adult would use. For example, children at first may say "dada" not only for "father" but also for other men, strangers, or boys. Another example of overextension is calling any animal with four legs a "dog." With time, overextensions decrease and eventually disappear. *Underextension* is the tendency to apply a word too narrowly; it occurs when children fail to use a word to name a relevant event or object. For example, a child might use the word *boy* to describe a 5-year-old neighbor but not apply the word to a male infant or to a 9-year-old male.

**Two-Word Utterances** By the time children are 18 to 24 months of age, they usually speak in two-word utterances. To convey meaning with just two words, the child relies heavily on gesture, tone, and context. The wealth of meaning children can communicate with a two-word utterance includes the following (Slobin, 1972):

- Identification: "See doggie."
- Location: "Book there."
- Repetition: "More milk."
- Negation: "Not wolf."
- Possession: "My candy."
- Attribution: "Big car."
- Agent-action: "Mama walk."
- Action-direct object: "Hit you."
- Action-indirect object: "Give Papa."
- Action-instrument: "Cut knife."
- Question: "Where ball?"

These are examples from children whose first language is English, German, Russian, Finnish, Turkish, or Samoan.

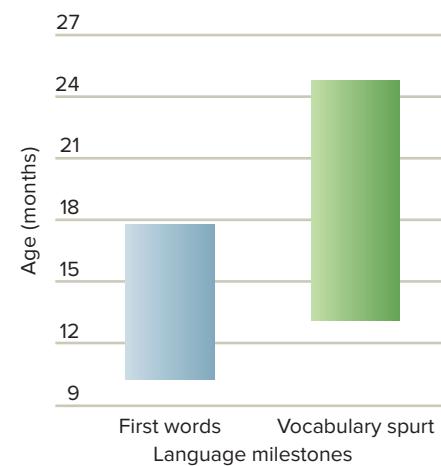

Notice that the two-word utterances omit many parts of speech and are remarkably succinct. In fact, in every language, a child's first combinations of words have this economical quality; they are telegraphic. **Telegraphic speech** is the use of short and precise words without grammatical markers such as articles, auxiliary verbs, and other connectives. Telegraphic speech is not limited to two words. "Mommy give ice cream" and "Mommy give Tommy ice cream" also are examples of telegraphic speech.

We have discussed a number of language milestones in infancy; Figure 13 summarizes the approximate ages at which infants typically reach these milestones.

## BIOLOGICAL AND ENVIRONMENTAL INFLUENCES

What makes it possible for infants to reach the milestones of language development described in Figure 13? Everyone who uses language in some way "knows" its rules and has the ability to create an infinite number of words and sentences. Where does this knowledge come from? Is it the product of biology? Is language learned and influenced by experiences?

**Biological Influences** The ability to speak and understand language requires a certain vocal apparatus as well as a nervous system with certain capabilities. The nervous system and vocal apparatus of humanity's predecessors changed over hundreds of thousands or millions of years. With advances in the nervous system and vocal structures, *Homo sapiens* went beyond the grunting and

##### Language

Much of language is processed in the brain's left hemisphere. Connect to "Physical Development in Infancy."

**Broca's area** An area in the brain's left frontal lobe that is involved in speech production.

**Wernicke's area** An area in the brain's left hemisphere that is involved in language comprehension.

**aphasia** A loss or impairment of language ability caused by brain damage.

##### language acquisition device (LAD)

shrieking of other animals to develop speech (Cataldo, Migliano, & Vinicius, 2018). Although estimates vary, many experts believe that humans acquired language about 100,000 years ago, which in evolutionary time represents a very recent acquisition. It gave humans an enormous edge over other animals and increased the chances of human survival (de Boer & Thompson, 2018; Pinker, 2015).

Some language scholars view the remarkable similarities in how children acquire language all over the world as strong evidence that language has a biological basis. There is evidence that particular regions of the brain are predisposed to be used for language (Coulson, 2017; Schutze, 2017). Two regions involved in language were first discovered in studies of brain-damaged individuals: **Broca's area**, an area in the left frontal lobe of the brain involved in producing words (Maher, 2018; Zhang & others, 2017), and **Wernicke's area**, a region of the brain's left hemisphere involved in language comprehension (see Figure 14) (Bruckner & Kammer, 2017; Greenwald, 2018). Damage to either of these areas produces types of **aphasia**, which is a loss or impairment of language processing. Individuals with damage to Broca's area have difficulty producing words correctly; individuals with damage to Wernicke's area have poor comprehension and often produce fluent but incomprehensible speech.

Linguist Noam Chomsky (1957) proposed that humans are biologically prewired to learn language at a certain time and in a certain way. He said that children are born into the world with a **language acquisition device (LAD)**, a biological endowment that enables the child to detect certain features and rules of language, including phonology, syntax, and semantics. Children are equipped by nature with the ability to detect the sounds of language, for example, and to follow rules such as how to form plurals and ask questions.

Chomsky's LAD is a theoretical construct, not a physical part of the brain. Is there evidence for the existence of a LAD? Supporters of the LAD concept cite the uniformity of language milestones across languages and cultures, evidence that children create language even in the absence of well-formed input, and biological substrates of language. But, as we will see, critics argue that even if infants have something like a LAD, it cannot explain the whole story of language acquisition.

**Environmental Influences** Our coverage of environmental influences on language development in infancy focuses on the important role of social interaction as well as child-directed speech and caregiver strategies.

**FIGURE 14**

**BROCA'S AREA AND WERNICKE'S AREA.** Broca's area is located in the frontal lobe of the brain's left hemisphere, and it is involved in the control of speech. Wernicke's area is a portion of the left hemisphere's temporal lobe that is involved in understanding language. *How does the role of these areas of the brain relate to lateralization?*

**The Role of Social Interaction** Language is not learned in a social vacuum. Most children are bathed in language from a very early age, unlike the Wild Boy of Aveyron, who never learned to communicate effectively, having lived in social isolation for years. Thus, social cues play an important role in infant language learning (Ahun & others, 2018; McGillion & others, 2017b).

The support and involvement of caregivers and teachers greatly facilitate a child's language learning (Brown & others, 2018; Clark, 2017; Marchman & others, 2018; Weisleder & others, 2018). In one study, both full-term and preterm infants who heard more caregiver talk based on all-day recordings at 16 months of age had better language skills (receptive and expressive language, language comprehension) at 18 months of age (Adams & others, 2018). And in another study, when mothers immediately smiled and touched their 8-month-old infants after they babbled, the infants subsequently made more complex speech-like sounds than when mothers responded to their infants in a random manner (Goldstein, King, & West, 2003) (see Figure 15).

Michael Tomasello (2006, 2014) stresses that young children are intensely interested in their social world and that early in their development they can understand the intentions of other people. His *interaction view* of language emphasizes that children learn language in specific contexts. For example, when a toddler and a father are jointly focused on a book, the father might say, "See the birdie." In this case, even a toddler understands that the father intends to name something and knows to look in the direction of the pointing. Through this kind of joint attention, early in their development children are able to use their social skills to acquire language (Mastin & Vogt, 2016). One study revealed that joint attention at 12 and 18 months predicted language skills at 24 months of age (Mundy & others, 2007). Also, in a study involving joint attention, infants' eye-gaze behaviors during Spanish tutoring sessions at 9.5 to 10.5 months of age predicted their second-language phonetic learning at 11 months of age, indicating a strong influence of social interaction at the earliest ages of learning a second language (Conboy & others, 2015).

Researchers have also found that the child's vocabulary development is linked to the family's socioeconomic status and the type of talk that parents direct to their children. Betty Hart and Todd Risley (1995) observed the language environments of children whose parents were professionals and children whose parents were on welfare (public assistance). Compared with the professional parents, the parents on welfare talked much less to their young children, talked less about past events, and provided less elaboration. As indicated in Figure 16, the children of the professional parents had a much larger vocabulary at 36 months of age than the children of the welfare parents. One study also found that at 18 to 24 months of age, infants in low-SES

**SOCIAL INTERACTION AND BABBLING.**

One study focused on two groups of mothers and their 8-month-old infants (Goldstein, King, & West, 2003). One group of mothers was instructed to smile and touch their infants immediately after the babies cooed and babbled; the other group was also told to smile and touch their infants but in a random manner, unconnected to sounds the infants made. The infants whose mothers immediately responded in positive ways to their babbling subsequently made more complex, speechlike sounds, such as "da" and "gu." The research setting for this study, which underscores how important caregivers are in the early development of language, is shown here.

**LANGUAGE INPUT IN PROFESSIONAL AND WELFARE FAMILIES AND YOUNG CHILDREN'S VOCABULARY DEVELOPMENT.**

(a) In this study (Hart & Risley, 1995), parents from professional families talked with their young children more than parents from welfare families. (b) All of the children learned to talk, but children from professional families developed vocabularies that were twice as large as those of children from welfare families. Thus, by the time children go to preschool, they already have experienced considerable differences in language input in their families and developed different levels of vocabulary that are linked to their socioeconomic context. Does this study indicate that poverty caused deficiencies in vocabulary development?

families already had a smaller vocabulary and less efficient language processing than their infant counterparts in middle-SES families (Fernald, Marchman, & Weisleder, 2013).

Other research has linked how much mothers speak to their infants with the size of the infants' vocabularies. For example, in one study by Janellen Huttenlocher and her colleagues (1991), infants whose mothers spoke more often to them had markedly higher vocabularies. By the second birthday, vocabulary differences were substantial. A study of low-SES Spanish-speaking families found that infants who experienced more child-directed speech were better at processing familiar words in real time and had larger vocabularies at 2 years of age (Weisleder & Fernald, 2013).

However, a study of 1- to 3-year-old children living in low-income families found that the sheer amount of maternal talk was not the best predictor of a child's vocabulary growth (Pan & others, 2005). Rather, it was maternal language and literacy skills and mothers' diversity of vocabulary use that best predicted children's vocabulary development. For example, when mothers used a more diverse vocabulary when talking with their children, their children's vocabulary benefited, but their children's vocabulary was not related to the total amount of their talkativeness with their children. Also, mothers who frequently used pointing gestures had children with a greater vocabulary. Pointing usually occurs in concert with speech, and it may enhance the meaning of mothers' verbal input to their children. These research studies and others (NICHD Early Child Care Research Network, 2005; Perkins, Finegood, & Swain, 2013) demonstrate the important effect that early speech input and poverty can have on the development of a child's language skills.

Given that social interaction is critical for infants to learn language effectively, might they also be able to learn language effectively through television and videos? Researchers have found that infants and young children cannot effectively learn language (phonology or words) from television or videos (Kuhl, 2007; Roseberry & others, 2009; Zosh & others, 2017). A study of toddlers found that frequent viewing of television increased the risk of delayed language development (Lin & others, 2015). Thus, just hearing language is not enough even when infants seemingly are fully engaged in the experience. However, one study revealed that Skype provides some improvement in child language learning over videos and TV (Roseberry, Hirsh-Pasek, & Golinkoff, 2014), and older children can use information provided from television in their language development.

Also, recently the American Academy of Pediatrics (AAP) (2016) concluded that for infants from 15 months to 2 years of age, evidence indicates that if parents co-watch educational videos with their infant and communicate with the infant about the information being watched, this shared activity can benefit the infant's development. These findings suggest that when parents treat an educational video or app like a picture book infants can benefit from it. However, the AAP still recommends that children under 18 months of age not watch videos alone.

**Child-Directed Speech and Other Caregiver Strategies** One intriguing component of the young child's linguistic environment is **child-directed speech** (also referred to as "parentese"), which is language spoken with a higher-than-normal pitch, slower tempo, and exaggerated intonation, with simple words and sentences (Broesch & Bryant, 2018; Hayashi & Mazuka, 2017; Sulpizio & others, 2018). It is hard to use child-directed speech when not in the presence of a baby, but parents shift into it when they start talking to a baby. Much of this is automatic and something most parents are not aware they are doing. Child-directed speech serves the important functions of capturing the infant's attention, maintaining communication and social interaction between infants and caregivers, and providing infants with information about their native language by heightening differences between speech directed to children and adults (Golinkoff & others, 2015). Even 4-year-olds speak in simpler ways to 2-year-olds than to their 4-year-old friends. In recent research, child-directed speech in a one-to-one social context at 11 to 14 months of age was related to productive vocabulary at 2 years of age for Spanish-English bilingual infants across languages and in each individual language (Ramirez-Esparza, Garcia-Sierra, & Kuhl, 2017). Most research on child-directed speech has involved mothers, but a recent study in several North American urban areas and a small society on the island of Tanna in the South Pacific Ocean found that fathers in both types of contexts engaged in child-directed speech with their infants (Broesch & Bryant, 2018).

Adults often use strategies other than child-directed speech to enhance the child's acquisition of language, including recasting, expanding, and labeling:

- *Recasting* is rephrasing something the child has said that might lack the appropriate morphology or contain some other error. The adult restates the child's immature utterance in the form of a fully grammatical sentence. For example, if a 2-year-old says, "dog bark," the adult can respond by saying, "Oh, you heard the dog barking!"

**child-directed speech** Language spoken in a higher pitch and slower speed than normal, with simple words and sentences.

The adult sentence provides an acknowledgement that the child was heard and then adds the morphology (*/ing/*) and the article (*the*) that the child's utterance lacked.

- *Expanding* is adding information to a child's incomplete utterance. For example, a child says, "Doggie eat," and the parent replies, "Yes, the dog is eating his food out of his special dish."
- *Labeling* is naming objects that children seem interested in. Young children are forever being asked to identify the names of objects. Roger Brown (1968) called this "the original word game." Children want more than the names of objects, though; they often want information about the object too.

Parents use these strategies naturally and in meaningful conversations. Parents do not need to use a particular method to teach their children to talk, even for children who are slow in learning language. Children usually benefit when parents follow the child's lead, talking about things the child is interested in at the moment, and when parents provide information that children can process. If children are not ready to take in some information, they are likely to let you know (perhaps by turning away). Thus, giving the child more information is not always better.

Remember that encouragement of language development during parents' interaction with their children, not drill and practice, is the key. Language development is not a simple matter of imitation and reinforcement.

Infants, toddlers, and young children benefit when adults read books to and with them (shared reading) (Brown & others, 2018; Marjanovic-Umek, Fekonja-Peklaj, & Socan, 2017; Sinclair & others, 2018; Wesseling, Christmann, & Lachmann, 2017). Storybook reading especially benefits children when parents extend the meaning of the text by discussing it with children and encouraging them to ask and answer questions (Harris, Golinkoff, & Hirsh-Pasek, 2011). In one study, a majority of U.S. mothers in low-income families reported that they were reading to their infants and toddlers with some regularity (Raikes & others, 2006). In this study, non-Latino White, more highly educated mothers who were parenting a first-born child were more likely to read books to their infants and toddlers than were African American and Latino mothers who were parenting later-born children. Reading daily to children at 14 to 24 months of age was positively related to the children's language and cognitive development at 36 months of age. And in one study, Japanese mothers who used more elaborative information-seeking responses during joint picture-book reading at 20 months had children with a better productive vocabulary at 27 months (Murase, 2014). To read further about ways that parents can facilitate children's language development, see *Connecting Development to Life*.

## AN INTERACTIONIST VIEW

If language acquisition depended only on biology, then the Wild Boy of Aveyron and Genie (discussed earlier in the chapter) should have talked without difficulty. A child's experiences influence language acquisition. But we have seen that language does have strong biological foundations. No matter how much you converse with a dog, it won't learn to talk. In contrast, children are biologically prepared to learn language. Children all over the world acquire language milestones at about the same time and in about the same order. However, there are cultural variations in the type of support given to children's language development. For example, caregivers in the Kaluli culture prompt young children to use a loud voice, to call out particular morphemes that direct the speech act the child is performing, and to refer to names, kinship relations, and places where there has been a shared past experience that indicates a closeness to the person being addressed (Ochs & Schieffelin, 2008; Schieffelin, 2005).

Environmental influences are also very important in developing competence in language (Ahun & others, 2018; Clark, 2017; Marchman & others, 2017; Pickard & others, 2018). Children whose parents provide them with a rich verbal environment show many positive benefits (Vallotton & others, 2017; Weisleder & others, 2018). Parents who pay attention to what their children are trying to say, expand their children's utterances, read to them, and label things in the environment, are providing valuable benefits for them (Capone Singleton, 2018; Yazejian & others, 2017).

## How Parents Can Facilitate Infants' and Toddlers' Language Development

Linguist Naomi Baron (1992) in *Growing Up with Language*, developmental psychologists Roberta Golinkoff and Kathy Hirsh-Pasek (2000) in *How Babies Talk*, and more recently Ellen Galinsky (2010) in *Mind in the Making* have provided ideas to help parents facilitate their infants' and toddlers' language development. Following is a summary of their suggestions:

- *Be an active conversational partner.* Talk to your baby from the time it is born. Initiate conversation with the baby. If the baby is in an all-day child-care program, ensure that the baby receives adequate language stimulation from adults.
- *Narrate your daily activities to the baby as you do them.* For example, talk about how you will put the baby in a high chair for lunch and ask what she would like to eat, and so on.
- *Talk in a slowed-down pace and don't worry about how you sound to other adults when you talk to your baby.* Talking in a slowed-down pace will help your baby detect words in the sea of sounds they experience. Babies enjoy and attend to the high-pitched sound of child-directed speech.
- *Use parent-look and parent-gesture, and name what you are looking at.* When you want your child to pay attention to something, look at it and point to it. Then name it—for example, you might say, "Look, Alex, there's an airplane."
- *When you talk with infants and toddlers, be simple, concrete, and repetitive.* Don't try to talk to them in abstract, high-level ways and think you have to say something new or different all of the time. Using familiar words often will help them remember the words.
- *Play games.* Use word games like peek-a-boo and pat-a-cake to help infants learn words.
- *Remember to listen.* Since toddlers' speech is often slow and laborious, parents are often tempted to supply words and thoughts for them. Be patient and let toddlers express themselves, no matter how painstaking the process is or how great a hurry you are in.
- *Expand and elaborate language abilities and horizons with infants and toddlers.* Ask questions that encourage answers other than "yes" or "no." Actively repeat, expand, and recast the utterances. Your toddler might say, "Dada." You could follow with, "Where's Dada?" and then you might continue, "Let's go find him."
- *Adjust to your child's idiosyncrasies instead of working against them.* Many toddlers have difficulty pronouncing words and making

It is a good idea for parents to begin talking to their babies at the start. themselves understood. Whenever possible, make toddlers feel that they are being understood.

- *Resist making normative comparisons.* Be aware of the ages at which your child reaches specific milestones (such as the first word, first 50 words), but do not measure this development rigidly against that of other children. Such comparisons can bring about unnecessary anxiety.

*The first suggestion above to parents of infants is to "be an active conversational partner." What did you learn earlier in the chapter about the amount of conversation mothers have with their infants? Does the amount of conversation or the mother's literacy skills and vocabulary diversity have more of a positive effect on infants' vocabulary?*

An *interactionist view* emphasizes that both *biology* and *experience* contribute to language development (Adams & others, 2017; McGillion & others, 2017b; Raymer & Gonzalez Rothi, 2018; Suskind & others, 2018). How much of language acquisition is biologically determined and how much depends on interaction with others is a subject of debate among linguists and psychologists. However, all agree that both biological capacity and relevant experience are necessary (Green & others, 2017; Novack & others, 2018; Peterson & others, 2017; Pickard & others, 2018; Schwab & others, 2018; Warren & others, 2017).

- How does language develop in infancy?
- What are some biological and environmental influences on language?
- To what extent do biological and environmental influences interact to produce language development?

### Connect

- The more years children spend living in poverty, the more their physiological indices of stress are elevated. In this chapter, you learned about the effects

of SES on children's language acquisition and vocabulary building. How might these effects influence children's school performance?

### Reflect Your Own Personal Journey of Life

- Would it be a good idea for you as a parent to hold large flash cards of words in front of your baby for several hours each day to help the baby learn language and to raise the baby's intelligence? Why or why not? What do you think Piaget would say about this activity?

## topical connections *looking forward*

Advances in infants' cognitive development are linked to their socioemotional development. In subsequent chapters, you will learn about the infant's developing social orientation and understanding, which involve perceiving people as engaging in intentional and goal-directed behavior, joint attention, and cooperation. You will read about two major theorists—Piaget and Vygotsky—and compare their views of how young children's thinking advances. You will see how young children become more capable of sustaining their attention; learn about the astonishing rate at which preschool children's vocabulary expands; and explore variations in early childhood education.

# Cognitive Development in Infancy

## 1 Piaget's Theory of Infant Development

Cognitive Processes

**LG1**

Summarize and evaluate Piaget's theory of infant development.

- In Piaget's theory, children actively construct their own cognitive worlds, building mental structures to adapt to their world. Schemes are actions or mental representations that organize knowledge. Behavioral schemes (physical activities) characterize infancy, whereas mental schemes (cognitive activities) develop in childhood. Assimilation occurs when children use their existing schemes to deal with new information; accommodation refers to children's adjustment of their schemes in the face of new information. Through organization, children group isolated behaviors into a higher-order, more smoothly functioning cognitive system.
- Equilibration is a mechanism Piaget proposed to explain how children shift from one cognitive stage to the next. As children experience cognitive conflict in trying to understand the world, they use assimilation and accommodation to attain equilibrium. The result is a new stage of thought.
- According to Piaget, there are four qualitatively different stages of thought. The first of these, the sensorimotor stage, is described in this chapter. The other three stages are discussed in subsequent chapters.

### The Sensorimotor Stage

- In sensorimotor thought, the first of Piaget's four stages, the infant organizes and coordinates sensations with physical movements. The stage lasts from birth to about 2 years of age.
- Sensorimotor thought has six substages: simple reflexes; first habits and primary circular reactions; secondary circular reactions; coordination of secondary circular reactions; tertiary circular reactions, novelty, and curiosity; and internalization of schemes. One key accomplishment of this stage is object permanence, the ability to understand that objects continue to exist even when the infant is no longer observing them. Another aspect involves infants' understanding of cause and effect.
- Piaget opened up a whole new way of looking at infant development in terms of coordinating sensory input with motoric actions. In recent decades, revisions of Piaget's view have been proposed based on research. For example, researchers have found that a stable and differentiated perceptual world is established earlier than Piaget envisioned, and infants begin to develop concepts earlier as well.
- The nature-nurture issue in regard to infant cognitive development continues to be debated. Spelke endorses a core knowledge approach which states that infants are born with domain-specific innate knowledge systems. Critics argue that Spelke has not given adequate attention to early experiences that infants have.

## 2 Learning, Attention, Remembering, and Conceptualizing

LG2

Describe how infants learn, focus attention, remember, and conceptualize.

### Conditioning

### Attention

### Memory

### Imitation

### Concept Formation and Categorization

- Operant conditioning techniques have been especially useful to researchers in demonstrating infants' perception and retention of information about perceptual-motor actions.
- Attention is the focusing of mental resources on select information, and in infancy attention is closely linked with habituation. In the first year, much of attention is of the orienting/investigative type, but sustained attention also becomes important.
- Habituation is the repeated presentation of the same stimulus, causing reduced attention to the stimulus. If a different stimulus is presented and the infant pays increased attention to it, dishabituation is occurring.
- Joint attention plays an important role in infant development, especially in the infant's acquisition of language.
- Memory is the retention of information over time. Infants as young as 2 to 6 months of age can retain information about perceptual-motor actions. However, many experts argue that what we commonly think of as memory (consciously remembering the past) does not occur until the second half of the first year of life. By the end of the second year, long-term memory is more substantial and reliable.
- The hippocampus and frontal lobes of the brain are involved in development of explicit memory in infancy. The phenomenon of not being able to remember events that occurred before the age of 3—known as infantile or childhood amnesia—may be due to the immaturity of the prefrontal lobes of the brain at that age.
- Meltzoff has shown that newborns can match their behaviors (such as protruding their tongue) to those of a model. His research also shows that deferred imitation occurs as early as 9 months of age.
- Mandler argues that it is not until about 7 to 9 months of age that infants form conceptual categories, although we do not know precisely when concept formation begins. Infants' first concepts are broad. Over the first two years of life, these broad concepts gradually become more differentiated.

## 3 Language Development

LG3

Describe the nature of language and how it develops in infancy.

### Defining Language

- Language is a form of communication, whether spontaneous, written, or signed, that is based on a system of symbols. Language consists of the words used by a community and the rules for varying and combining them. Language is characterized by infinite generativity.

- Language's Rule Systems
  - How Language Develops
  - Biological and Environmental Influences
  - An Interactionist View
- Phonology is the sound system of a language, including the sounds that are used and how they may be combined. Morphology refers to the units of meaning involved in word formation. Syntax is the way words are combined to form acceptable phrases and sentences. Semantics involves the meaning of words and sentences. Pragmatics is the appropriate use of language in different contexts.
  - Among the milestones in infant language development are crying (birth), cooing (1 to 2 months), babbling (6 months), making the transition from universal linguist to language-specific listener (6 to 12 months), using gestures (8 to 12 months), comprehending words (8 to 12 months), speaking one's first word (13 months), undergoing a vocabulary spurt (19 months), rapidly expanding one's understanding of words (18 to 24 months), and producing two-word utterances (18 to 24 months).
  - In evolution, language clearly gave humans an enormous advantage over other animals and increased their chances of survival. Broca's area and Wernicke's area are important locations for language processing in the brain's left hemisphere.
  - Chomsky argues that children are born with the ability to detect basic features and rules of language. In other words, they are biologically equipped to learn language with a prewired language acquisition device (LAD). Adults help children acquire language by engaging in child-directed speech, recasting, expanding, and labeling.
  - Environmental influences are demonstrated by differences in the language development of children as a consequence of being exposed to different language environments in the home. Parents should talk extensively with an infant, especially about what the baby is attending to.
  - Today, most language researchers believe that children everywhere arrive in the world with special social and linguistic capacities that make language acquisition not just likely but inevitable for virtually all children. How much of the language is biologically determined, and how much depends on interaction with others, is a subject of debate among linguists and psychologists. However, all agree that both biological capacity and relevant experience are necessary.

The Family  
Child Care

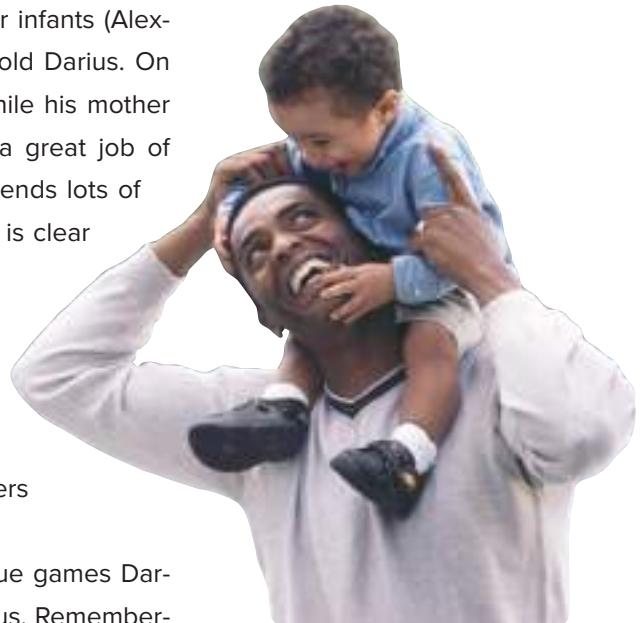

## An increasing number of fathers are staying home to care for their children

(Bartel & others, 2018; Dette-Hagenmeyer, Erzinger, & Reichle, 2016). And researchers are finding improved outcomes when fathers are positively engaged with their infants (Alexander & others, 2017; Sethna & others, 2018). Consider 17-month-old Darius. On weekdays, Darius' father, a writer, cares for him during the day while his mother works full-time as a landscape architect. Darius' father is doing a great job of caring for him. He keeps Darius nearby while he is writing and spends lots of time talking to him and playing with him. From their interactions, it is clear that they genuinely enjoy each other.

Last month, Darius began spending one day a week at a child-care center. His parents carefully selected the center after observing a number of centers and interviewing teachers and center directors. His parents placed him in the center one day a week because they wanted to help Darius get some experience with peers and to give his father some time out from his caregiving.

Darius' father looks to the future and imagines the Little League games Darius will play in and the many other activities he can enjoy with Darius. Remembering how little time his own father spent with him, he is dedicated to making sure that Darius has an involved, nurturing experience with his father.

When Darius' mother comes home in the evenings, she spends considerable time with him. Darius has a secure attachment with both his mother and his father.

Many fathers are spending more time with their infants today than in the past.

### topical connections *looking back*

Until now, we have only discussed the social situations and emotions of parents before and after the arrival of their infants, focusing on such topics as parents' feelings of joy, anticipation, anxiety, and stress during pregnancy; how a mother's optimism may lead to better outcomes for her fetus; and parents' emotional and psychological adjustments during the postpartum period. In this chapter, we will explore the infant's socioemotional development.

# preview

You have read about how the infant perceives, learns, and remembers. Infants also are socioemotional beings, capable of displaying emotions and initiating social interaction with people close to them. The main topics that we will explore in this chapter are emotional and personality development, social understanding and attachment, and the social contexts of the family and child care.

Anyone who has been around infants for even a brief time detects that they are emotional beings. Not only do infants express emotions, but they also vary in their temperaments. Some are shy and others are outgoing. Some are active and others much less so. In this section, we will explore these and other aspects of emotional and personality development in infants.

### EMOTIONAL DEVELOPMENT

Imagine your life without emotion. Emotion is the color and music of life, as well as the tie that binds people together. How do psychologists define and classify emotions, and why are they important to development? How do emotions develop during the first two years of life?

**What Are Emotions?** For our purposes, we will define **emotion** as feeling, or affect, that occurs when a person is in a state or an interaction that is important to him or her, especially to his or her well-being. Especially in infancy, emotions play important roles in (1) communication with others, and (2) behavioral organization (Ekas, Braungart-Rieker, & Messinger, 2018; Perry & Calkins, 2018). Through emotions, infants communicate important aspects of their lives such as joy, sadness, interest, and fear (Taylor & Workman, 2018). In terms of behavioral organization, emotions influence infants' social responses and adaptive behavior as they interact with others in their world (Cole, 2016; Cole & Hollenstein, 2018).

Psychologists classify the broad range of emotions in many ways, but almost all classifications designate an emotion as either positive or negative (Parsons & others, 2017; Planalp & others, 2017). Positive emotions include enthusiasm, joy, and love. Negative emotions include anxiety, anger, guilt, and sadness.

**Biological, Cognitive, and Environmental Influences** Emotions are influenced by biological foundations, cognitive processes, and a person's experiences (Forouge, 2018; Perry & Calkins, 2018). Biology's importance to emotion is apparent in the changes in a baby's emotional capacities (Thompson & Goodvin, 2016). Certain regions of the brain that develop early in life (such as the brain stem, hippocampus, and amygdala) play a role in distress, excitement, and rage, and even infants display these emotions (van den Boomen, Munsters, & Kenner 2018; Tottenham, 2017). But, as we discuss later in the chapter, infants only gradually develop the ability to regulate their emotions, and this ability seems tied to the gradual maturation of the frontal regions of the cerebral cortex that can exert control over other areas of the brain (Bell, Broomell, & Patton, 2018; Bell & others, 2018).

Cognitive processes, both in immediate "in the moment" contexts, and across childhood development, influence infants' and children's emotional development (Bell, Diaz, & Liu, 2018; Jiang & others, 2017). Attention toward or away from an experience can influence infants' and children's emotional responses. For example, children who can distract themselves from a stressful encounter show a lower level of negative affect in the context and less anxiety over time (Crockenberg & Leerkes, 2006). Also, as children become older, they develop cognitive strategies for controlling their emotions and become more adept at modulating their emotional arousal (Bell, Diaz, & Liu, 2018; Kaunhoven & Dorjee, 2017).

How do biological, cognitive, and environmental factors influence the infant's emotional development?

©Lawren/Getty Images

**emotion** Feeling, or affect, that occurs when a person is in a state or interaction that is important to him or her. Emotion is characterized by behavior that reflects (expresses) the pleasantness or unpleasantness of the state a person is in or the transactions being experienced.

Biological evolution has endowed human beings to be *emotional*, but embeddedness in relationships and culture with others provides diversity in emotional experiences (Bedford & others, 2017; Ostlund & others, 2017; Perry & Calkins, 2018). Emotional development and coping with stress are influenced by whether caregivers have maltreated or neglected children and whether children's caregivers are depressed or not (Almy & Cicchetti, 2018; Cicchetti, 2017). When infants become stressed, they show better biological recovery from the stressors when their caregivers engage in sensitive caregiving with them (Granat & others, 2017; Sullivan & Wilson, 2018).

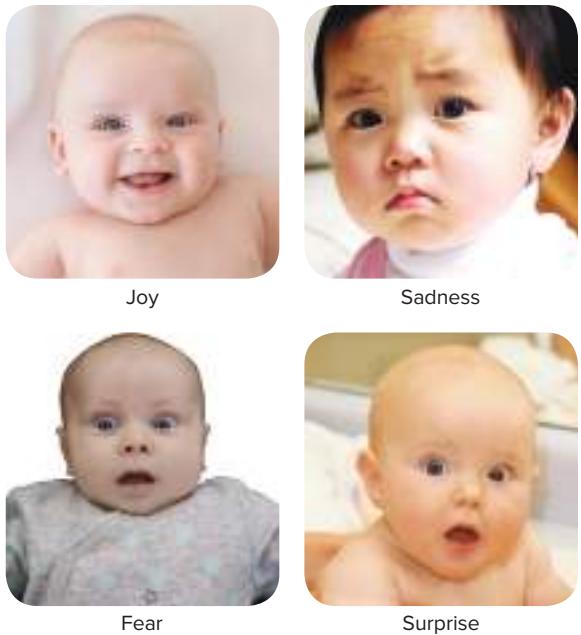

Social relationships provide the setting for the development of a rich variety of emotions (Cole, Lougheed, & Ram, 2018; Morris & others, 2018; Thompson, 2016). When toddlers hear their parents quarreling, they often react with distress and inhibit their play. Well-functioning families make each other laugh and may develop a light mood to defuse conflicts.

Cultural differences occur in emotional experiences (Cole, 2016; Qu & Telzer, 2017). For example, researchers have found that East Asian infants display less frequent and less intense positive and negative emotions than non-Latino White infants (Cole & Tan, 2015). Further, Japanese parents try to prevent their children from experiencing negative emotions, whereas non-Latino White mothers are more likely to respond after their children become distressed and then help them cope (Cole & Tan, 2015).

**Early Emotions** A leading expert on infant emotional development, Michael Lewis (2007, 2008, 2010, 2015, 2016) distinguishes between primary emotions and self-conscious emotions. **Primary emotions** are present in humans and other animals; these emotions appear in the first 6 months of the human infant's development. Primary emotions include surprise, interest, joy, anger, sadness, fear, and disgust (see Figure 1 for infants' facial expressions of some of these early emotions). In Lewis' classification, **self-conscious emotions** require self-awareness that involves consciousness and a sense of "me." Self-conscious emotions include jealousy, empathy, embarrassment, pride, shame, and guilt, most of these occurring for the first time at some point in the second half of the first year through the second year. Some experts on emotion call self-conscious emotions such as embarrassment, shame, guilt, and pride *other-conscious emotions* because they involve the emotional reactions of others when they are generated (Saarni & others, 2006). For example, approval from parents is linked to toddlers' beginning to show pride when they successfully complete a task.

Researchers such as Joseph Campos (2005) and Michael Lewis (2016) debate how early in the infant and toddler years the emotions that we have described first appear and in what sequence. As an indication of the controversy regarding when certain emotions first are displayed by infants, consider jealousy. Some researchers argue that jealousy does not emerge until approximately 15 to 18 months of age (Lewis, 2016), whereas others assert that it is displayed much earlier at about 9 months (Hart, 2018).

Consider the results of two research studies. In the first one, 9-month-old infants engaged in more approach-style, jealousy-related behaviors when their mothers gave attention to a social rival (a lifelike doll) than to a non-social rival (a book) (Mize & others, 2014). Further, in this study, the infants showed EEG activity during the social-rival condition that is associated with jealousy. In a second study, 6-month-old infants observed their mothers in situations similar to the first study: either giving attention to a lifelike baby doll (hugging or gently rocking it, for example) or to a book (Hart & Carrington, 2002). When mothers directed their attention to the doll, the infants were more likely to display negative emotions, such as anger and sadness, which may have indicated their jealousy (see Figure 2). On the other hand, their expressions of anger and sadness may have reflected frustration in not being able to have the novel doll to play with.

**IS THIS THE EARLY EXPRESSION OF JEALOUSY?** In the study by Hart and Carrington (2002), the researchers concluded that the 6-month-old infants who observed their mothers giving attention to a baby doll displayed negative emotions—such as anger and sadness—which may indicate the early appearance of jealousy. However, experts on emotional development, such as Michael Lewis (2007) and Jerome Kagan (2010), argue that it is unlikely emotions such as jealousy appear in the first year. *Why do they conclude that it is unlikely jealousy occurs in the first year?*

Debate about the onset of an emotion such as jealousy illustrates the complexity and difficulty of indexing early emotions. That said, some experts on infant socioemotional development, such as Jerome Kagan (2010), conclude that the structural immaturity of the infant brain makes it unlikely that emotions which require thought—such as guilt, pride, despair, shame, empathy, and jealousy—can be experienced during the first year. Nonetheless, some leading researchers have argued that research now indicates empathy can be expressed before the infant's first birthday (Davidov & others, 2013).

### Emotional Expression and Social Relationships

Emotional expressions are involved in infants' first relationships. The ability of infants to communicate emotions permits coordinated interactions with their caregivers and the beginning of an emotional bond between them (Perry & Calkins, 2018; Thompson, 2015, 2016). Not only do parents change their emotional expressions in response to infants' emotional expressions, but infants also modify their emotional expressions

in response to their parents' emotional expressions (Frick & others, 2018; Johnson, 2018). In other words, these interactions are mutually regulated. Because of this coordination, the interactions are described as reciprocal, or synchronous, when all is going well. Sensitive, responsive parents help their infants grow emotionally, whether the infants respond in distressed or happy ways (Bedford & others, 2017). A recent observational study of mother-infant interaction found that maternal sensitivity was linked to a lower level of infant fear (Gartstein, Hancock, & Iverson, 2017). Another study revealed that parents' elicitation of talk about emotion with toddlers was associated with the toddlers' sharing and helping (Brownell & others, 2013).

One study documented that babies pick up on their mothers' stress (Waters, West, & Mendes, 2014). In this study, mothers were separated from their babies and asked to give a 5-minute speech, on which half of the mothers received a positive evaluation, the other half a negative evaluation. Mothers who received negative feedback reported an increase in negative emotion and cardiac stress, while those who were given positive feedback reported an increase in positive emotion. The babies quickly detected and responded to their mothers' stress, as reflected in an increased heart rate when reunited with them. And the greater the mother's stress response, the more her baby's heart rate increased.

Cries and smiles are two emotional expressions that infants display when interacting with parents. These are babies' first forms of emotional communication.

**Crying** Crying is the most important mechanism newborns have for communicating with their world. The first cry verifies that the baby's lungs have filled with air. Cries also may provide information about the health of the newborn's central nervous system. A recent study found that excessive infant crying in 3-month-olds doubled the risk of behavioral, hyperactive, and mood problems at 5 to 6 years of age (Smarius & others, 2017).

Babies have at least three types of cries:

- **Basic cry.** A rhythmic pattern that usually consists of a cry, followed by a briefer silence, then a shorter whistle that is somewhat higher in pitch than the main cry, then another brief rest before the next cry. Some infancy experts believe that hunger is one of the conditions that incites the basic cry.
- **Anger cry.** A variation of the basic cry in which more excess air is forced through the vocal cords.
- **Pain cry.** A sudden long, initial loud cry followed by breath holding; no preliminary moaning is present. The pain cry is stimulated by a high-intensity stimulus.

Most adults can determine whether an infant's cries signify anger or pain (Zeskind, Klein, & Marshall, 1992). Parents can distinguish the cries of their own baby better than those of another baby.

**Smiling** Smiling is a key social signal and a very important aspect of positive social interaction in developing a new social skill (Martin & Messinger, 2018). Researchers have found that smiling and laughter at 7 months of age are associated with self-regulation at 7 years of age (Posner & others, 2014). The power of the infant's smiles was appropriately captured by British

theorist John Bowlby (1969): “Can we doubt that the more and better an infant smiles the better he is loved and cared for? It is fortunate for their survival that babies are so designed by nature that they beguile and enslave mothers.” Two types of smiling can be distinguished in infants:

- **Reflexive smile.** A smile that does not occur in response to external stimuli and appears during the first month after birth, usually during sleep.
- **Social smile.** A smile that occurs in response to an external stimulus, typically a face in the case of the young infant. Social smiling occurs as early as 2 months of age.

The infant’s social smile can have a powerful impact on caregivers (Martin & Messinger, 2018). Following weeks of seemingly endless demands, fatigue, and little reinforcement, an infant starts smiling at them and all of the caregivers’ efforts are rewarded. One study found that higher maternal effortful control and positive emotionality predicted more initial infant smiling and laughter, while a higher level of parenting stress predicted a lower trajectory of infant smiling and laughter (Bridgett & others, 2013).

**Fear** One of a baby’s earliest emotions is fear, which typically first appears at about 6 months of age and peaks at about 18 months. However, abused and neglected infants can show fear as early as 3 months (Witherington & others, 2010). Researchers have found that infant fear is linked to guilt, empathy, and low aggression at 6 to 7 years of age (Rothbart, 2007).

The most frequent expression of an infant’s fear involves **stranger anxiety**, in which an infant shows a fear and wariness of strangers (Van Hulle & others, 2017). Stranger anxiety usually emerges gradually. It first appears at about 6 months of age in the form of wary reactions. By age 9 months, the fear of strangers is often more intense, reaching a peak toward the end of the first year of life and then decreasing thereafter (Scher & Harel, 2008).

Not all infants show distress when they encounter a stranger. Besides individual variations, whether an infant shows stranger anxiety also depends on the social context and the characteristics of the stranger.

Infants show less stranger anxiety when they are in familiar settings. For example, in one study 10-month-olds showed little stranger anxiety when they met a stranger in their own home but much greater fear when they encountered a stranger in a research laboratory (Sroufe, Waters, & Matas, 1974). Thus, it appears that when infants feel secure, they are less likely to show stranger anxiety.

Who the stranger is and how the stranger behaves also influence stranger anxiety in infants. Infants are less fearful of child strangers than adult strangers. They also are less fearful of friendly, outgoing, smiling strangers than of passive, unsmiling strangers (Bretherton, Stolberg, & Kreye, 1981).

In addition to stranger anxiety, infants experience fear of being separated from their caregivers. The result is **separation protest**—crying when the caregiver leaves. Separation protest is initially displayed by infants at approximately 7 to 8 months and peaks at about 15 months among U.S. infants (Kagan, 2008). In fact, one study found that separation protest peaked at about 13 to 15 months in four different cultures (Kagan, Kearsley, & Zelazo, 1978). Although the percentage of infants who engaged in separation protest varied across cultures, the infants reached a peak of protest at about the same age—just before the middle of the second year of life.

**Emotion Regulation and Coping** During the first year of life, the infant gradually develops an ability to inhibit, or minimize, the intensity and duration of emotional reactions (Calkins & Perry, 2016; Ekas, Braungart-Rieker, & Messinger, 2018). From early in infancy, babies put their thumbs in their mouths to soothe themselves. But at first, infants mainly depend on caregivers to help them soothe their emotions, as when a caregiver rocks an infant to sleep, sings lullabies to the infant, gently strokes the infant, and so on. In a recent study, researchers found that young infants with a negative temperament used fewer attention regulation strategies, and maternal sensitivity to infants was linked to more adaptive emotion regulation (Thomas & others, 2017).

Later in infancy, when they become aroused, infants sometimes redirect their attention or distract themselves in order to reduce their arousal. By 2 years of age, toddlers can use language to define their feeling states and the context that is upsetting them. A toddler might say, “Doggy scary.” This type of communication may help caregivers to assist the child in regulating emotion.

Contexts can influence emotion regulation (Groh & others, 2018; Morris & others, 2018; Thompson & Goodvin, 2016). Infants are often affected by fatigue, hunger, time of day, which

people are around them, and where they are. Infants must learn to adapt to different contexts that require emotion regulation. Further, new demands appear as the infant becomes older and parents modify their expectations. For example, a parent may take it in stride if a 6-month-old infant screams in a restaurant but may react very differently if a 6-year-old starts screaming.

To soothe or not to soothe—should a crying baby be given attention and soothed, or does this spoil the infant? Many years ago, the behaviorist John Watson (1928) argued that parents spend too much time responding to infant crying. As a consequence, he said, parents reward crying and increase its incidence. Also, behaviorist Jacob Gewirtz (1977) found that a caregiver's quick, soothing response to crying increased crying. In contrast, infancy experts Mary Ainsworth (1979) and John Bowlby (1989) stress that it is not possible to respond too much to infant crying in the first year of life. They believe that a quick, comforting response to the infant's cries is an important ingredient in developing a strong bond between the infant and caregiver. In one of Ainsworth's studies, infants whose mothers responded quickly when they cried at 3 months of age cried less later in the first year of life (Bell & Ainsworth, 1972). Another study found that mothers were more likely than fathers to use soothing techniques to reduce infant crying (Dayton & others, 2015). Further, a recent study revealed that depressed mothers rocked and touched their crying infants less than non-depressed mothers (Esposito & others, 2017a).

Controversy still surrounds the question of whether or how parents should respond to an infant's cries (Zeifman & St. James-Roberts, 2017). However, developmentalists increasingly argue that infants cannot be spoiled in the first year of life, which suggests that parents should soothe a crying infant. This response should help infants develop a sense of trust and secure attachment to the caregiver. One study revealed that mothers' negative emotional reactions (anger and anxiety) to crying increased the risk of subsequent attachment insecurity (Leerkes, Parade, & Gudmundson, 2011). Another study found that problems in infant soothability at 6 months of age were linked to insecure attachment at 12 months of age (Mills-Koonce, Propper, & Barnett, 2012).

## TEMPERAMENT

Do you become upset often? Does it take much to get you angry, or to make you laugh? Even at birth, babies seem to have different emotional styles. One infant is cheerful and happy much of the time; another baby seems to cry constantly. These tendencies reflect **temperament**, which involves individual differences in behavioral styles, emotions, and characteristic ways of responding. With regard to its link to emotion, temperament refers to individual differences in how quickly the emotion is shown, how strong it is, how long it lasts, and how quickly it fades away.

Another way to describe temperament is in terms of predispositions toward emotional reactivity and self-regulation (Bates & Pettit, 2015). *Reactivity* involves variations in the speed and intensity with which an individual responds to situations with positive or negative emotions. *Self-regulation* involves variations in the extent or effectiveness of an individual's ability to control his or her emotions.

**Describing and Classifying Temperament** How would you describe your temperament or the temperament of a friend? Researchers have described and classified the temperaments of individuals in different ways (Abulizi & others, 2017; Gartstein, Putnam, & Kliwewer, 2016; Janssen & others, 2017). Here we will examine three of those ways.

**Chess and Thomas' Classification** Psychiatrists Alexander Chess and Stella Thomas (Chess & Thomas, 1977; Thomas & Chess, 1991) identified three basic types, or clusters, of temperament:

- An **easy child** is generally in a positive mood, quickly establishes regular routines in infancy, and adapts easily to new experiences.
- A **difficult child** reacts negatively and cries frequently, engages in irregular daily routines, and is slow to accept change.
- A **slow-to-warm-up child** has a low activity level, is somewhat negative, and displays a low intensity of mood.

In their longitudinal investigation, Chess and Thomas found that 40 percent of the children they studied could be classified as easy, 10 percent as difficult, and 15 percent as slow to warm up. Notice that 35 percent did not fit any of the three patterns. Researchers have found that these three basic clusters of temperament are moderately stable across the childhood years.

**temperament** Involves individual differences in behavioral styles, emotions, and characteristic ways of responding.

**easy child** A child who is generally in a positive mood, quickly establishes regular routines in infancy, and adapts easily to new experiences.

**difficult child** A child who tends to react negatively and cry frequently, engages in irregular daily routines, and is slow to accept change.

**slow-to-warm-up child** A child who has a low activity level, is somewhat negative, and displays a low intensity of mood.

**Kagan's Behavioral Inhibition** Another way of classifying temperament focuses on the differences between a shy, subdued, timid child and a sociable, extraverted, bold child. Jerome Kagan (2002, 2008, 2010, 2013) regards shyness with strangers (peers or adults) as one feature of a broad temperament category called inhibition to the unfamiliar. Inhibited children react to many aspects of unfamiliarity with initial avoidance, distress, or subdued affect, beginning at about 7 to 9 months of age.

Kagan has found that inhibition shows considerable stability from infancy through early childhood. One study classified toddlers into extremely inhibited, extremely uninhibited, and intermediate groups (Pfeifer & others, 2002). Follow-up assessments were conducted at 4 and 7 years of age. Continuity was demonstrated for both inhibition and lack of inhibition, although a substantial number of the inhibited children had moved into the intermediate groups by 7 years of age. Researchers found that having an inhibited temperament at 2 to 3 years of age was related to having social phobia symptoms at 7 years of age (Lahat & others, 2014). Further, research findings also indicate that infants and young children who have an inhibited temperament are at risk for developing social anxiety disorder in adolescence and adulthood (Perez-Edgar & Guyer, 2014; Rapee, 2014). And in another study, if parents had a childhood history of behavioral inhibition, their children who had a high level of behavioral inhibition were at risk for developing anxiety disorders (Stumper & others, 2017).

**Rothbart and Bates' Classification** New classifications of temperament continue to be forged. Mary Rothbart and John Bates (2006) argue that prior classifications of temperament have not included a key temperament style: effortful control (self-regulation). They conclude that the following three broad dimensions best represent what researchers have found to characterize the structure of temperament: extraversion/surgency, negative affectivity, and effortful control (self-regulation):

- *Extraversion/surgency* includes approach, pleasure, activity, smiling, and laughter. Kagan's uninhibited children fit into this category. One study revealed that preschool children with high levels of surgency were more likely to engage in a number of obesity-related eating behaviors such as eating in the absence of hunger (Leung & others, 2014).
- *Negative affectivity* includes "fear, frustration, sadness, and discomfort" (Rothbart, 2004, p. 495). These children are easily distressed; they may fret and cry often. Kagan's inhibited children fit this category. In the study mentioned above, preschool children with higher levels of negative affectivity were more likely to have tantrums if they were denied food, but less likely to eat in the absence of hunger (Leung & others, 2014).
- *Effortful control (self-regulation)* includes "attentional focusing and shifting, inhibitory control, perceptual sensitivity, and low-intensity pleasure" (Rothbart, 2004, p. 495). Infants who are high on effortful control show an ability to keep their arousal from getting too high and have strategies for soothing themselves. By contrast, children low on effortful control are often unable to control their arousal; they become easily agitated and intensely emotional.

A number of studies have supported the view that effortful control is an important influence on children's development. For example, one study found that young children higher in effortful control were more likely to wait longer to express anger and were more likely to use a self-regulatory strategy, distraction (Tan, Armstrong, & Cole, 2013). Another study revealed that effortful control was a strong predictor of academic success skills (including school readiness, math skills, and reading skills) in kindergarten children from low-income families (Morris & others, 2013). Further, a recent study revealed that self-regulation capacity at 4 months of age was linked to school readiness at 4 years of age (Gartstein, Putnam, & Kliewer, 2016). And in two recent studies, lower levels of effortful control were linked to attention deficit hyperactivity disorder (ADHD). In the first study, a lower level of children's temperament regulation at 3 years of age predicted the presence of ADHD symptoms in the first grade (Willoughby, Gottfredson, & Stifter, 2016). In the second study, children with a lower level of effort control at 3 years of age were more likely to have ADHD symptoms at 13 years of age (Einziger & others, 2018).

In Rothbart's (2004, p. 497) view, "early theoretical models of temperament stressed the way we are moved by our positive and negative emotions or level of arousal, with our actions

driven by these tendencies.” The more recent focus on effortful control, however, emphasizes that individuals can engage in a more cognitive, flexible approach to stressful circumstances. It is Rothbart and Bates’ addition of effortful control (self-regulation) that is their most important contribution to our understanding of temperament.

An important point about temperament classifications such as those of Chess and Thomas or Rothbart and Bates is that children should not be pigeonholed as having only one temperament dimension, such as “difficult” or “negative affectivity.” A good strategy when attempting to classify a child’s temperament is to think of temperament as consisting of multiple dimensions (Bates, 2012a, b). For example, a child might be extraverted, show little negative affectivity, and have good self-regulation. Another child might be introverted, show little negative affectivity, and have a low level of self-regulation.

The development of temperament capabilities such as effortful control allows individual differences to emerge (Bates & Pettit, 2015). For example, although maturation of the brain’s prefrontal lobes must occur for any child’s attention to improve and the child to achieve effortful control, some children develop effortful control while others do not. And it is these individual differences in children that are at the heart of what temperament is (Bates, 2012a, b; Bates & Pettit, 2015).

**Biological Foundations and Experience** How does a child acquire a certain temperament? Kagan (2002, 2010, 2013) argues that children inherit a *physiology* that biases them to have a particular type of temperament. However, through experience they may learn to modify their temperament to some degree. Thus, Kagan stresses that temperament has both a physiological and experiential basis. For example, children may inherit a physiology that biases them to be fearful and inhibited, but they can learn to reduce their fear and inhibition to some degree.

**Biological Influences** Physiological characteristics have been linked with different temperaments (Bates & Pettit, 2015). In particular, an inhibited temperament is associated with a unique physiological pattern that includes high and stable heart rate, high level of the hormone *cortisol*, and high activity in the right frontal lobe of the brain (Kagan, 2008, 2010). This pattern may be tied to the excitability of the amygdala, a structure of the brain that plays an important role in fear and inhibition.

What is heredity’s role in the biological foundations of temperament? Twin and adoption studies suggest that heredity has a moderate influence on differences in temperament within a group of people (Plomin & others, 2009). The *contemporary view* is that temperament is a biologically based but evolving aspect of behavior; it evolves as the child’s experiences are incorporated into a network of self-perceptions and behavioral preferences that characterize the child’s personality (Thompson & Goodvin, 2016).

*What are some ways that developmentalists have classified infants’ temperaments? Which classification makes the most sense to you, based on your observations of infants?*

Too often the biological foundations of temperament are interpreted to mean that temperament cannot develop or change. However, important self-regulatory dimensions of temperament such as adaptability, soothability, and persistence look very different in a 1-year-old and a 5-year-old (Thompson, 2015). These temperament dimensions develop and change with the growth of the neurobiological foundations of self-regulation (Calkins & Perry, 2016).

**Gender, Culture, and Temperament** Gender may be an important factor shaping the environmental context that influences temperament (Gaias & others, 2012). Parents might react differently to an infant's temperament depending on whether the baby is a boy or a girl. For example, in one study, mothers were more responsive to the crying of irritable girls than to the crying of irritable boys (Crockenberg, 1986).

Similarly, the caregiver's reaction to an infant's temperament may depend in part on culture (Matsumoto & Juang, 2017). For example, behavioral inhibition is more highly valued in China than in North America, and researchers have found that Chinese children are more inhibited than Canadian infants are (Chen & others, 1998). The cultural differences in temperament were linked to parental attitudes and behaviors. Canadian mothers of inhibited 2-year-olds were less accepting of their infants' inhibited temperament, whereas Chinese mothers were more accepting. Also, one study revealed that U.S. infants showed more temperamental fearfulness while Finnish infants engaged in more positive affect, such as effortful control (Gaias & others, 2012).

In short, many aspects of a child's environment can encourage or discourage the persistence of temperament characteristics (Parade & others, 2018; Schumann & others, 2017). For example, researchers found that fathers' internalizing problems (anxiety and depression, for example) were linked to a higher level of negative affectivity in 6-month-olds (Potapova,

Gartstein, & Bridgett, 2014). And another study revealed that maternal negativity and child problem behavior were most strongly linked for children who were low in effortful control and living in chaotic homes (Chen, Deater-Deckard, & Bell, 2014). One useful way of thinking about temperament-environment connections involves the concept of goodness of fit, which we examine next.

**Goodness of Fit and Parenting** Goodness of fit refers to the match between a child's temperament and the environmental demands the child must cope with. Suppose Jason is an active toddler who is made to sit still for long periods of time, and Jack is a slow-to-warm-up toddler who is abruptly pushed into new situations on a regular basis. Both Jason and Jack face a lack of fit between their temperament and environmental demands. Lack of fit can produce adjustment problems (Planalp & others, 2017; Rothbart, 2011).

Some temperament characteristics pose more parenting challenges than others, at least in modern Western societies (Bates & Pettit, 2015). When children are prone to distress, as exhibited by frequent crying and irritability, their parents may

## Parenting and the Child's Temperament

What are the implications of temperamental variations for parenting?

Although answers to this question necessarily are speculative, the following conclusions regarding the best parenting strategies to use in relation to children's temperament were reached by temperament experts Ann Sanson and Mary Rothbart (1995):

- *Attention to and respect for individuality.* Good parenting involves sensitivity to the child's individual characteristics. A goal might be accomplished in one way with one child and in another way with another child, depending on the child's temperament.
- *Structuring the child's environment.* Crowded, noisy environments can pose greater problems for some children (such as a "difficult child") than others (such as an "easy child"). We might also expect that a fearful, withdrawing child would benefit from slower entry into new contexts.
- *The "difficult child" and packaged parenting programs.* Programs for parents often focus on dealing with children who have "difficult" temperaments. In some cases, "difficult child" refers to Thomas and Chess' description of a child who reacts negatively, cries frequently, engages in irregular daily routines, and is slow to accept change. In others, the concept might be used to describe a child who is irritable, displays anger frequently, does not follow directions well, or shows some other negative characteristic. Acknowledging that some children are harder to parent than other children is often helpful, and advice on how to handle specific difficult characteristics can be useful. However, whether a particular characteristic is difficult depends on its fit with the environment. Labeling a child "difficult" can create a self-fulfilling prophecy. If a child is identified as "difficult," people may treat the child in a way that actually elicits "difficult" behavior.

Too often, we pigeonhole children into categories without considering the context (Bates, 2012a, b; Rothbart, 2011). Instead of

doing this, caregivers need to take children's temperament into account. Research does not yet allow for many highly specific recommendations, but in general, caregivers should (1) be sensitive to the individual characteristics of the child, (2) be flexible in responding to these characteristics, and (3) avoid applying negative labels to the child.

eventually respond by ignoring the child's distress or trying to force the child to "behave." In one research study, though, extra support and training for mothers of distress-prone infants improved the quality of mother-infant interaction (van den Boom, 1989). The training led the mothers to alter their demands on the child, improving the fit between the child and the environment. Researchers also have found that decreases in infants' negative emotionality are linked to higher levels of parental sensitivity, involvement, and responsiveness (Bates & Pettit, 2015; Gartstein, Hancock, & Iverson, 2018; Parade & others, 2018). To read further about some positive strategies for parenting that take into account the child's temperament, see the *Connecting Development to Life* interlude.

A final comment about temperament is that recently the *differential susceptibility model* and the *biological sensitivity to context model* have been proposed and studied (Baptista & others, 2017; Belsky & Pluess, 2016; Belsky & van IJzendoorn, 2017; Belsky & others, 2015; Simpson & Belsky, 2016). These models emphasize that certain characteristics—such as a difficult temperament—that render children more vulnerable to difficulty in adverse contexts also make them more susceptible to optimal growth in very supportive conditions. These models put "negative" temperament characteristics in a new light.

## PERSONALITY DEVELOPMENT

Emotions and temperament form key aspects of *personality*, the enduring personal characteristics of individuals. Let's now examine characteristics that often are thought of as central to personality development during infancy: trust and the development of self and independence.

**Trust** According to Erik Erikson (1968), the first year of life is characterized by the trust-versus-mistrust stage of development. Following a life of regularity, warmth, and protection in the mother's womb, the infant faces a world that is less secure. Erikson proposed that infants learn trust when they are cared for in a consistent, warm manner. If the infant is not well fed and kept warm on a consistent basis, a sense of mistrust is likely to develop.

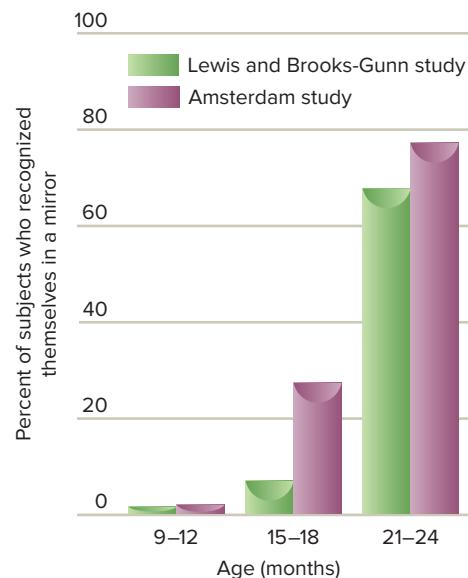

The issue of trust versus mistrust is not resolved once and for all in the first year of life. It arises again at each successive stage of development and can have positive or negative outcomes. For example, children who leave infancy with a sense of trust can still have their sense of mistrust activated at a later stage, perhaps if their parents are separated or divorced under conflictual circumstances.

**The Developing Sense of Self** When does the individual begin to sense a separate existence from others? Studying the development of a sense of self in infancy is difficult mainly because infants cannot verbally express their thoughts and impressions. They also cannot understand complex instructions from researchers.

One ingenious strategy to test infants' visual self-recognition is the use of a mirror technique, in which an infant's mother first puts a dot of rouge on the infant's nose. Then an observer watches to see how often the infant touches its nose. Next, the infant is placed in front of a mirror, and observers detect whether nose touching increases. Why does this matter? The idea is that increased nose touching indicates that the infant recognizes the self in the mirror and is trying to touch or rub off the rouge because the rouge violates the infant's view of the self. Increased touching indicates that the infant realizes that it is the self in the mirror but that something is not right since the real self does not have a dot of rouge on it.

Figure 3 displays the results of two investigations that used the mirror technique. The researchers found that before they were 1 year old, infants did not recognize themselves in the mirror (Amsterdam, 1968; Lewis & Brooks-Gunn, 1979). Signs of self-recognition began to appear among some infants when they were 15 to 18 months old. By the time they were 2 years old, most children recognized themselves in the mirror. In sum, infants begin to develop a self-understanding called self-recognition at approximately 18 months of age (Hart & Karmel, 1996; Lewis, 2005).

However, mirrors are not familiar to infants in all cultures (Rogoff, 2003). Thus, physical self-recognition may be a more important marker of self-recognition in Western than non-Western cultures (Thompson & Virmani, 2010). Supporting this cultural variation view, one study revealed that 18- to 20-month-old toddlers from urban middle-SES German families were

The graph shows the findings of two studies in which infants less than 1 year of age did not recognize themselves in a mirror. more likely to recognize their mirror images than were toddlers from rural Cameroon farming families (Keller & others, 2005).

Late in the second year and early in the third year, toddlers show other emerging forms of self-awareness that reflect a sense of “me” (Thompson, Winer, & Goodvin, 2011). For example, they refer to themselves by making statements such as “me big”; they label their internal experiences such as emotions; they monitor themselves, as when a toddler says, “do it myself”; and they declare that things are theirs (Bates, 1990; Fasig, 2000).

Also, researchers have found that infants begin developing an understanding of others (Carpendale & Lewis, 2015; McDonald & Perdue, 2018). Research indicates that as early as 13 months of age, infants seem to consider another’s perspective when predicting their actions (Choi & Luo, 2015).

**Independence** Erik Erikson (1968) stressed that independence is an important issue in the second year of life. Erikson describes the second stage of development as the stage of autonomy versus shame and doubt. Autonomy builds as the infant’s mental and motor abilities develop. At this point in development, not only can infants walk, but they can also climb, open and close, drop, push and pull, and hold and let go. Infants feel pride in these new accomplishments and want to do everything themselves, whether the activity is flushing a toilet, pulling the wrapping off a package, or deciding what to eat. It is important for parents to recognize the motivation of toddlers to do what they are capable of doing at their own pace. Then they can learn to control their muscles and their impulses themselves. But when caregivers are impatient and do for toddlers what they are capable of doing themselves, shame and doubt develop. Every parent has rushed a child from time to time. It is only when parents consistently overprotect toddlers or criticize accidents (wetting, soiling, spilling, or breaking, for example) that children develop an excessive sense of shame and doubt about their ability to control themselves and their world. As we discuss in later chapters, Erikson emphasized that the stage of autonomy versus shame and doubt has important implications for the individual’s future development.

So far, we have discussed how emotions and emotional competence change as children develop. We have also examined the role of emotional style; in effect, we have seen how emotions set the tone of our experiences in life. But emotions also write the lyrics because they are at the core of our relationships with others.

## SOCIAL ORIENTATION/UNDERSTANDING

In Ross Thompson's (2006, 2011, 2013, 2014, 2015, 2016) view, infants are socioemotional beings who show a strong interest in their social world and are motivated to orient to it and understand it. In previous chapters, we described many of the biological and cognitive foundations that contribute to the infant's development of social orientation and understanding. In this chapter, we will call attention to relevant biological and cognitive factors as we explore social orientation; locomotion; intention and goal-directed behavior; social referencing; and social sophistication and insight. Discussing biological, cognitive, and social processes together reminds us of an important aspect of development: These processes are intricately intertwined (Perry & Calkins, 2018).

**Social Orientation** From early in their development, infants are captivated by the social world. As we discussed in our coverage of infant perception, young infants stare intently at faces and are attuned to the sounds of human voices, especially the voices of their caregivers (Singarajah & others, 2017; Sugden & Moulson, 2017). Later, they become adept at interpreting the meaning of facial expressions and voices (Weatherhead & White, 2017).

Face-to-face play often begins to characterize caregiver-infant interactions when the infant is about 2 to 3 months of age. The focused social interaction of face-to-face play may include vocalizations, touch, and gestures (Beebe & others, 2016). Such play illustrates many mothers' motivation to create a positive emotional state in their infants (Laible, Thompson, & Froimson, 2015).

In part because of such positive social interchanges between caregivers and infants, by 2 to 3 months of age infants respond in different ways to people and objects, showing more positive emotion to people than to inanimate objects such as puppets (Legerstee, 1997). At this age, most infants expect people to react positively when the infants initiate a behavior, such as a smile or a vocalization.

Even though infants as young as 6 months of age show an interest in each other, their interaction with peers increases considerably in the last half of the second year. Between 18 and 24 months of age, children markedly increase their imitative and reciprocal play, such as imitating nonverbal actions like jumping and running (Eckerman & Whitehead, 1999). One study involved presenting 1- and 2-year-olds with a simple cooperative task that consisted of pulling a lever to get an attractive toy (Brownell, Ramani, & Zerwas, 2006) (see Figure 4). Any coordinated actions of the 1-year-olds appeared to be coincidental rather than cooperative, whereas the 2-year-olds' behavior was characterized by active cooperation to reach a goal.

**Locomotion** Recall from earlier in the chapter the growing importance of independence for infants, especially during the second year of life. As infants develop the ability to crawl, walk, and run, they are able to explore and expand their social world. These newly developed, self-produced locomotion skills allow the infant to independently initiate social interchanges on a more frequent basis (Laible, Thompson, & Froimson, 2015). The development of these gross motor skills results from factors such as the development of the nervous system, the goal the infant is motivated to reach, and environmental support for the skill (Adolph, 2018; Kretch & Adolph, 2018).

The infant's and toddler's push for independence also is likely paced by the development of locomotion skills. Of further importance is locomotion's motivational implications. Once infants have the ability to move in goal-directed pursuits, the rewards from these pursuits lead to further efforts to explore and develop skills.

**Intention, Goal-Directed Behavior, and Meaningful Interactions with Others** Perceiving people as engaging in intentional and goal-directed behavior is an important social cognitive accomplishment that initially occurs toward the end of the first year (Thompson, 2015). Another important aspect of infant development is engaging in meaningful interactions with others.

Joint attention and gaze-following help the infant to understand that other people have intentions (McClure & others, 2018; Yu & Smith, 2016). *Joint attention* occurs when the caregiver and infant focus on the same object

or event. We indicated that emerging aspects of joint attention occur at about 7 to 8 months, but at about 10 to 11 months of age joint attention intensifies and infants begin to follow the caregiver's gaze. By their first birthday, infants have begun to direct the caregiver's attention to objects that capture their interest (Marsh & Legerstee, 2017).

Amanda Woodward and her colleagues (Krogh-Jespersen, Liberman, & Woodward, 2015; Krogh-Jespersen & Woodward, 2016; Liberman, Woodward, & Kinzler, 2018; Shneidman & Woodward, 2016; Shneidman & others, 2016; Sodian & others, 2016) argue that infants' ability to understand and respond to others' meaningful intentions is a critical cognitive foundation for effectively engaging in the social world. They especially emphasize that an important aspect of this ability is the capacity to grasp social knowledge quickly in order to make an appropriate social response. Although processing speed is an important contributor to social engagement, other factors are involved such as infants' motivation to interact with someone, the infant's social interactive history with the individual, the interactive partner's social membership, and culturally specific aspects of interaction (Krogh-Jespersen & Woodward, 2016; Liberman, Woodward, & Kinzler, 2018).

**Social Referencing** Another important social cognitive accomplishment in infancy is developing the ability to “read” the emotions of other people (Carbalaj-Valenzuela & others, 2017; Hart, 2017). **Social referencing** is the term used to describe “reading” emotional cues in others to help determine how to act in a particular situation. The development of social referencing helps infants to interpret ambiguous situations more accurately, as when they encounter a stranger and need to know whether to fear the person (Stenberg, 2017). By the end of the first year, a mother’s facial expression—either smiling or fearful—influences whether an infant will explore an unfamiliar environment.

Infants become better at social referencing in the second year of life. At this age, they tend to “check” with their mother before they act; they look at her to see if she is happy, angry, or fearful. For example, in one study 14- to 22-month-old infants were more likely to look at their mother’s face to get information about how to act in a situation than were 6- to 9-month-old infants (Walden, 1991).

**Infants’ Social Sophistication and Insight** In sum, researchers are discovering that infants are more socially sophisticated and insightful at younger ages than was previously envisioned (Steckler & others, 2018; Thompson & Goodvin, 2016). This sophistication and insight is reflected in infants’ perceptions of others’ actions as intentionally motivated and goal-directed and their motivation to share and participate in that intentionality by their first birthday. The more advanced social cognitive skills of infants likely influence their understanding and awareness of attachment to a caregiver.

## ATTACHMENT AND ITS DEVELOPMENT

**Attachment** is a close emotional bond between two people. There is no shortage of theories about infant attachment. Three theorists discussed earlier—Freud, Erikson, and Bowlby—proposed influential views.

Freud emphasized that infants become attached to the person or object that provides oral satisfaction. For most infants, this is the mother, since she is most likely to feed the infant. Is feeding as important as Freud thought? A classic study by Harry Harlow (1958) reveals that the answer is no (see Figure 5).

Harlow removed infant monkeys from their mothers at birth; for six months they were reared by surrogate (substitute) “mothers.” One surrogate mother was made of wire, the other of cloth. Half of the infant monkeys were fed by the wire mother, half by the cloth mother. Periodically, the amount of time the infant monkeys spent with either the wire or the cloth mother was computed. Regardless of which mother fed them, the infant monkeys spent far more time with the cloth mother. Even if the wire mother, but not the cloth mother, provided nourishment, the infant monkeys spent more time with the cloth mother. And when Harlow frightened the monkeys, those “raised” by the cloth mother ran to the mother and clung to it; those raised by the wire mother did not. Whether the mother provided comfort seemed to determine whether the monkeys associated the mother with security. This study clearly demonstrated that feeding is not the crucial element in the attachment process and that contact comfort is important.

Physical comfort also plays a role in Erik Erikson's (1968) view of the infant's development. Recall Erikson's proposal that the first year of life represents the stage of trust versus mistrust. Physical comfort and sensitive care, according to Erikson (1968), are key to establishing a basic sense of trust in infants. The infant's sense of trust, in turn, is the foundation for attachment and sets the stage for a lifelong expectation that the world will be a good and pleasant place to be.

The ethological perspective of British psychiatrist John Bowlby (1969, 1989) also stresses the importance of attachment in the first year of life and the responsiveness of the caregiver. Bowlby maintains that both infants and their primary caregivers are biologically predisposed to form attachments. He argues that the newborn is biologically equipped to elicit attachment behavior. The baby cries, clings, coos, and smiles. Later, the infant crawls, walks, and follows the mother. The immediate result is to keep the primary caregiver nearby; the long-term effect is to increase the infant's chances of survival.

Attachment does not emerge suddenly but rather develops in a series of phases, moving from a baby's general preference for human beings to a partnership with primary caregivers. Following are four such phases based on Bowlby's conceptualization of attachment (Schaffer, 1996):

- *Phase 1: From birth to 2 months.* Infants instinctively direct their attachment to human figures. Strangers, siblings, and parents are equally likely to elicit smiling or crying from the infant.
- *Phase 2: From 2 to 7 months.* Attachment becomes focused on one figure, usually the primary caregiver, as the baby gradually learns to distinguish familiar from unfamiliar people.
- *Phase 3: From 7 to 24 months.* Specific attachments develop. With increased locomotor skills, babies actively seek contact with regular caregivers, such as the mother or father.
- *Phase 4: From 24 months on.* Children become aware of others' feelings, goals, and plans and begin to take these into account in forming their own actions.

Bowlby argued that infants develop an *internal working model* of attachment, a simple mental model of the caregiver, their relationship, and the self as deserving of nurturant care. The infant's internal working model of attachment with the caregiver influences the infant's and later the child's subsequent responses to other people (Cassidy, 2016; Hoffman & others, 2017). The internal model of attachment also has played a pivotal role in the discovery of links between attachment and subsequent emotional understanding, conscience development, and self-concept (Bretherton & Munholland, 2016; Vacaru, Sterkenburg, & Schuengel, 2018).

## INDIVIDUAL DIFFERENCES IN ATTACHMENT

Although attachment to a caregiver intensifies midway through the first year, isn't it likely that the quality of babies' attachment experiences varies? Mary Ainsworth (1979) thought so. Ainsworth created the **Strange Situation**, an observational measure of infant attachment that takes about 20 minutes in which the infant experiences a series of introductions, separations, and reunions with the caregiver and an adult stranger in a prescribed order. In using the Strange Situation, researchers hope that their observations will provide information about the infant's motivation to be near the caregiver and the degree to which the caregiver's presence provides the infant with security and confidence (Brownell & others, 2015; Solomon & George, 2016).

Based on how babies respond in the Strange Situation, they are described as being securely attached or insecurely attached (in one of three ways) to the caregiver:

- **Securely attached babies** use the caregiver as a secure base from which to explore the environment. When they are in the presence of their caregiver, securely attached infants explore the room and examine toys that have been placed in it. When the caregiver departs, securely attached infants might protest mildly, and when the caregiver returns these infants reestablish positive interaction with her, perhaps by smiling or climbing onto her lap. Subsequently, they often resume playing with the toys in the room.
- **Insecure avoidant babies** show insecurity by avoiding the caregiver. In the Strange Situation, these babies engage in little interaction with the caregiver, are not distressed when she leaves the room, usually do not reestablish contact when she returns, and may even turn their back on her. If contact is established, the infant usually leans away or looks away.

**CROSS-CULTURAL COMPARISON OF ATTACHMENT.** In one study, infant attachment in three countries—the United States, Germany, and Japan—was measured in the Ainsworth Strange Situation (van IJzendoorn & Kroonenberg, 1988). The dominant attachment pattern in all three countries was secure attachment. However, German infants were more avoidant and Japanese infants were less avoidant and more resistant than U.S. infants. *What are some explanations for differences in how German, Japanese, and American infants respond to the Strange Situation?*

uncertainty itself. Japanese mothers rarely let anyone unfamiliar with their babies care for them. Thus, the Strange Situation might create considerably more stress for Japanese infants than for American infants, who are more accustomed to separation from their mothers (Miyake, Chen, & Campos, 1985).

Even though there are cultural variations in attachment classification, the most frequent classification in every culture studied so far is secure attachment (Mooya, Sichimba, & Bakermans-Kranenburg, 2016; Mesman, van IJzendoorn, & Sagi-Schwartz, 2016).

**insecure resistant babies** Babies who often cling to the caregiver, then resist the caregiver by fighting against the closeness, perhaps by kicking or pushing away.

**insecure disorganized babies** Babies who show insecurity by being disorganized and disoriented.

- **Insecure resistant babies** often cling to the caregiver and then resist her by fighting against the closeness, perhaps by kicking or pushing away. In the Strange Situation, these babies often cling anxiously to the caregiver and don't explore the playroom. When the caregiver leaves, they often cry loudly and then push away if she tries to comfort them on her return.
- **Insecure disorganized babies** appear disoriented. In the Strange Situation, these babies might seem dazed, confused, and fearful. To be classified as disorganized, babies must show strong patterns of avoidance and resistance or display certain specified behaviors, such as extreme fearfulness around the caregiver.

**Evaluating the Strange Situation** Does the Strange Situation capture important differences among infants? As a measure of attachment, it may be culturally biased (Gernhardt, Keller, & Rubeling, 2016). For example, German and Japanese babies often show patterns of attachment different from those of American infants. As illustrated in Figure 6, German infants are more likely to show an avoidant attachment pattern and Japanese infants are less likely to display this pattern than U.S. infants (van IJzendoorn & Kroonenberg, 1988). The avoidant pattern in German babies likely occurs because their caregivers encourage them to be independent (Grossmann & others, 1985). Also as shown in Figure 6, Japanese babies are more likely than American babies to be categorized as resistant. This may have more to do with the Strange Situation as a measure of attachment than with attachment insecurities.

Japanese mothers rarely let anyone unfamiliar with their babies care for them. Thus, the Strange Situation might create considerably more stress for Japanese infants than for American infants, who are more accustomed to separation from their mothers (Miyake, Chen, & Campos, 1985).

Even though there are cultural variations in attachment classification, the most frequent classification in every culture studied so far is secure attachment (Mooya, Sichimba, & Bakermans-Kranenburg, 2016; Mesman, van IJzendoorn, & Sagi-Schwartz, 2016).

**Interpreting Differences in Attachment** Do individual differences in attachment matter? Ainsworth argues that secure attachment in the first year of life provides an important foundation for psychological development later in life. The securely attached infant moves freely away from the mother but keeps track of where she is through periodic glances. The securely attached infant responds positively to being picked up by others, and when put back down, freely moves away to play. An insecurely attached infant, by contrast, avoids the mother or is ambivalent toward her, fears strangers, and is upset by minor, everyday separations.

If early attachment to a caregiver is important, it should be linked to a child's social behavior later in development. For some children, early attachments seem to foreshadow later functioning (Dozier & others, 2018; Hoffman & others, 2017; Sroufe, 2016; Woodhouse & others, 2017). In the extensive longitudinal study conducted by Alan

Sroufe and his colleagues (2005), early secure attachment (assessed by the Strange Situation at 12 and 18 months) was linked with positive emotional health, high self-esteem, self-confidence, and socially competent interaction with peers, teachers, camp counselors, and romantic partners through adolescence. Also, a meta-analysis concluded that secure attachment in infancy was related to social competence with peers in early childhood (Groh & others, 2014). Another study revealed that attachment security at 2 years of age was linked to lower rates of peer conflict at 3 years of age (Raikes & others, 2013). Further, researchers have found that infant attachment

insecurity (especially insecure resistant attachment) and early childhood behavioral inhibition predicts adolescent social anxiety symptoms (Lewis-Morrarty & others, 2015).

Few studies have assessed infants' attachment security to the mother and the father separately. However, one study revealed that infants who were insecurely attached to their mother and father ("double-insecure") at 15 months of age had more externalizing problems (out-of-control behavior, for example) during their elementary school years than their counterparts who were securely attached to at least one parent (Kochanska & Kim, 2013).

An important issue regarding attachment is whether infancy is a critical or sensitive period for development. The studies just described show continuity, with secure attachment in infancy predicting subsequent positive development in childhood and adolescence. For some children, though, there is little continuity. Not all research reveals the power of infant attachment to predict subsequent development (Lamb & Lewis, 2015; Roisman & Groh, 2011). In one longitudinal study, attachment classification in infancy did not predict attachment classification at 18 years of age (Lewis, Feiring, & Rosenthal, 2000). In this study, the best predictor of an insecure attachment classification at 18 was the occurrence of parental divorce in the intervening years.

Consistently positive caregiving over a number of years is likely an important factor in connecting early attachment with the child's functioning later in development. Indeed, researchers have found that early secure attachment and subsequent experiences, especially maternal care and life stresses, are linked with children's later behavior and adjustment (Risman & Cicchetti, 2017; Thompson, 2015, 2016). For example, a longitudinal study revealed that changes in attachment security/insecurity from infancy to adulthood were linked to stresses and supports in socioemotional contexts (Van Ryzin, Carlson, & Sroufe, 2011). These results suggest that attachment continuity may reflect stable social contexts as much as early working models. The study just described (Van Ryzin, Carlson, & Sroufe, 2011) reflects an increasingly accepted view of the development of attachment and its influence on development. That is, it is important to recognize that attachment security in infancy does not always by itself produce long-term positive outcomes, but rather is linked to later outcomes through connections with the way children and adolescents subsequently experience various social contexts as they develop.

The Van Ryzin, Carlson, and Sroufe (2011) study reflects a **developmental cascade model**, which involves connections across domains over time that influence developmental pathways and outcomes (Almy & Cicchetti, 2018; Masten & Kalstabakken, 2017; Pasco-Fearon & others, 2016). Developmental cascades can include connections between a wide range of biological, cognitive, and socioemotional processes (attachment, for example), and also can involve social contexts such as families, peers, schools, and culture. Further, links can produce positive or negative outcomes at different points in development, such as infancy, early childhood, middle and late childhood, adolescence, and adulthood.

In addition to challenging the assumption that infancy is a critical or sensitive period for creating a secure attachment with a caregiver, some developmentalists argue that the secure attachment concept does not adequately consider certain biological factors in development, such as genes and temperament (Bakermans-Kranenburg & van IJzendoorn, 2016; Belsky & van IJzendoorn, 2017; Esposito & others, 2017b; Kim & others, 2017). For example, Jerome Kagan (1987, 2002) points out that infants are highly resilient and adaptive; he argues that they are evolutionarily equipped to stay on a positive developmental course even in the face of wide variations in parenting. Kagan and others stress that genetic characteristics and temperament play more important roles in a child's social competence than the attachment theorists, such as Bowlby and Ainsworth, are willing to acknowledge (Bakermans-Kranenburg & van IJzendoorn, 2011). For example, if some infants inherit a low tolerance for stress, this characteristic, rather than an insecure attachment bond, may be responsible for an inability to get along with peers. One study found links between disorganized attachment in infancy, a specific gene, and levels of maternal responsiveness (Spangler & others, 2009). In this study, infants with the short version of the serotonin transporter gene, 5-HTTLPR, developed a disorganized attachment style only when mothers were slow in responding to them. Also, in a longitudinal study, infant attachment security only predicted adult attachment security when individuals were in their twenties if they had a particular variant of the oxytocin receptor gene (OXTR G/G) (Raby & others, 2013). In this study, the 5-HTTLPR gene and a dopamine gene (DRD4) did not consistently influence the link between infant attachment and adult attachment. Other researchers have not always found support for genetic influences on infant-mother attachment (Leerkes & others, 2017b) or for gene-environment interactions related to infant attachment (Fraley & others, 2013).

A third criticism of attachment theory (in addition to the critical/sensitive period issue and inadequate attention to biological-based factors) is that it ignores the diversity of socializing agents and contexts that exists in an infant's world. A culture's value system can influence the nature of attachment (Mesman, van IJzendoorn, & Sagi-Schwartz, 2016). In some contexts and cultures, infants show attachments to many people (Howes & Spieker, 2016). Among the Hausa (who live in Nigeria), both grandmothers and siblings provide a significant amount of care for infants (Harkness & Super, 1995). Infants in agricultural societies tend to form attachments to older siblings, who are assigned a major responsibility for younger siblings' care. In a recent study in Zambia where siblings were substantially involved in caregiving activities, infants showed strong attachments to both their mothers and their sibling caregivers (Mooya, Sichimba, & Bakermans-Kranenburg, 2016). In this study, secure attachment was the most frequent attachment classification for both mother-infant and sibling-infant relationships.

Researchers recognize the influence of competent, nurturant caregivers on an infant's development (Almy & Cicchetti, 2018; Cicchetti, 2017; Grusec & Davidov, 2015). At issue, though, is whether or not secure attachment, especially to a single caregiver, is critical (Fearon & Roisman, 2017; Lamb, 2015; Thompson, 2015, 2016).

Despite such criticisms, there is ample evidence that secure attachment is important in development (Cassidy, 2016; Hoffman & others, 2017; Marvin, Britner, & Russell, 2016; Thompson, 2015, 2016; Pasco-Fearon & others, 2016; Sroufe, 2016; Taylor & Workman, 2018; Woodhouse & others, 2017). Is secure attachment the sole predictor of positive developmental outcomes for infants? No, and neither is any other single factor. Nonetheless, secure attachment in infancy is important because it reflects a positive parent-infant relationship and provides a foundation that supports healthy socioemotional development in the years that follow.

## CAREGIVING STYLES AND ATTACHMENT

Is the style of caregiving linked with the quality of the infant's attachment? Securely attached babies have caregivers who are sensitive to their signals and are consistently available to respond to their infants' needs (Groh & Haydon, 2018; Hoffman & others, 2017). These caregivers often let their babies have an active part in determining the onset and pacing of interaction in the first year of life. A recent study revealed that maternal sensitivity and a better home environment in infancy predicted higher self-regulation at 4 years of age (Birmingham, Bub, & Vaughn, 2017). Further, recent research indicates that providing parents who engage in inadequate and problematic caregiving with practice and feedback focused on interacting sensitively with infants enhances parent-infant attachment security (Dozier & Bernard, 2017; Dozier, Bernard, & Roben, 2017; Woodhouse & others, 2017).

How do the caregivers of insecurely attached babies interact with them? Caregivers of avoidant babies tend to be unavailable or rejecting (Posada & Kaloustian, 2010). They often don't respond to their babies' signals and have little physical contact with them. When they do interact with their babies, they may behave in an angry and irritable way. Caregivers of resistant babies tend to be inconsistent; sometimes they respond to their babies' needs and sometimes they don't. In general, they tend not to be very affectionate with their babies and show little synchrony when interacting with them. Caregivers of disorganized babies often neglect or physically abuse them (Almy & Cicchetti, 2018; Cicchetti, 2017). In some cases, these caregivers are depressed.

## DEVELOPMENTAL SOCIAL NEUROSCIENCE AND ATTACHMENT

The emerging field of developmental social neuroscience examines connections between socioemotional processes, development, and the brain (Esposito & others, 2017b; Silvers & others, 2017; Steinberg & others, 2017; Sullivan & Wilson, 2018). Attachment has been a major focus of theory and research on developmental social neuroscience. The connections between attachment and the brain involve the neuroanatomy of the brain, neurotransmitters, and hormones.

Theory and research on the role of the brain's regions in mother-infant attachment is just emerging (Esposito & others, 2017b; Feldman, 2017; Sullivan & Wilson, 2018). One theoretical view proposed that the prefrontal cortex likely has an important role in maternal attachment behavior, as do the subcortical (areas of the brain lower than the cortex) regions of the

amygdala (which is strongly involved in emotion) and the hypothalamus (Gonzalez, Atkinson, & Fleming, 2009).

Research on the role of hormones and neurotransmitters in attachment has emphasized the importance of the neuropeptide hormone *oxytocin* and the neurotransmitter *dopamine* in the formation of the maternal-infant bond (Feldman, 2017; Kim, Strathearn, & Swain, 2016; Sullivan & Wilson, 2018). Oxytocin, a mammalian hormone that also acts as a neurotransmitter in the brain, is released during breast feeding and by contact and warmth. Oxytocin is especially thought to be a likely candidate in the formation of infant-mother attachment (Ehrlich & others, 2016). A research review indicated strong links between levels or patterns of maternal oxytocin and aspects of mother-infant attachment (Galbally & others, 2011).

In mothers, the experience of pleasure and reward is linked to activation of the brain's dopamine circuits when mothers care for their infant and are exposed to their infants' cues, such as eye contact, smiling, and so on (Feldman, 2017; Kim, Strathearn, & Swain, 2016; Sullivan & Wilson, 2018). These experiences and brain changes likely promote mother-infant attachment and sensitive parenting (Feldman, 2017; Kohlhoff & others, 2017). Also, the influence of oxytocin on dopamine in the mother's nucleus accumbens (a collection of neurons in the forebrain that are involved in pleasure) likely is important in motivating the mother's approach to the baby (de Haan & Gunnar, 2009).

In sum, it is likely that a number of brain regions, neurotransmitters, and hormones are involved in the development of infant-mother attachment (Feldman, 2017; Sullivan & Wilson, 2018). Key candidates for influencing this attachment are connections between the prefrontal cortex, amygdala, and hypothalamus; the neuropeptide oxytocin and the activity of the neurotransmitter dopamine in the nucleus accumbens. Figure 7 shows the regions of the brain we have described that are likely to play important roles in infant-mother attachment.

Although oxytocin release is stimulated by birth and lactation in mothers, might it also be released in fathers? Oxytocin is secreted in males, and one research study found that at both 6 weeks and 6 months after birth, when fathers engaged in more stimulation contact with babies, encouraged their exploration, and directed their attention to objects, the fathers' oxytocin levels increased (Gordon & others, 2010). In this study, mothers' behaviors that increased their oxytocin levels involved more affectionate parenting, such as gazing at their babies, expressing positive affect toward them, and touching them. Another study found that fathers with lower testosterone levels engaged in more optimal parenting with their infants (Weisman, Zagoory-Sharon, & Feldman, 2014). Also in this study, when fathers were administered oxytocin, their parenting behavior improved, as evidenced in increased positive affect, social gaze, touch, and vocal synchrony when interacting with their infants.

What characterizes the transition to parenting?

Now that we have explored the infant's emotional and personality development and attachment to caregivers, let's examine the social contexts in which these processes occur. We will begin by studying a number of aspects of the family and then turn to a social context in which infants increasingly spend time—child care.

## THE FAMILY

The family can be thought of as a constellation of subsystems—a complex whole made up of interrelated, interacting parts—defined in terms of generation, gender, and role. Each family member participates in several subsystems (Solomon-Moore & others, 2018; Williams, Sawyer, & Wahlstrom, 2017). The father and child represent one subsystem, the mother and father another, the mother-father-child yet another, and so on.

These subsystems have reciprocal influences on each other (Maccoby, 2015; Schwartz & Scott, 2018). For example, Jay Belsky (1981) emphasizes that the marital relationship, parenting, and infant behavior and development can have both direct and indirect effects on each other (see Figure 8). An example of a direct effect is the influence of the parents' behavior on the child. An indirect effect is how the relationship between the spouses mediates the way a parent acts toward the child (Dubow & others, 2017). For example, marital conflict might reduce the efficiency of parenting, in which case marital conflict would indirectly affect the child's behavior. The simple fact that two people are becoming parents may have profound effects on their relationship.

**The Transition to Parenthood** When people become parents through pregnancy, adoption, or stepparenting, they face disequilibrium and must adapt (Carlson & VanOrman, 2017). Parents want to develop a strong attachment with their infant, but they also want to maintain strong attachments to their spouse and friends, and possibly continue their careers. Parents ask themselves how the presence of this new individual will change their lives. A baby places new restrictions on partners; no longer will they be able to rush out to a movie on a moment's notice, and money may not be readily available for vacations and other luxuries.

Dual-career parents ask, "Will it harm our baby if we place her in child care? Will we be able to find responsible babysitters?"

In a longitudinal investigation that tracked couples from late pregnancy until 3½ years after their baby was born, couples enjoyed more positive marital relations before the baby was born than after (Cowan & Cowan, 2000; Cowan & others, 2005). Still, almost one-third reported an increase in marital satisfaction. Some couples said that the baby had both brought them closer together and moved them farther apart; being parents enhanced their sense of themselves and also gave them a new, more stable identity as a couple. Babies opened men up to a concern with intimate relationships, and the demands of juggling work and family roles stimulated women to manage family tasks more efficiently and to pay attention to their own personal growth.

Other studies have explored the transition to parenthood (Kuersten-Hogan, 2017). One study indicated that women and less avoidantly attached new parents adapted to the introduction of child care tasks better than most men, especially men who were avoidantly attached (Fillo & others, 2015). In another study, mothers experienced unmet expectations in the transition to parenting, with fathers doing less than their partners had anticipated (Biehle & Mickelson, 2012). Also, in a study of dual-earner couples, a gender division of labor across the transition to parenthood occurred (Yavorsky & others, 2015). In this study, a gender gap was not present prior to the transition to parenthood, but after a child was born, women did more than 2 hours of additional work per day compared with an additional 40 minutes for men. And in another study, in comparison with married fathers, cohabiting fathers' personal dedication and relationship confidence decreased and their feelings of constraint increased across the transition to parenting (Kamp Dush & others, 2014).

#### Cognitive Theory

A version of scaffolding is an important aspect of Lev Vygotsky's sociocultural cognitive theory of development. Connect to "Physical and Cognitive Development in Early Childhood."

The Bringing Home Baby project is a workshop that helps new parents to strengthen their relationship, understand and become acquainted with their baby, resolve conflict, and develop parenting skills (Gottman, 2018). Evaluations of the project revealed that participants improved their ability to work together as parents; fathers became more involved with their baby and sensitive to the baby's behavior; mothers had a lower incidence of postpartum depression symptoms; and babies showed better overall development than infants whose parents were part of a control group (Gottman, Shapiro, & Parthermer, 2004; Shapiro & Gottman, 2005).

**Reciprocal Socialization** The mutual influence that parents and children exert on each other goes beyond specific interactions in games such as peek-a-boo; it extends to the whole process of socialization (Klein & others, 2018). Socialization between parents and children is not a one-way process (Maccoby, 2015). Parents do socialize children, but socialization in families is reciprocal. **Reciprocal socialization** is socialization that is bidirectional; children socialize parents just as parents socialize children. These reciprocal interchanges and mutual influence processes are sometimes referred to as *transactional* (Kuczynski, Parkin, & Pitman, 2015; Lamb & Lewis, 2015; Sameroff, 2009, 2012).

When reciprocal socialization has been studied in infancy, mutual gaze or eye contact plays an important role in early social interaction (Stern, 2010). In one investigation, the mother and infant engaged in a variety of behaviors while they looked at each other (Stern & others, 1977). By contrast, when they looked away from each other, the rate of such behaviors dropped considerably. The types of behaviors involved in reciprocal socialization in infancy are temporally connected, mutually contingent behaviors such as one partner imitating the sound of another or the mother responding with a vocalization to the baby's arm movements.

An important form of reciprocal socialization is **scaffolding**, in which parents time interactions in such a way that the infant experiences turn taking with the parents. Scaffolding involves parental behavior that supports children's efforts, allowing them to be more skillful than they would be if they had to rely only on their own abilities (Norona & Baker, 2017). In using scaffolding, caregivers provide a positive, reciprocal framework in which they and their children interact (Maitre & others, 2017; Mermelshrine, 2017). For example, in the game peek-a-boo, the mother initially covers the baby. Then she removes the cover and registers "surprise" at the infant's reappearance. As infants become more skilled at peek-a-boo, pat-a-cake, and so on, caregivers initiate other games that exemplify scaffolding and turn-taking sequences. Turn taking and games like peek-a-boo reflect the development of joint attention by the caregiver and infant (Melzi, Schick, & Kennedy, 2011).

Research supports the importance of scaffolding in infant development. For example, a recent study found that when adults used explicit scaffolding (encouragement and praise) with 13- and 14-month-old infants they were twice as likely to engage in helping behavior as were their counterparts who did not receive the scaffolding (Dahl & others, 2017). Another study of disadvantaged families revealed that an intervention designed to enhance maternal scaffolding with infants was linked to improved cognitive skills when the children were 4 years old (Obradovic & others, 2016).

Increasingly, genetic and epigenetic factors are being studied to discover not only parental influences on children but also children's influence on parents (Bakermans-Kranenburg & van IJzendoorn, 2016; Baptista & others, 2017; Belsky & Pluess, 2016; Lomanowska & others, 2017). The *epigenetic view* emphasizes that development is the result of an ongoing, bidirectional interchange between heredity and the environment (Moore, 2015, 2017). For example, harsh, hostile parenting is associated with negative outcomes for children, such as being defiant and oppositional (Deater-Deckard, 2013; Thompson & others, 2017). This likely reflects bidirectional influences rather than a unidirectional parenting effect. That is, the parents' harsh, hostile parenting and the children's defiant, oppositional behavior may influence each other. In this bidirectional influence, the parents' and children's behavior may have genetic linkages as well as experiential connections.

**Managing and Guiding Infants' Behavior** In addition to sensitive parenting that involves warmth and caring that can help babies become securely attached to their parents, other important aspects of parenting infants involve managing and guiding their behavior in an attempt to reduce or eliminate undesirable behaviors (Holden, Vittrup, & Rosen, 2011). This management process includes (1) being proactive and childproofing the environment so infants won't encounter potentially dangerous objects or situations, and (2) engaging in corrective methods when infants engage in undesirable behaviors such as excessive fussing and crying, throwing objects, and so on.

### PARENTS' METHODS FOR MANAGING AND CORRECTING INFANTS' UNDESIRABLE BEHAVIOR.

Shown here are the percentages of parents who had used various corrective methods by the time the infants were 12 and 24 months old.

Source: Vittrup, B., Holden, G. W., & Buck, M. "Attitudes Predict the Use of Physical Punishment: A Prospective Study of the Emergence of Disciplinary Practices," *Pediatrics*, 117, 2006, 2055–2064.

One study assessed results of disciplinary and corrective methods that parents had used by the time infants were 12 and 24 months old (Vittrup, Holden, & Buck, 2006). As indicated in Figure 9, the main method parents used by the time infants were 12 months old was diverting the infants' attention, followed by reasoning, ignoring, and negotiating. Also note in Figure 9 that more than one-third of parents had yelled at their infant, about one-fifth had slapped the infant's hands or threatened the infant, and approximately one-sixth had spanked the infant before his or her first birthday.

As infants move into the second year of life and become more mobile and capable of exploring a wider range of environments, parental management of the toddler's behavior often triggers even more corrective feedback and discipline (Holden, Vittrup, & Rosen, 2011). As indicated in Figure 9, in the study just described, yelling increased from 36 percent at 1 year of age to 81 percent at 2 years of age, slapping the infant's hands increased from 21 percent at 1 year to 31 percent at age 2, and spanking increased from 14 percent at 1 year to 45 percent at age 2 (Vittrup, Holden, & Buck, 2006).

An important aspect of understanding why parents might increase their disciplinary corrective feedback in the second year involves their expectations for their toddlers' behavior. A national poll of parents who had children 3 years of age and younger found that parents have stronger expectations for their toddlers' ability to control their behavior than is warranted based on the maturation of the prefrontal cortex (Newton & Thompson, 2010). Thus, some of parents' corrective feedback likely arises because parents anticipate that toddlers and young children should be exercising greater self-control over their emotions and impulses than they are capable of achieving.

A special concern is that such corrective discipline tactics not become abusive. Too often what starts out as mild to moderately intense discipline on the part of parents can move into highly intense anger. Later you will read more extensively about the use of punishment with children and child abuse.

**Maternal and Paternal Caregiving** As mentioned at the beginning of this chapter, an increasing number of U.S. fathers stay home full-time with their children (Bartel & others, 2018; Dette-Hagenmeyer, Erzinger, & Reichle, 2016). According to one survey, the number of stay-at-home dads in the United States was estimated to be 2 million in 2012 (Livingston, 2014). The 2 million figure represents a significant increase from 1.6 million in 2004 and 1.1 million in 1989.

Many of these full-time fathers have career-focused wives who provide most of the family income. One study revealed that the stay-at-home fathers were as satisfied with their marriage as traditional parents, although they indicated that they missed their daily life in the workplace (Rochlen & others, 2008). In this study, the stay-at-home fathers reported that they tended to be ostracized when they took their children to playgrounds and often were excluded from parent groups.

Can fathers take care of infants as competently as mothers can? Observations of fathers and their infants suggest that fathers have the ability to act as sensitively and responsively as mothers with their infants (Cabrera & Roggman, 2017; Clarke-Stewart & Parke, 2014). Consider the Aka pygmy culture in Africa where fathers spend as much time interacting with their infants as do their mothers (Hewlett, 1991, 2000; Hewlett & MacFarlan, 2010). Further, researchers found that infants who showed a higher level of externalizing, disruptive problems at 1 year of age had fathers who displayed a low level of engagement with them as early as the third month of life (Ramchandani & others, 2013). And in a recent study, children whose fathers' behavior was more withdrawn and depressed at 3 months had a lower level of cognitive development at 24 months of age (Sethna & others, 2018). Also in this study, children whose fathers were more engaged and sensitive, as well as less controlling, at 24 months of age showed a higher level of cognitive development at that age. Further, a recent study revealed that both fathers' and mothers' sensitivity, as assessed when infants were 10 to 12 months old, were linked to children's cognitive development at 18 months and language development at 36 months (Malmberg & others, 2016). Other recent studies indicate that when fathers are positively engaged with their children, improved developmental outcomes occur (Alexander & others, 2017).

Remember, however, that although fathers can be active, nurturing, involved caregivers with their infants, as Aka pygmy fathers are, in many cultures men have not chosen to follow this pattern (Parkinson, 2010). Also, if fathers have mental health problems, they may not interact as effectively with their infants.

Do fathers and mothers interact with their infants in different ways? Maternal interactions usually center on child-care activities such as feeding, changing diapers, or bathing. Paternal interactions are more likely to include play (Lamb & Lewis, 2015). Fathers engage in more rough-and-tumble play than mothers do. Nonetheless, mothers engage in play with their children three times as often as fathers do and mothers and fathers play differently with their children (Cabrera & Roggman, 2017). They bounce infants, throw them up in the air, tickle them, and so on. Mothers do play with infants, but their play is less physical, less arousing, and more predictable than that of fathers (Lamb & Lewis, 2015). In a recent study of low-income families, fathers' playfulness with 2-year-olds was associated with more advanced vocabulary skills at 4 years of age while mothers' playfulness with 2-year-olds was linked to a higher level of emotion regulation at 4 years of age (Cabrera & others, 2017).

## CHILD CARE

Many U.S. children today experience multiple caregivers. Most do not have a parent staying home to care for them; instead, the children have some type of care provided by others—"child care." Many parents worry that child care will reduce their infants' emotional attachment to them, harm the infants' cognitive development, fail to teach them how to control anger, and allow them to become unduly influenced by their peers. How extensively is child care used by families? Are the worries of these parents justified?

**Parental Leave** Today far more young children are in child care than at any other time in history. About 2 million children in the United States currently receive formal, licensed child care, and uncounted millions of children are cared for by unlicensed babysitters. In part, these numbers reflect the fact that U.S. adults do not receive paid leave from their jobs to care for their young children.

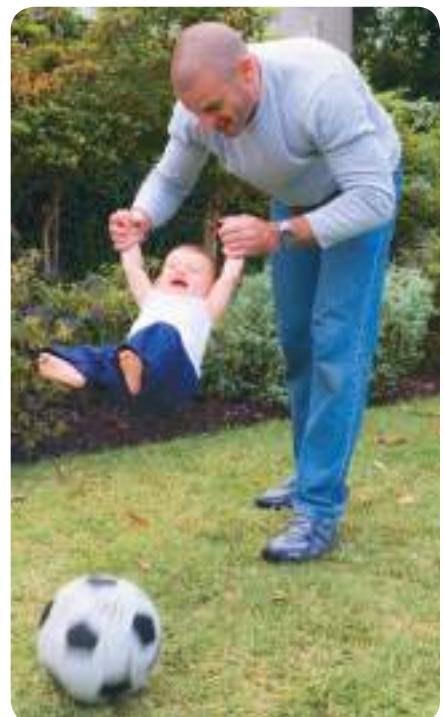

Child-care policies around the world vary (Burchinal & others, 2015; Sanders & Guerra, 2016). Europe led the way in creating new standards of parental leave: The European Union (EU) mandated a paid 14-week maternity leave in 1992. In most European countries today, working parents on leave receive from 70 to 100 percent of their prior wage, and paid leave averages about 16 weeks (Tolani & Brooks-Gunn, 2008). The United States currently grants up to 12 weeks of unpaid leave to workers caring for a newborn.

Most countries provide parental benefits only to women who have been employed for a minimum time prior to childbirth. In Denmark, however, even unemployed mothers are eligible for extended parental leave related to childbirth. In Germany, child-rearing leave is available to almost all parents. The Nordic countries (Denmark, Norway, and Sweden) have extensive gender-equity family leave policies for childbirth that emphasize the contributions of both women and men (O'Brien & Moss, 2010; Tolani & Brooks-Gunn, 2008). For example, in Sweden, parents can take an 18-month job-protected parental leave with benefits that can be shared by parents and applied to full-time or part-time work.

**Variations in Child Care** Because the United States does not have a policy of paid leave for new parents, child care in the United States has become a major national concern (Shivers & Farago, 2016). Many factors influence the effects of child care, including the age of the child, the type of child care, and the quality of the program.

In the United States, approximately 15 percent of children 5 years of age and younger attend more than one child-care arrangement. One study of 2- and 3-year-old children revealed that an increase in the number of child-care arrangements the children experienced was linked to an increase in behavioral problems and a decrease in prosocial behavior (Morrissey, 2009).

The type of child care varies extensively (Hasbrouck & Pianta, 2016). Child care is provided in large centers with elaborate facilities and in private homes. Some child-care centers are commercial operations; others are nonprofit centers run by churches, civic groups, and employers. Some child-care providers are professionals; others are mothers who want to earn extra money.

## Wanda Mitchell, Child-Care Director

Wanda Mitchell is the Child-Care Director at the Hattie Daniels Day Care Center in Wilson, North Carolina. Her responsibilities include directing the operation of the center, which involves creating and maintaining an environment in which young children can learn effectively, and ensuring that the center meets state licensing requirements. Wanda obtained her undergraduate degree from North Carolina A & T University, majoring in Child Development. Prior to her current position, she was an education coordinator for Head Start and an instructor at Wilson Technical Community College. Describing her work, Wanda says, “I really enjoy working in my field. This is my passion. After graduating from college, my goal was to advance in my field.”

**FIGURE 10**  
**PRIMARY CARE ARRANGEMENTS IN THE UNITED STATES FOR CHILDREN UNDER 5 YEARS OF AGE WITH EMPLOYED MOTHERS**

Infants and toddlers are more likely to be found in family child care and informal care settings, while older children are more likely to be in child care centers and preschool and early education programs. Figure 10 presents the primary care arrangements for children under 5 years of age with employed mothers (Clarke-Stewart & Miner, 2008).

Child-care quality makes a difference (Howes, 2016; Vu, 2016). What constitutes a high-quality child-care program for infants? In high-quality child care (Clarke-Stewart & Miner, 2008, p. 273):

Caregivers encourage the children to be actively engaged in a variety of activities, have frequent, positive interactions that include smiling, touching, holding, and speaking at the child's eye level, respond properly to the child's questions or requests, and encourage children to talk about their experiences, feelings, and ideas.

Children are more likely to experience poor-quality child care if they come from families with few resources (psychological, social, and economic). Many researchers have examined the role of poverty in the quality of child care (Howes, 2016; Shivers & Farago, 2016). One study found that extensive child care was harmful to low-income children only when the care was of low quality (Votruba-Drzal, Coley, & Chase-Lansdale, 2004). Another study revealed that children from low-income families benefited in terms of school readiness and language development when their parents selected higher-quality child care (McCartney & others, 2007).

High-quality child care also involves providing children with a safe environment, access to age-appropriate toys and participation in age-appropriate activities, and a low caregiver-to-child ratio that allows caregivers to spend considerable time with children on an individual basis. An Australian study revealed that higher-quality child care that included positive child-caregiver relationships at 2 to 3 years of age was linked to children's better self-regulation of attention and emotion at 4 to 5 and 6 to 7 years of age (Gialamas & others, 2014). Quality of child care matters in children's development, and according to UNICEF, the United States meets or exceeds only 3 of 10 child care quality benchmarks.

To read about one individual who provides quality child care to individuals from impoverished backgrounds, see *Connecting with Careers*. Do children in low-income families usually get quality child care? To answer that question and to learn more about the effects of child care, read *Connecting Through Research*.

## How Does the Quality and Quantity of Child Care Affect Children?

In 1991, the National Institute of Child Health and Human Development (NICHD) began a comprehensive, longitudinal study of child-care experiences. Data were collected on a diverse sample of almost 1,400 children and their families at 10 locations across the United States over a period of seven years. Researchers used multiple methods (trained observers, interviews, questionnaires, and testing) and measured many facets of children's development, including physical health, cognitive development, and socioemotional development. Following are some of the results of what is now referred to as the NICHD Study of Early Child Care and Youth Development or NICHD SECCYD (NICHD Early Child Care Research Network, 2001, 2002, 2003, 2004, 2005, 2006, 2010).

- **Patterns of use.** Many families placed their infants in child care very soon after the child's birth, and there was considerable instability in the child-care arrangements. By 4 months of age, nearly three-fourths of the infants had entered some form of nonmaternal child care. Almost half of the infants were cared for by a relative when they first entered care; only 12 percent were enrolled in child-care centers.

Socioeconomic factors were linked to the amount and type of care. For example, mothers with higher incomes and families that were more dependent on the mother's income placed their infants in child care at an earlier age. Mothers who believed that maternal employment has positive effects on children were more likely than other mothers to place their infant in nonmaternal care for more hours. Low-income families were more likely than more affluent families to use child care, but infants from low-income families who were in child care averaged as many hours as other income groups. In the preschool years, mothers who were single, those with more education, and families with higher incomes used more hours of center care than other families. Minority families and mothers with less education used more hours of care by relatives.

- **Quality of care.** Evaluations of quality of care were based on characteristics such as group size, child-adult ratio, physical environment, caregiver characteristics (such as formal education, specialized training, and child-care experience), and caregiver behavior (such as sensitivity to children). An alarming conclusion is that a majority of the child care in the first three years of life was of unacceptably low quality. Positive caregiving by nonparents in child-care settings was

infrequent—only 12 percent of the children studied had experienced positive nonparental child care (such as positive talk, lack of detachment and flat affect, and language stimulation). Further, infants from low-income families experienced lower-quality child care than did infants from higher-income families. When quality of caregivers' care was high, children performed better on cognitive and language tasks, were more cooperative with their mothers during play, showed more positive and skilled interaction with peers, and had fewer behavior problems. Caregiver training and good child-staff ratios were linked

with higher cognitive and social competence when children were 54 months of age. Using data collected as part of the NICHD early child care longitudinal study, a research analysis indicated that higher-quality early childhood care, especially at 27 months of age, was linked to children's higher vocabulary scores in the fifth grade (Belsky & others, 2007).

Higher-quality child care was also related to higher-quality mother-child interaction among the families that used nonmaternal care. Further, poor-quality care was related to higher rates of insecure attachment to the mother among infants who were 15 months of age, but only

when the mother was low in sensitivity and responsiveness. However, child-care quality was not linked to attachment security at 36 months of age. In one study, higher-quality child care from birth to 4½ years of age was linked to higher cognitive-academic achievement at 15 years of age (Vandell & others, 2010). In this study, early high-quality care also was related to youth reports of less externalizing behavior (lower rates of delinquency, for example). In another study, high-quality infant-toddler child care was linked to better memory skills at the end of the preschool years (Li & others, 2013).

- **Amount of child care.** In general, when children spent 30 hours or more per week in child care, their development was less than optimal (Ramey, 2005). In one study, more time spent in early non-relative child care was related to higher levels of risk taking and impulsivity at 15 years of age (Vandell & others, 2010).
- **Family and parenting influences.** The influence of families and parenting was not weakened by extensive child care. Parents played a significant role in helping children to regulate their emotions. Especially important parenting influences were being sensitive to children's needs, being involved with children, and cognitively stimulating them. Indeed, parental sensitivity has been

the most consistent predictor of a secure attachment, with child-care experiences being relevant in many cases only when mothers engage in insensitive parenting (Friedman, Melhuish, & Hill, 2010).

An important point about the extensive NICHD research is that findings show that family factors are considerably stronger and more consistent predictors of a wide variety of child outcomes than are child-care experiences (such as quality, quantity, type). The worst outcomes for children occur when both home and child-care settings are of poor quality. For example, a study involving the NICHD SECCYD

data revealed that worse socioemotional outcomes (more problem behavior, lower levels of prosocial behavior) for children occurred when they experienced both home and child-care environments that conferred risk (Watamura & others, 2011).

This study reinforces the conclusion reached by other researchers cited earlier in this section of the chapter—it is not the quantity as much as the quality of child care a child receives that is important. What is also significant to note is the emphasis on the positive effect families and parents can have on children's child-care experiences.

We have all the knowledge necessary to provide absolutely first-rate child care in the United States. What is missing is the commitment and the will.

What are some strategies parents can follow in regard to child care? Child-care expert Kathleen McCartney (2003, p. 4) offered this advice:

- *Recognize that the quality of your parenting is a key factor in your child's development.*
- *Monitor your child's development.* "Parents should observe for themselves whether their children seem to be having behavior problems." They need to talk with their child-care providers and pediatricians about their child's behavior.
- *Take some time to find the best child care.* Observe different child-care facilities and be certain that you like what you see. "Quality child care costs money, and not all parents can afford the child care they want. However, state subsidies, and other programs like Head Start, are available for families in need."

In another chapter we will discuss socioemotional development in early childhood. Babies no more, young children make considerable progress in the development of their self, their emotions, and their social interactions. In early childhood, they show increased self-understanding and understanding of others, as well as an increased capacity to regulate their emotions. Many of the advances in young children's socioemotional development become possible because of the remarkable changes in their brain and cognitive development. In early childhood, relationships and interactions with parents and peers expand their knowledge of and connections with the social world. Additionally, play becomes something they not only enjoy doing on a daily basis but also a wonderful context for advancing both their socioemotional and cognitive development.

## Socioemotional Development in Infancy

### 1 Emotional and Personality Development

Emotional Development

LG1

Discuss the development of emotions and personality in infancy.

- Emotion is feeling, or affect, that occurs when a person is in a state or an interaction that is important to him or her. The broad range of emotions includes enthusiasm, joy, and love (positive emotions) and anxiety, anger, and sadness (negative emotions). Psychologists stress that emotions, especially facial expressions of emotions, have a biological foundation. Biological evolution endowed humans to be emotional, but embeddedness in culture and relationships provides diversity in emotional experiences.
- Emotions are the first language with which parents and infants communicate, and emotions play key roles in parent-child relationships. Infants display a number of emotions early in their development, although researchers debate the onset and sequence of these emotions. Lewis distinguishes between primary emotions and self-conscious emotions.
- Crying is the most important mechanism newborns have for communicating with the people in their world. Babies have at least three types of cries—basic, anger, and pain cries. Controversy swirls about whether babies should be soothed when they cry, although increasingly experts recommend immediately responding in a caring way during the first year. Social smiling occurs as early as 2 months of age. Two fears that infants develop are stranger anxiety and separation from a caregiver (which is reflected in separation protest). As infants develop, it is important for them to engage in emotion regulation.
- Temperament involves individual differences in behavioral styles, emotions, and characteristic ways of responding. Chess and Thomas classified infants as (1) easy, (2) difficult, or (3) slow to warm up. Kagan proposed that inhibition to the unfamiliar is an important temperament category. Rothbart and Bates' view of temperament emphasizes this classification: (1) extraversion/surgency, (2) negative affectivity, and (3) effortful control (self-regulation).
- Physiological characteristics are associated with different temperaments. Children inherit a physiology that biases them to have a particular type of temperament, but through experience they learn to modify their temperament style to some degree.
- Goodness of fit refers to the match between a child's temperament and the environmental demands the child must cope with. Goodness of fit can be an important aspect of a child's adjustment. Although research evidence is sketchy at this point, some general recommendations are that caregivers should (1) be sensitive to the individual characteristics of the child, (2) be flexible in responding to these characteristics, and (3) avoid negatively labeling the child.
- Erikson argued that an infant's first year is characterized by the stage of trust versus mistrust. The infant begins to develop a self-understanding called self-recognition at about 18 months of age. Independence becomes a central theme in the second year of life. Erikson stressed that the second year of life is characterized by the stage of autonomy versus shame and doubt.

### 2 Social Orientation/Understanding and Attachment

Social Orientation/  
Understanding

LG2

Describe social orientation/understanding and the development of attachment in infancy.

- Infants show a strong interest in their social world and are motivated to understand it. Infants orient to the social world early in their development. Face-to-face play with a caregiver begins to occur at about 2 to 3 months of age. Newly developed self-produced locomotion skills significantly expand the infant's ability to initiate social interchanges and explore their social world more independently.

- Perceiving people as engaging in intentional and goal-directed behavior is an important social cognitive accomplishment that occurs toward the end of the first year. Also, engaging in meaningful interactions is an important aspect of infant development. Social referencing increases during the second year of life.
- Attachment is a close emotional bond between two people. In infancy, contact comfort and trust are important in the development of attachment. Bowlby's ethological theory stresses that the caregiver and the infant are biologically predisposed to form an attachment. Attachment develops in four phases during infancy.
- Securely attached babies use the caregiver, usually the mother, as a secure base from which to explore the environment. Three types of insecure attachment are avoidant, resistant, and disorganized.
- Ainsworth created the Strange Situation, an observational measure of attachment. Ainsworth points out that secure attachment in the first year of life provides an important foundation for psychological development later in life. The strength of the link found between early attachment and later development has varied somewhat across studies.
- Three criticisms of the emphasis on secure attachment in infancy are (1) there is insufficient support for the assertion that infancy serves as a critical/sensitive period for later development; (2) biologically based factors such as genes and temperament have not been given adequate consideration; and (3) diversity of social agents and contexts have received insufficient attention. A current trend in attachment research reflects the developmental cascade model by considering not only attachment but also stability and change in stresses and social contexts as children and adolescents develop. Despite these criticisms, there is ample evidence that attachment is an important aspect of human development. Cultural variations in attachment have been found, but in all cultures secure attachment is the most common classification.
- Caregivers of securely attached babies are sensitive to the babies' signals and are consistently available to meet their needs. Caregivers of insecure avoidant babies tend to be unavailable or rejecting. Caregivers of insecure resistant babies tend to be inconsistently available to their babies and usually are not very affectionate. Caregivers of insecure disorganized babies often neglect or physically abuse their babies.
- Increased interest has been directed toward the role of the brain in the development of attachment. The hormone oxytocin is a key candidate for influencing the development of maternal-infant attachment.

### 3 Social Contexts

The Family

Child Care

**LG3**

Explain how social contexts influence the infant's development.

- The transition to parenthood requires considerable adaptation and adjustment on the part of parents. Children socialize parents, just as parents socialize children. Parent-infant synchrony and scaffolding are important aspects of reciprocal socialization. Belsky's model describes direct and indirect effects of marital relations, parenting, and infant behavior. Parents use a wide range of methods to manage and guide infants' behavior. The mother's primary role when interacting with the infant usually is caregiving; the father's is playful interaction.
- More U.S. children are in child care now than at any earlier point in history. The quality of child care is uneven, and child care remains a controversial topic. Quality child care can be achieved and seems to have few adverse effects on children. In the NICHD child-care study, infants from low-income families were more likely to receive the lowest quality of care. Also, higher-quality child care was linked with fewer problems in children.

## Early Childhood

In early childhood, our greatest untold poem was being only 4 years old. We skipped and ran and played all the sun long, never in our lives so busy, busy being something we had not quite grasped yet. Who knew our thoughts, which we worked up into small mythologies all our own? Our thoughts and images and drawings took wings. The blossoms of our heart, no wind could touch. Our small world widened as we discovered new refuges and new people. When we said “I,” we meant something totally unique, not to be confused with any other. This section consists of two chapters: “Physical and Cognitive Development in Early Childhood” and “Socioemotional Development in Early Childhood.”

# PHYSICAL AND COGNITIVE DEVELOPMENT IN EARLY CHILDHOOD

## chapter outline

### ① Physical Changes

**Learning Goal 1** Identify physical changes in early childhood.

- Body Growth and Change
- Motor and Perceptual Development
- Sleep
- Nutrition and Exercise
- Illness and Death

### ② Cognitive Changes

**Learning Goal 2** Describe three views of the cognitive changes that occur in early childhood.

- Piaget's Preoperational Stage
- Vygotsky's Theory
- Information Processing

### ③ Language Development

**Learning Goal 3** Summarize how language develops in early childhood.

- Understanding Phonology and Morphology
- Changes in Syntax and Semantics
- Advances in Pragmatics
- Young Children's Literacy

### ④ Early Childhood Education

**Learning Goal 4** Evaluate different approaches to early childhood education.

- Variations in Early Childhood Education
- Education for Young Children Who Are Disadvantaged
- Controversies in Early Childhood Education

**T**he Reggio Emilia approach is an educational program for young children that was developed in the northern Italian city of Reggio Emilia. Children of single parents and children with disabilities have priority in admission; other children are admitted according to a scale of needs. Parents pay on a sliding scale based on income.

The children are encouraged to learn by investigating and exploring topics that interest them (Bredekamp, 2017; Follari, 2019). A wide range of stimulating media and materials is available for children to use as they learn music, movement, drawing, painting, sculpting, collages, puppets and disguises, and photography, for example (Bond, 2015).

In this program, children often explore topics in a group, which fosters a sense of community, respect for diversity, and a collaborative approach to problem solving. Two co-teachers are present to serve as guides for children. The Reggio Emilia teachers treat each project as an adventure that may be sparked by an

adult's suggestion, a child's idea, or an event such as a snowfall or something else unexpected. The teachers allow children enough time to think about a topic and craft a project.

At the core of the Reggio Emilia approach is the image of children who are competent and have rights, especially the right to receive outstanding care and education. Parent participation is considered essential, and cooperation is a major theme in the schools. Many early childhood education experts believe the Reggio Emilia approach provides a supportive, stimulating context in which children are motivated to explore their world in a competent and confident manner (Feeney, Moravcik, & Nolte, 2019; Morrison, 2017, 2018).

## topical connections *looking back*

Physical growth in infancy is dramatic. Even though physical growth in early childhood slows, it is not difficult to distinguish young children from infants when you look at them. Most young children lose their “baby fat,” and their legs and trunks become longer. In addition to what you can see with the naked eye, much development also continues below the surface in the brain. In infancy, myelination of axons in the brain paved the way for development of such functions as full visual capacity. Continued myelination in early childhood provides children with much better hand-eye coordination. In terms of cognitive development, you learned that infants make amazing progress in their attentional, memory, concept formation, and language skills. In this chapter, you will discover that these information-processing skills continue to show remarkable advances in early childhood.

# preview

Parents and educators who clearly understand how young children develop can play an active role in creating programs that foster their natural interest in learning, rather than stifling it. In this chapter we will explore the physical, cognitive, and language changes that typically occur as the toddler develops into the preschooler, and then examine different approaches to early childhood education.

## 1 Physical Changes

LG1

Identify physical changes in early childhood.

Body Growth and Change

Motor and Perceptual Development

Sleep

Nutrition and Exercise

Illness and Death

Recall that an infant's growth in the first year is rapid and follows cephalocaudal and proximodistal patterns. Improvement in fine motor skills—such as being able to turn the pages of a book one at a time—also contributes to the infant's sense of mastery in the second year. The growth rate continues to slow down in early childhood. If it did not, we would be a species of giants.

### BODY GROWTH AND CHANGE

Growth in height and weight is the obvious physical change that characterizes early childhood. Unseen changes in the brain and nervous system are no less significant, however, in preparing children for advances in cognition and language.

**Height and Weight** The average child grows 2½ inches in height and gains 5 to 10 pounds a year during early childhood. As the preschool child grows older, the percentage of increase in height and weight decreases with each additional year (Goldstone & Reynolds, 2014). Girls are only slightly smaller and lighter than boys during these years, a difference that continues until puberty. During the preschool years, both boys and girls slim down as the trunks of their bodies lengthen. Although their heads are still somewhat large for their bodies, by the end of the preschool years most children have lost their top-heavy look. Body fat also shows a slow, steady decline during the preschool years. The chubby baby often looks much leaner by the end of early childhood. Girls have more fatty tissue than boys; boys have more muscle tissue.

Growth patterns vary individually (Kliegman & others, 2016; London & others, 2017). Think back to your preschool years. This was probably the first time you noticed that some children were taller than you, some shorter; some were fatter, some thinner; some were stronger, some weaker. Much of the variation was due to heredity, but environmental experiences were also involved (Bindler & others, 2017). A review of the height and weight of children around the world concluded that the two most important contributors to height differences are ethnic origin and nutrition (Meredith, 1978). Urban, middle-socioeconomic-status, and firstborn children were taller than rural, lower-socioeconomic-status, and later-born children. In the United States, African American children are taller than non-Latino White children.

Why are some children unusually short? The primary contributing influences are congenital factors (genetic or prenatal problems), growth hormone deficiency, a physical problem that develops in childhood, maternal smoking during pregnancy, or an emotional difficulty (Hay & others, 2017; Krebs & others, 2016).

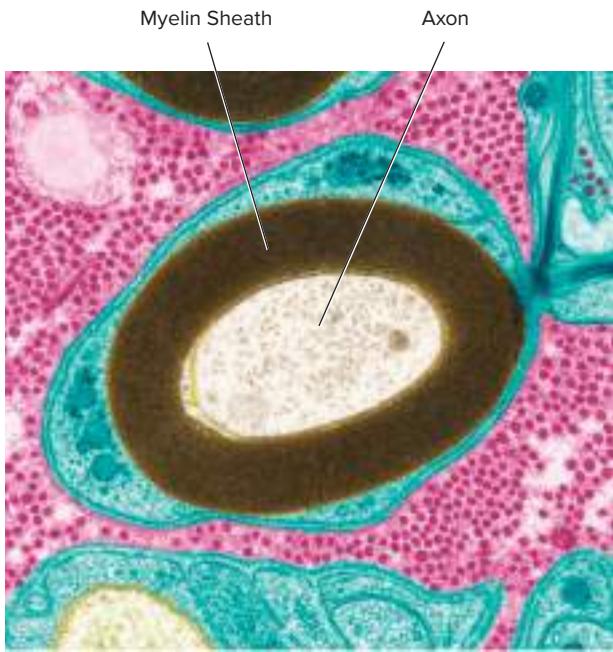

**Growth hormone deficiency** is the absence or deficiency of growth hormone produced by the pituitary gland to stimulate the body to grow (Krebs & others, 2016). Growth hormone deficiency may occur during infancy or later in childhood (Collin, Whitehead, & Walker, 2016; Grimberg & Allen, 2017). As many as 10,000 to 15,000 U.S. children may have growth hormone deficiency (Stanford University Medical Center, 2012). Without treatment, most children with growth hormone deficiency will not reach a height of five feet. Twice as many boys as girls are treated with growth hormone, likely because there is a greater stigma attached to boys being

#### Brain Development

In middle and late childhood, cortical thickening occurs in the frontal lobes, which may be linked to improvements in language abilities such as reading. Connect to “Physical and Cognitive Development in Middle and Late Childhood.”

short. A recent study of children born small for gestational age or short in stature revealed that five years of growth hormone treatment in childhood was linked to an increase to close to average height (Ross & others, 2015). And one study also revealed that growth hormone treatment of children who were very short in stature was linked to an increase in height as well as improvements in self-esteem and mood (Chaplin & others, 2012). Also, a recent review concluded that accurate assessment of growth hormone deficiency is difficult and that many children diagnosed with growth hormone deficiency re-test normal later in childhood (Murray, Dattani, & Clayton, 2016).

**The Brain** One of the most important physical developments during early childhood is the continuing development of the brain and nervous system (Bell & others, 2018). Although the brain continues to grow in early childhood, it does not grow as rapidly as it did in infancy. By the time children reach 3 years of age, the brain is three-quarters of its adult size. By age 6, the brain has reached about 95 percent of its adult size (Lenroot & Giedd, 2006). Thus, the brain of a 5-year-old is nearly the size it will be when the child reaches adulthood, but as we will see in later chapters, the development that occurs inside the brain continues through the remaining years of childhood and adolescence (Bell, Ross, & Patton, 2018; Cohen & Casey, 2017; Goddings & Mills, 2017).

Some of the brain's interior changes involve increases in dendritic connections as well as **myelination**, in which nerve cells are covered and insulated with a layer of fat cells (see Figure 1). Myelination has the effect of increasing the speed and efficiency of information traveling through the nervous system. Myelination is important in the development of a number of abilities during childhood (Juraska & Willing, 2017; van Tilborg & others, 2018). For example, myelination in the areas of the brain related to hand-eye coordination is not complete until about 4 years of age. In a recent study, young children with higher cognitive ability showed increased myelination by 3 years of age (Deoni & others, 2016).

Researchers also have discovered that children's brains undergo dramatic anatomical changes between the ages of 3 and 15 (Bell, Ross, & Patton, 2018; Cohen & Casey, 2017). By repeatedly obtaining brain scans of the same children for up to four years, they have found that children's brains undergo rapid, distinct spurts of growth. The amount of brain material in some areas can nearly double within as little as a year, followed by a drastic loss of tissue as unneeded cells are purged and the brain continues to reorganize itself. The scientists have discovered that the overall size of the brain does not show dramatic growth in the 3- to 15-year age range. However, what does dramatically change are local patterns within the brain. Researchers have found that in children from 3 to 6 years of age the most rapid growth takes place in the frontal lobe areas involved in planning and organizing new actions, and in maintaining attention to tasks (Carlson, Zelazo, & Faja, 2013).

Recently, researchers have found that contextual factors such as poverty and parenting quality are linked to the development of the brain (Black & others, 2017; Lomanowska & others, 2017; Marshall & others, 2018). In one study, children from the poorest homes had significant maturational lags in their frontal and temporal lobes at 4 years of age, and these lags were associated with lower attainment of school readiness skills (Hair & others, 2015). In another study, higher levels of maternal sensitivity in early childhood were associated with higher total brain volume (Kok & others, 2015).

## MOTOR AND PERCEPTUAL DEVELOPMENT

Most preschool children are more active than they will ever be at any later period in the life span. Let's explore what this activity involves in young children's lives, as well as advances in their perceptual skills.

**Gross Motor Skills** The preschool child no longer has to make an effort simply to stay upright and to move around. As children move their legs with more confidence and carry themselves more purposefully, moving around in the environment becomes more automatic (Perry & others, 2018). However, there are large individual differences in young children's gross motor skills (Kliegman & others, 2016).

**myelination** The process by which the nerve cells are covered and insulated with a layer of fat cells, which increases the speed at which information travels through the nervous system.

At 3 years of age, children enjoy simple movements, such as hopping, jumping, and running back and forth, just for the sheer delight of performing these activities. They take considerable pride in showing how they can run across a room and jump all of 6 inches. The run-and-jump will win no Olympic gold medals, but for the 3-year-old the activity is a source of considerable pride in accomplishment.

At 4 years of age, children are still enjoying the same kind of activities, but they have become more adventurous. They scramble over low jungle gyms as they display their athletic prowess.

At 5 years of age, children are even more adventuresome than when they were 4. It is not unusual for self-assured 5-year-olds to perform hair-raising stunts on practically any climbing object. Five-year-olds run hard and enjoy races with each other and their parents.

How can early childhood educators support young children's motor development? Young children need to practice skills in order to learn them, so instruction should be followed with ample time for practice (Follari, 2019; Morrison, 2017, 2018). A recent study of 4-year-old girls found that a nine-week motor skills intervention improved the girls' ball skills (Veldman & others, 2017).

There can be long-term negative effects for children who fail to develop basic motor skills (Barnett, Salmon, & Hesketh, 2016; Gorgon, 2018). These children will not be as able to join in group games or participate in sports during their school years and in adulthood. In a recent study, children with a low level of motor competence had a lower motivation for sports participation and had lower global self-worth than their counterparts with a high level of motor competence (Bardid & others, 2018). Another recent study found that higher motor proficiency in preschool was linked to higher levels of physical activity in adolescence (Venetsanou & Kambas, 2017).

**Fine Motor Skills** At 3 years of age, although children have had the ability to pick up the tiniest objects between their thumb and forefinger for some time, they are still somewhat clumsy at it. Three-year-olds can build surprisingly high block towers, placing each block with intense concentration but often not in a completely straight line. When 3-year-olds play with a simple jigsaw puzzle, they are rather rough in placing the pieces. Even when they recognize the hole a piece fits into, they are not very precise in positioning the piece. They often try to force the piece into the hole or pat it vigorously.

By 4 years of age, children's fine motor coordination has improved substantially and become much more precise. Sometimes 4-year-old children have trouble building high towers with blocks because, in their attempts to place each of the blocks perfectly, they may upset those already stacked. By age 5, children's fine motor coordination has improved further. Hand, arm, and body all move together under better command of the eye.

**Perceptual Development** Changes in children's perceptual development continue in childhood (Bank & others, 2015). When children are about 4 or 5 years old, their eye muscles usually are developed enough that they can move their eyes efficiently across a series of letters. Many preschool children are farsighted, unable to see close up as well as they can see far away. By the time they enter the first grade, though, most children can focus their eyes and sustain their attention effectively on close-up objects.

What are the signs of vision problems in children? They include rubbing the eyes, blinking or squinting excessively, appearing irritable when playing games that require good distance vision, shutting or covering one eye, and tilting the head or thrusting it forward when looking at something. A child who shows any of these behaviors should be examined by an ophthalmologist.

After infancy, children's visual expectations about the physical world continue to develop. In one study, 2- to 4½-year-old children were given a task in which the goal was to find a ball that had been dropped through an opaque tube (Hood, 1995). As shown in Figure 2, if the ball is dropped into the tube at the top left, it will land in the box at the bottom right. However, in this task, most of the 2-year-olds, and even some of the 4-year-olds, persisted in searching in the box directly beneath the dropping point. For them, gravity ruled and they had failed to perceive the end location of the curved tube.

In one study 3-year-olds were presented with the same task shown in Figure 2 (Joh, Jaswal, & Keen, 2011). In the group that was told to imagine the various paths the ball might take, the young children were more accurate in predicting where the ball would land. In another recent study, 3-year-olds improved their performance on the ball-dropping task shown in Figure 2 when they were instructed to follow the tube with their eyes to the bottom (Bascandziev & Harris, 2011). Thus, in these two studies, 3-year-olds were able to overcome the gravity bias and their impulsive tendencies when they were given verbal instructions from a knowledgeable adult (Keen, 2011).

**FIGURE 2**  
**VISUAL EXPECTATIONS ABOUT THE PHYSICAL WORLD.** When young children see the ball dropped into the tube, many of them will search for it immediately below the dropping point.

#### Sleep

What sleep disorder in infancy leads to the most infant deaths and at what age is the infant most at risk for this disorder? Connect to "Physical Development in Infancy."

How do children learn to deal with situations like that in Figure 2, and how do they come to understand other laws of the physical world? These questions are addressed by studies of cognitive development, which we discuss later in this chapter.

## SLEEP

Getting a good night's sleep is important for children's development (Kouros & El-Sheikh, 2017; Paul & Pinto, 2017; Rangan & others, 2018). Experts recommend that young children get 11 to 13 hours of sleep each night (National Sleep Foundation, 2016). Most young children sleep through the night and have one daytime nap. Not only do children need a certain amount of sleep, but also uninterrupted sleep (Owens & Mindell, 2011). However, it sometimes is difficult to get young children to go to sleep as they drag out their bedtime routine. Studies often report that young children don't get adequate sleep (Palermo, 2014). A recent study of children 36 to 42 months old found that a consistent bedtime routine was associated with more nightly sleep and an increase in nightly sleep minutes across a 6-month period (Staples, Bates, & Petersen, 2015).

Children can experience a number of sleep problems (El-Sheikh, Hinnant, & Philbrook, 2017; Huhdanpaa & others, 2018). These include narcolepsy (extreme daytime sleepiness) (Inocente & others, 2014), insomnia (difficulty getting to sleep or staying asleep) (Miano & Peraita-Adrados, 2014), and nightmares (Akinsanya, Marwaha, & Tampi, 2017). One estimate indicates that more than 40 percent of children experience a sleep problem at some point in their development (Boyle & Cropley, 2004). The following research studies indicate links between children's sleep problems and negative developmental outcomes:

- Sleep problems in early childhood were associated with subsequent attention problems that in some cases persisted into early adolescence (O'Callaghan & others, 2010).
- In a Chinese study, preschool children who slept seven hours per day or less had a worse school readiness profile (including language/cognitive deficits and emotional immaturity) (Tso & others, 2016). Also in this study, preschool children who used electronic devices three or more hours per day had shortened sleep durations.
- Preschool children with a longer sleep duration were more likely to have better peer acceptance, social skills, and receptive vocabulary (Vaughn & others, 2015).
- Short sleep duration in children was linked with being overweight (Hart, Cairns, & Jelalian, 2011).
- In 2- to 5-year-old children, each additional hour of daily screen time was associated with a decrease in sleep time, less likelihood of sleeping 10 hours or more per night, and later bedtime (Xu & others, 2016).
- Four-year-old children who had insomnia were characterized by hostile-aggressive and hyperactive-distractible problems (Armstrong & others, 2014).

To improve children's sleep, Mona El-Sheikh (2013) recommends making sure that the bedroom is cool, dark, and comfortable; maintaining consistent bedtimes and wake times; and building positive family relationships. Also, helping the child slow down before bedtime often contributes to less resistance to going to bed. Reading the child a story, playing quietly with the child in the bath, and letting the child sit on the caregiver's lap while listening to music are quieting activities.

## NUTRITION AND EXERCISE

Eating habits are important aspects of development during early childhood (Blake, Munoz, & Volpe, 2019; Thompson & Manore, 2018; Wardlaw, Smith, & Collene, 2018). What children eat affects their skeletal growth, body shape, and susceptibility to disease. Exercise and physical activity also are very important aspects of young children's lives (Powers & Dodd, 2017; Powers & Howley, 2018; Walton-Fisette & Wuest, 2018).

**Overweight Young Children** Being overweight has become a serious health problem in early childhood (Donatelle, 2019; Perry & others, 2017). A national study revealed that 45 percent of children's meals exceed recommendations for saturated and trans fats, which can raise cholesterol levels and increase the risk of heart disease (Center for Science in the Public Interest, 2008). The same study found that one-third of children's daily caloric intake comes from restaurants—twice the

percentage consumed away from home in the 1980s. Further, 93 percent of almost 1,500 possible choices at 13 major fast-food chains exceeded 430 calories—one-third of what the National Institute of Medicine recommends that 4- to 8-year-old children consume in a day. Nearly all of the children's meal options at KFC, Taco Bell, Sonic, Jack in the Box, and Chick-fil-A were too high in calories. One study of U.S. 2- and 3-year-olds found that French fries and other fried potatoes were the vegetable they were most likely to consume (Fox & others, 2010).

Young children's eating behavior is strongly influenced by their caregivers' behavior (Black & Hurley, 2017; Brown, 2017; Lindsay & others, 2018; Sorte, Daeschel, & Amador, 2017; Tan & Holub, 2015). Young children's eating behavior improves when caregivers eat with children on a predictable schedule, model choosing nutritious food, make mealtimes pleasant occasions, and engage in certain feeding styles. Distractions from television, family arguments, and competing activities should be minimized so that children can focus on eating. A sensitive/responsive caregiver feeding style, in which the caregiver is nurturant, provides clear information about what is expected, and appropriately responds to children's cues, is recommended (Black & Hurley, 2017). Forceful and restrictive caregiver behaviors are not recommended (Tylka, Lumeng, & Eneli, 2015).

The Centers for Disease Control and Prevention (2018) has established categories for obesity, overweight, and at risk of being overweight. These categories are determined by body mass index (BMI), which is computed using a formula that takes into account height and weight. Children and adolescents at or above the 97th percentile are classified as obese, those at the 95th or 96th percentile as overweight, and those from the 85th to the 94th percentile as at risk of being overweight.

The percentages of young children who are overweight or at risk of being overweight in the United States have increased dramatically in recent decades, but in the last several years there are indications that fewer preschool children are obese (Wardlaw, Smith, & Collene, 2018). In 2009–2010, 12.1 percent of U.S. 2- to 5-year-olds were classified as obese, compared with 5 percent in 1976–1980 (Ogden & others, 2012). However, in 2013–2014, a substantial drop in the obesity rate of 2- to 5-year-old children occurred in comparison with their counterparts in 2009–2010 (Ogden & others, 2016). In 2013–2014, 9.4 percent of 2- to 5-year-olds were obese compared with 12.1 percent in 2009–2010. It is not clear precisely why this drop occurred, but among the possibilities are families buying lower-calorie foods and the Special Supplementation Program for Women, Infants, and Children (which subsidizes food for women in low-income families) emphasizing reduced consumption of fruit juice, cheese, and eggs and increased consumption of whole fruits and vegetables. In a recent study, 2½-year-olds' liking for fruits and vegetables was related to their eating more fruits and vegetables at 7 years of age (Fletcher & others, 2018).

The risk that overweight children will continue to be overweight when they are older was underscored by a recent U.S. study of nearly 8,000 children (Cunningham, Kramer, & Narayan, 2014). In this study, overweight 5-year-olds were four times more likely to be obese at 14 years of age than their 5-year-old counterparts who began kindergarten at a normal weight. Also, in the study described earlier in which obesity rates were decreasing among preschool children, preschool children who were obese were five times more likely to be overweight or obese as adults (Ogden & others, 2014).

One comparison of 34 countries revealed that the United States had the second highest rate of childhood obesity (Janssen & others, 2005). Obesity contributes to a number of health problems in young children (Walker & others, 2015). For example, physicians are now seeing type 2 (adult-onset) diabetes (a condition directly linked with obesity and a low level of fitness) and hypertension in children as young as 5 years of age (Chaturvedi & others, 2014).

Many aspects of children's lives can contribute to becoming overweight or obese (Labayen Goni & others, 2018; Sun & others, 2018). Recently, the following 5-2-1-0 obesity prevention guidelines have been issued for young children: 5 or more servings of fruits and vegetables, 2 hours or less of screen time, minimum of 1 hour of physical activity, and 0 sugar-sweetened beverages daily (Khalsa & others, 2017). Prevention of obesity in children includes helping children, parents, and teachers see food as a way to satisfy hunger and meet nutritional needs, not as proof of love or as a reward for good behavior (Roberts, Marx, & Musher-Eizenman, 2018; Smith & Collene, 2019). Snack foods should be low in fat, in simple sugars, and in salt, as well as high in fiber. Routine physical activity should be a daily occurrence (Lintu & others, 2016). A recent research study found that viewing as little as 1 hour of television daily was associated with an increase in body mass index (BMI) between kindergarten and the first grade

(Peck & others, 2015). A recent intervention study with children attending Head Start programs found that getting parents involved in such activities as nutrition counseling, becoming more aware of their child's weight status, and developing healthy lifestyles was effective in lowering children's rate of obesity, increasing children's physical activity, reducing children's TV viewing, and improving children's eating habits (Davison & others, 2013). Other researchers also are finding that interventions with parents can reduce children's likelihood of being overweight or obese (Byrne & others, 2018). A recent research review concluded that family-based interventions were often effective in helping obese children lose weight (Kothandan, 2014).

**Malnutrition in Young Children from Low-Income Families** Malnutrition is a problem for many U.S. children, with approximately 11 million preschool children experiencing malnutrition that places their health at risk. Poverty is an especially strong risk factor for malnutrition in young children (Black & others, 2017; Blake, 2017; Schiff, 2019). One of the most common nutritional problems in early childhood is iron deficiency anemia, which results in chronic fatigue. This problem results from the failure to eat adequate amounts of quality meats and dark green vegetables. Young children from low-income families are the most likely to develop iron deficiency anemia (Petry & others, 2017).

**Exercise** Routine physical activity should be a daily occurrence for young children (Innella & others, 2016; Insel & Roth, 2018; Lintu & others, 2016). Too often children are not getting adequate exercise (Dowda & others, 2017; Walton-Fisette & Wuest, 2018). Recently, four expert panels from Australia, Canada, the United Kingdom, and the United States issued physical activity guidelines for young children that were quite similar (Pate & others, 2015). The guidelines recommend that young children get 15 or more minutes of physical activity per hour over a 12-hour period, or about 3 hours per day total. These guidelines reflect an increase from earlier guidelines (National Association for Sport and Physical Education, 2002). The child's life should center around activities, not meals (Powers & Dodd, 2017; Powers & Howley, 2018).

## ILLNESS AND DEATH

What are the greatest risks to the health of young children in the United States? How pervasive is death among young children around the world?

**The United States** Young children's active and exploratory nature, coupled with their unawareness of danger in many instances, often puts them in situations in which they are at risk for injuries. In 2015 in the United States, accidents (unintentional injuries) were the leading cause of death in young children, followed by congenital malformations, deformations, and chromosomal abnormalities (Centers for Disease Control and Prevention, 2017). Drowning was the most common cause of accidental death in young children, with other causes of accidental death in young children in order involving motor vehicles, homicide, and suffocation.

**Children's Safety** Children's safety is influenced not only by their own skills and safety behaviors but also by aspects of their family and home, school and peers, and community (Naranjo, 2017; Onders & others, 2018; Saunders & others, 2017; Simon-Tov, Peleg, & Baron-Epel, 2018). Figure 3 describes steps that can be taken in each of these contexts to enhance children's safety and prevent injury (Sleet & Mercy, 2003). Children in poverty have higher rates of accidents, death, and asthma than do children from higher-income families (Hughes & others, 2017; Lin & Seo, 2017).

**Environmental Tobacco Smoke** Estimates indicate that approximately 22 percent of children and adolescents in the United States are exposed to tobacco smoke in the home. An increasing number of studies reach the conclusion that children are at risk for health problems when they live in homes in which a parent smokes (Miyahara & others, 2017; Pugmire, Sweeting, & Moore, 2017). Children exposed to tobacco smoke in the home are more likely to develop wheezing symptoms and asthma than are children in nonsmoking families (Hatoun & others, 2018; Merianos, Dixon, & Mahabee-Gittens, 2017; Rosen & others, 2018; Vo & others, 2017). One study found that parental smoking was a risk factor for higher blood pressure in children (Simonetti & others, 2011). Also, a recent study revealed that maternal cigarette smoking and alcohol consumption when children were 5 years of age were linked to onset of smoking in early adolescence (Hayatbakhsh & others, 2013). Further, a recent study revealed that children living in low-income families are more likely to be exposed to environmental tobacco smoke than their counterparts in middle-income families (Kit & others, 2013). And a recent study found that young children who were exposed to environmental tobacco smoke were more likely to engage in antisocial behavior when they were 12 years old (Pagani & others, 2017).

**The State of Illness and Health of the World's Children** Devastating effects on the health of young children occur in countries where poverty rates are high (UNICEF, 2018). The poor are the majority in nearly one out of every five nations in the world. They often experience hunger, malnutrition, illness, inadequate access to health care, unsafe water, and a lack of protection from harm (Black & others, 2017).

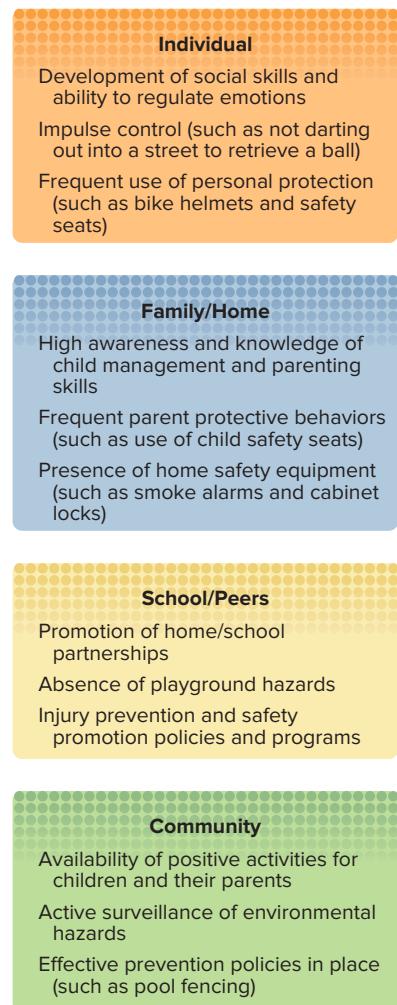

In the last decade, there has been a dramatic increase in the number of young children who have died because HIV/AIDS was transmitted to them by their parents (UNICEF, 2018). Deaths of young children due to HIV/AIDS especially occur in countries with high rates of poverty and low levels of education (Tomlinson & others, 2016).

Many of the deaths of young children around the world could be prevented by reductions in poverty and improvements in nutrition, sanitation, education, and health services (Black & others, 2017; UNICEF, 2018).

Many children in impoverished countries die before reaching the age of 5 from dehydration and malnutrition brought about by diarrhea. *What are some of the other main causes of death in young children around the world?*

#### Cognitive Theory

Object permanence is an important accomplishment in the sensorimotor stage. Connect to “Cognitive Development in Infancy.”

### PIAGET'S PREOPERATIONAL STAGE

Recall that during Piaget's first stage of development, the sensorimotor stage, the infant progresses in the ability to organize and coordinate sensations and perceptions with physical movements and actions. The **preoperational stage**, which lasts from approximately 2 to 7 years of age, is the second Piagetian stage. In this stage, children begin to represent the world with words, images, and drawings. They form stable concepts and begin to reason. At the same time, the young child's cognitive world is dominated by egocentrism and magical beliefs.

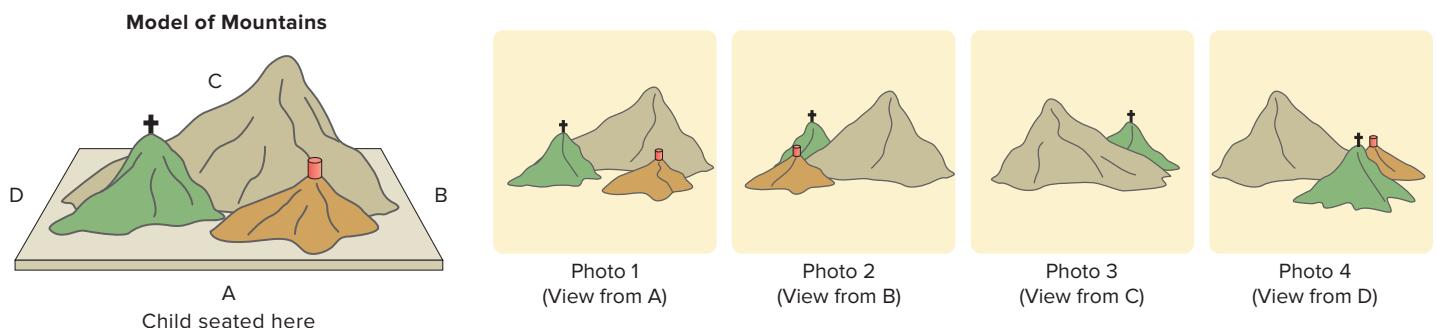

Because Piaget called this stage “preoperational,” it might sound like an unimportant waiting period. Not so. Instead, the label *preoperational* emphasizes that the child does not yet perform **operations**, which are reversible mental actions that allow children to do mentally what before they could do only physically. Adding and subtracting numbers mentally are examples of operations. *Preoperational thought* is the beginning of the ability to reconstruct in thought what has been established in behavior. This developmental stage can be divided into two substages: the symbolic function substages and the intuitive thought substages.

**The Symbolic Function Substage** The **symbolic function substage** is the first substage of preoperational thought, occurring roughly between the ages of 2 and 4. During this substage, the young child gains the ability to mentally represent an object that is not present. This ability vastly expands the child's mental world (Callaghan & Corbit, 2015). Young children use scribble designs to represent people, houses, cars, clouds, and so on; they begin to use language and engage in pretend play. However, although young children make distinct progress during this substage, their thought still has important limitations, two of which are egocentrism and animism.

**preoperational stage** Piaget's second stage, lasting from about 2 to 7 years of age, during which children begin to represent the world with words, images, and drawings, and symbolic thought goes beyond simple connections of sensory information and physical action; stable concepts are formed, mental reasoning emerges, egocentrism is present, and magical beliefs are constructed.

**operations** In Piaget's theory, these are reversible mental actions that allow children to do mentally what they formerly did physically.

**symbolic function substage** Piaget's first substage of preoperational thought, in which the child gains the ability to mentally represent an object that is not present (between about 2 and 4 years of age).

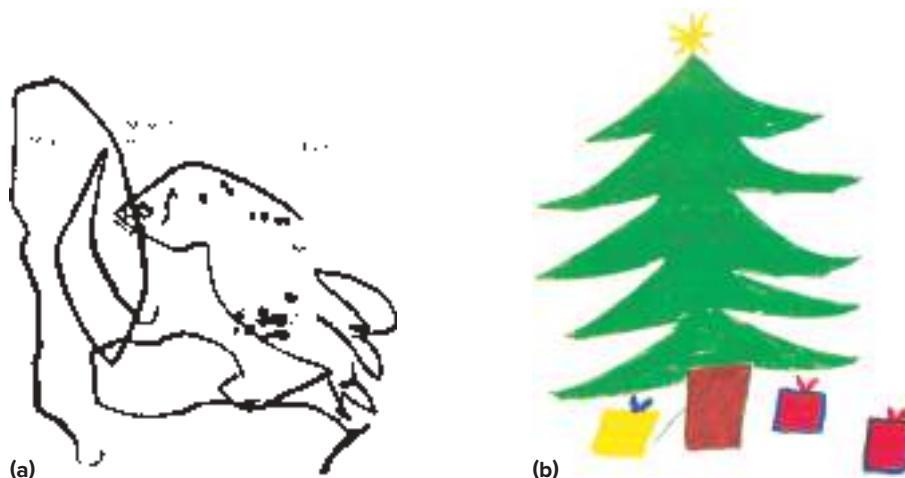

**FIGURE 4**

**THE THREE MOUNTAINS TASK.** View 1 shows the child's perspective from where he or she is sitting. View 2 is an example of one of the photographs the child would be shown, along with other photographs taken from different perspectives. It shows what the mountains look like to a person sitting at spot B. When asked what a view of the mountains looks like from position B, the preoperational child selects a photograph taken from location A, the child's view at the time. A child who thinks in a preoperational way cannot take the perspective of a person sitting at another spot.

**Egocentrism** is the inability to distinguish between one's own perspective and someone else's perspective. Piaget and Barbel Inhelder (1969) initially studied young children's egocentrism by devising the three mountains task (see Figure 4). The child walks around the model of the mountains and becomes familiar with what the mountains look like from different perspectives, and she can see that there are different objects on the mountains. The child is then seated on one side of the table on which the mountains are placed. The experimenter moves a doll to different locations around the table, at each location asking the child to select from a series of photos the one photo that most accurately reflects the view that the doll is seeing. Children in the preoperational stage often pick their own view rather than the doll's view. Preschool children frequently show the ability to take another's perspective on some tasks but not others.

**Animism**, another limitation of preoperational thought, is the belief that inanimate objects have lifelike qualities and are capable of action. A young child might show animism by saying, "That tree pushed the leaf off, and it fell down," or "The sidewalk made me mad; it made me fall down." A young child who uses animism fails to distinguish the appropriate occasions for using human and nonhuman perspectives (Opfer & Gelman, 2011).

Possibly because young children are not very concerned about reality, their drawings are fanciful and inventive. Suns are blue, skies are yellow, and cars float on clouds in their symbolic, imaginative world. One 3½-year-old looked at a scribble he had just drawn and described it as a pelican kissing a seal (see Figure 5a). The symbolism is simple but strong, like

**FIGURE 5**

**THE SYMBOLIC DRAWINGS OF YOUNG CHILDREN.** (a) A 3½-year-old's symbolic drawing. Halfway into his drawing, the 3½-year-old artist said it was a "pelican kissing a seal." abstractions found in some modern art. Twentieth-century Spanish artist Pablo Picasso commented, “I used to draw like Raphael but it has taken me a lifetime to draw like young children.” During the elementary school years, a child’s drawings become more realistic, neat, and precise (see Figure 5b) (Winner, 1986).

**The Intuitive Thought Substage** The **intuitive thought substage** is the second substage of preoperational thought, occurring between approximately 4 and 7 years of age. In this substage, children begin to use primitive reasoning and want to know the answers to all sorts of questions. Consider 4-year-old Tommy, who is at the beginning of the intuitive thought substage. Although he is starting to develop his own ideas about the world he lives in, his ideas are still simple, and he is not very good at thinking things out. He has difficulty understanding events that he knows are taking place but that he cannot see. His fantasized thoughts bear little resemblance to reality. He cannot yet answer the question “What if?” in any reliable way. For example, he has only a vague idea of what would happen if a car were to hit him. He also has difficulty negotiating traffic because he cannot do the mental calculations necessary to estimate whether an approaching car will hit him when he crosses the road.

By the age of 5, children have just about exhausted the adults around them with “why” questions. The child’s questions signal the emergence of interest in reasoning and in figuring out why things are the way they are. Following are some samples of the questions children ask during the questioning period of 4 to 6 years of age (Elkind, 1976): “What makes you grow up?” “Who was the mother when everybody was a baby?” “Why do leaves fall?” “Why does the sun shine?” Piaget called this substage intuitive because young children seem so sure about their knowledge and understanding yet are unaware of how they know what they know. That is, they know something but know it without the use of rational thinking.

**Centration and the Limits of Preoperational Thought** One limitation of preoperational thought is **centration**, a centering of attention on one characteristic to the exclusion of all others. Centration is most clearly evidenced in young children’s lack of **conservation**, the awareness that altering an object’s or a substance’s appearance does not change its basic properties. For example, to adults, it is obvious that a certain amount of liquid stays the same, regardless of a container’s shape. But this is not at all obvious to young children. Instead, they are struck by the height of the liquid in the container; they focus on that characteristic to the exclusion of others.

The situation that Piaget devised to study conservation is his most famous task. In the conservation task, children are presented with two identical beakers, each filled to the same level with liquid (see Figure 6). They are asked if these beakers have the same amount of liquid, and they usually say yes. Then the liquid from one beaker is poured into a third beaker, which is taller and thinner than the first two. The children are then asked if the amount of liquid in

(b) The child is asked if these beakers (A and C) have the same amount of liquid. Number	 <p>Two identical rows of objects are shown to the child, who agrees they have the same number.</p>	 <p>One row is lengthened and the child is asked whether one row now has more objects.</p>	Yes, the longer row.
Matter	 <p>Two identical balls of clay are shown to the child. The child agrees that they are equal.</p>	 <p>The experimenter changes the shape of one of the balls and asks the child whether they still contain equal amounts of clay.</p>	No, the longer one has more.
Length	 <p>Two sticks are aligned in front of the child. The child agrees that they are the same length.</p>	 <p>The experimenter moves one stick to the right, then asks the child if they are equal in length.</p>	No, the one on the top is longer.

**FIGURE 7**

**SOME DIMENSIONS OF CONSERVATION: NUMBER, MATTER, AND LENGTH.** *What characteristics of preoperational thought do children demonstrate when they fail these conservation tasks?*

the tall, thin beaker is equal to that which remains in one of the original beakers. Children who are less than 7 or 8 years old usually say no and justify their answers in terms of the differing height or width of the beakers. Older children usually answer yes and justify their answers appropriately (“If you poured the water back, the amount would still be the same”).

In Piaget’s theory, failing the conservation-of-liquid task is a sign that children are at the preoperational stage of cognitive development. The failure demonstrates not only centration but also an inability to mentally reverse actions. For example, in the conservation of matter example shown in Figure 7, preoperational children say that the longer shape has more clay because they assume that “longer is more.” Preoperational children cannot mentally reverse the clay-rolling process to see that the amount of clay is the same in both the shorter ball shape and the longer stick shape.

In addition to failing to conserve volume, preoperational children also fail to conserve number, matter, length, and area. However, children often vary in their performance on different conservation tasks. Thus, a child might be able to conserve volume but not number. A recent fMRI brain-imaging study of conservation of number revealed that advances in a network in the parietal and frontal lobes were linked to 9- and 10-year-olds’ conservation success in comparison with non-conserving 5- and 6-year-olds (Houde & others, 2011).

Some developmentalists disagree with Piaget’s estimate of when children’s conservation skills emerge. For example, Rochel Gelman (1969) showed that when the child’s attention to relevant aspects of the conservation task is improved, the child is more likely to conserve. Gelman has also demonstrated that attentional training on one dimension, such as number, improves the preschool child’s performance on another dimension, such as mass. Thus, Gelman argues that conservation appears earlier than Piaget thought and that attention is especially important in explaining conservation.

## VYGOTSKY’S THEORY

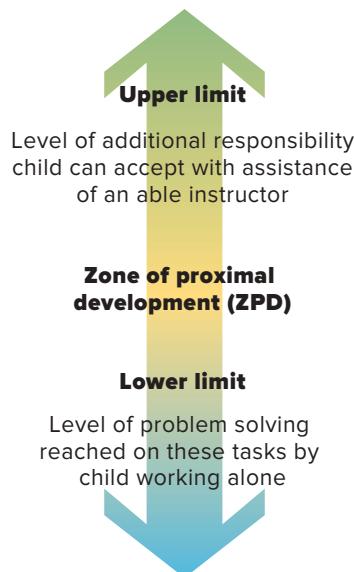

Piaget’s theory is a major developmental theory. Another developmental theory that focuses on children’s cognition is Vygotsky’s theory. Like Piaget, Vygotsky (1962) emphasized that children actively construct their knowledge and understanding. In Piaget’s theory, children develop ways of thinking and understanding by their actions and interactions with the physical world. In Vygotsky’s theory, children are more often described as social creatures than in Piaget’s theory (Moura da Costa & Tuleski, 2017; Yu & Hu, 2017). They develop their ways of thinking and understanding primarily through social interaction (Clara, 2017). Their cognitive development depends on the tools provided by society, and their minds are shaped by the cultural context in which they live (Daniels, 2017; Gauvain, 2016; Holzman, 2017; Yasnitcky & Van der Veer, 2016).

**FIGURE 8**

**VYGOTSKY'S ZONE OF PROXIMAL DEVELOPMENT.** Vygotsky's zone of proximal development has a lower limit and an upper limit. Tasks in the ZPD are too difficult for the child to perform alone. They require assistance from an adult or a more-skilled child. As children experience the verbal instruction or demonstration, they organize the information in their existing mental structures so that they can eventually perform the skill or task alone.

#### Parenting

Scaffolding also is an effective strategy for parents to adopt in interacting with their infants. Connect to “Socioemotional Development in Infancy.”

**Scaffolding** Closely linked to the idea of the ZPD is the concept of scaffolding. *Scaffolding* means changing the level of support. Over the course of a teaching session, a more-skilled person (a teacher or advanced peer) adjusts the amount of guidance to fit the child's current performance (Daniels, 2017). When the student is learning a new task, the skilled person may use direct instruction. As the student's competence increases, less guidance is given. A recent study found that scaffolding techniques that heighten engagement, direct exploration, and facilitate “sense-making,” such as guided play, improved 4- to 5-year-old children's acquisition of geometric knowledge (Fisher & others, 2013).

**Language and Thought** The use of dialogue as a tool for scaffolding is only one example of the important role of language in a child's development. According to Lev Vygotsky, children use speech not only to communicate socially but also to help them solve tasks. Vygotsky (1962) further believed that young children use language to plan, guide, and monitor their behavior. This use of language for self-regulation is called *private speech* (Lantolf, 2017). For Piaget, private speech is egocentric and immature, but for Vygotsky it is an important tool of thought during the early childhood years.

Vygotsky said that language and thought initially develop independently of each other and then merge. He emphasized that all mental functions have external, or social, origins. Children must use language to communicate with others before they can focus inward on their own thoughts. Children also must communicate externally and use language for a long period of time before they can make the transition from external to internal speech. This transition period occurs between 3 and 7 years of age and involves talking to oneself. After a while, the self-talk becomes second nature to children, and they can act without verbalizing. When they gain this skill, children have internalized their egocentric speech in the form of *inner speech*, which becomes their thoughts.

Vygotsky reasoned that children who use a lot of private speech are more socially competent than those who don't. He argued that private speech represents an early transition in becoming more socially communicative. In Vygotsky's view, when young children talk to themselves they are using language to govern their behavior and guide themselves. For example, a child working on a puzzle might say to herself, “Which pieces should I put

### The Zone of Proximal Development

Vygotsky's belief in the role of social influences, especially instruction, in children's cognitive development is reflected in his concept of the zone of proximal development. **Zone of proximal development (ZPD)** is Vygotsky's term for the range of tasks that are too difficult for the child to master alone but can be learned with guidance and assistance from adults or more-skilled children. Thus, the lower limit of the ZPD is the level of skill reached by the child working independently. The upper limit is the level of additional responsibility the child can accept with the assistance of an able instructor (see Figure 8). The ZPD captures the child's cognitive skills that are in the process of maturing and can be accomplished only with the assistance of a more-skilled person (Clara, 2017; Holzman, 2017). Vygotsky (1962) called these the “buds” or “flowers” of development, to distinguish them from the “fruits” of development, which the child already can accomplish independently.

What are some factors that can influence the effectiveness of the ZPD in children's learning and development? Researchers have found that the following factors can enhance the ZPD's effectiveness (Gauvain & Perez, 2015): better emotion regulation, secure attachment, absence of maternal depression, and child compliance.

#### zone of proximal development (ZPD)

Vygotsky's term for tasks that are too difficult for children to master alone but can be mastered with the assistance of adults or more-skilled children.

together first? I'll try those green ones first. Now I need some blue ones. No, that blue one doesn't fit there. I'll try it over here."

Piaget maintained that self-talk is egocentric and reflects immaturity. However, researchers have found support for Vygotsky's view that private speech plays a positive role in children's development (Winsler, Carlton, & Barry, 2000).

**Teaching Strategies** Vygotsky's theory has been embraced by many teachers and has been successfully applied to education (Adams, 2015; Clara, 2017; Holzman, 2017). Here are some ways Vygotsky's theory can be incorporated in classrooms:

1. *Assess the child's ZPD.* Like Piaget, Vygotsky did not recommend formal, standardized tests as the best way to assess children's learning. Rather, Vygotsky argued that assessment should focus on determining the child's zone of proximal development. The skilled helper presents the child with tasks of varying difficulty to determine the best level at which to begin instruction.
2. *Use the child's ZPD in teaching.* Teaching should begin toward the zone's upper limit, so that the child can reach the goal with help and move to a higher level of skill and knowledge. Offer just enough assistance. You might ask, "What can I do to help you?" Or simply observe the child's intentions and attempts and provide support when it is needed. When the child hesitates, offer encouragement. And encourage the child to practice the skill. You may watch and appreciate the child's practice or offer support when the child forgets what to do.
3. *Use more-skilled peers as teachers.* Remember that it is not just adults who are important in helping children learn. Children also benefit from the support and guidance of more-skilled children.
4. *Place instruction in a meaningful context.* Educators today are moving away from abstract presentations of material; instead, they provide students with opportunities to experience learning in real-world settings. For example, rather than just memorizing math formulas, students work on math problems with real-world implications.
5. *Transform the classroom with Vygotskian ideas.* What does a Vygotskian classroom look like? The Kamehameha Elementary Education Program (KEEP) in Hawaii is based on Vygotsky's theory (Tharp, 1994). The ZPD is the key element of instruction in this program. Children might read a story and then interpret its meaning. Many of the learning activities take place in small groups. All children spend at least 20 minutes each morning in a setting called "Center One." In this context, scaffolding is used to improve children's literacy skills. The instructor asks questions, responds to students' queries, and builds on the ideas that students generate.

*Connecting Development to Life* further explores the implications of Vygotsky's theory for children's education.

**Evaluating Vygotsky's Theory** Even though their theories were proposed at about the same time, most of the world learned about Vygotsky's theory later than they learned about Piaget's theory. Thus, Vygotsky's theory has not yet been evaluated as thoroughly. However, Vygotsky's view of the importance of sociocultural influences on children's development fits with the current belief that it is important to evaluate the contextual factors in learning (Gauvain, 2016; Holzman, 2017).

We already have compared several aspects of Vygotsky's and Piaget's theories, such as Vygotsky's emphasis on the importance of inner speech in development and Piaget's view that such speech is immature. Although both theories are constructivist, Vygotsky's theory takes a **social constructivist approach**, which emphasizes the social contexts of learning and the construction of knowledge through social interaction (Gauvain, 2016; Holzman, 2017; Yu & Hu, 2017).

In moving from Piaget to Vygotsky, the conceptual shift is one from the individual to collaboration, social interaction, and sociocultural activity (Daniels, 2017). The endpoint of

Lev Vygotsky (1896–1934), shown here with his daughter, reasoned that children's cognitive development is advanced through social interaction with more-skilled individuals embedded in a sociocultural backdrop. *How is Vygotsky's theory different from Piaget's?*

**social constructivist approach** An approach that emphasizes the social contexts of learning and asserts that knowledge is mutually built and constructed. Vygotsky's theory reflects this approach.

## Tools of the Mind

Tools of the Mind is an early childhood education curriculum that emphasizes children's development of self-regulation and the cognitive foundations of literacy. The curriculum was created by Elena Bodrova and Deborah Leong (2007, 2015a, b) and has been implemented in more than 200 classrooms. Most of the children in the Tools of the Mind programs are at risk because of their living circumstances, which in many instances involve poverty and other difficult conditions such as being homeless and having parents with drug problems.

Tools of the Mind is grounded in Vygotsky's (1962) theory with special attention given to cultural tools, development of self-regulation, use of the zone of proximal development, scaffolding, private speech, shared activity, and play as important activity. In a Tools of the Mind classroom, dramatic play has a central role. Teachers guide children in creating themes that are based on the children's interests, such as treasure hunt, store, hospital, and restaurant. Teachers also incorporate field trips, visitor presentations, videos, and books in the development of children's play. They help children develop a play plan, which increases the maturity of their play. Play plans describe what the children expect to do in the play period, including the imaginary context, roles, and props to be used. The play plans increase the quality of their play and self-regulation.

Scaffolding writing is another important theme in the Tools of the Mind classroom. Teachers guide children in planning their own message

by drawing a line to stand for each word the child says. Children then repeat the message, pointing to each line as they say the word. Then, the child writes on the lines, trying to represent each word with some letters or symbols. Figure 9 shows how the scaffolding writing process improved a 5-year-old child's writing over the course of two months.

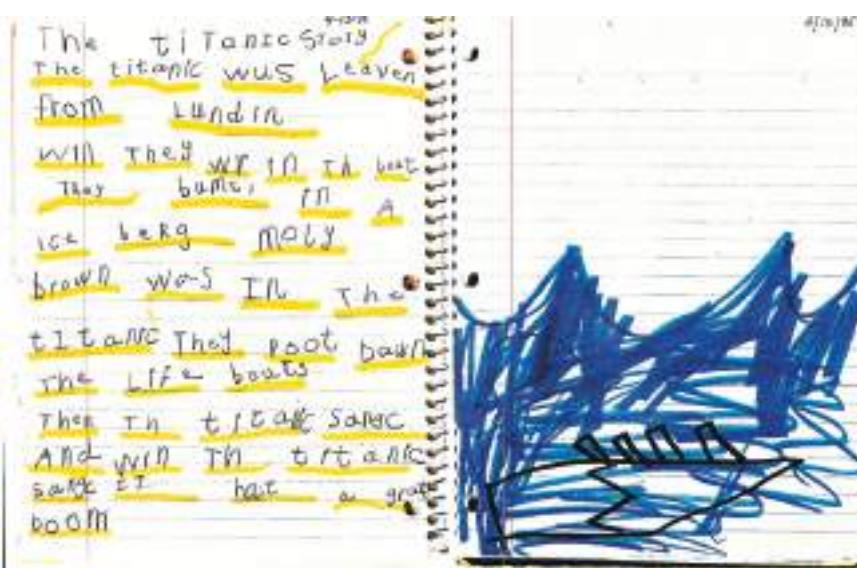

Research assessments of children's writing in Tools of the Mind classrooms revealed that they have more advanced writing skills than children in other early childhood programs (Bodrova & Leong, 2007) (see Figure 9). For example, they write more complex messages, use more words, spell more accurately, show better letter recognition, and have a better understanding of the concept of a sentence.

Also, the effectiveness of the Tools of the Mind approach was examined in 29 schools, 79 classrooms, and 759 schools (Blair & Raver, 2014). Positive effects of the Tools of the Mind program were found for the cognitive processes of executive function (improved self-regulation, for example) and attention control. Further, the Tools of the Mind program improved children's reading, vocabulary, and mathematics performance at the end of kindergarten and into the first grade. The most significant improvements occurred in high-poverty schools.

*How does the Reggio Emilia approach to education that you read about in the story that opened this chapter compare with the Tools of the Mind approach described here?*

		Vygotsky	Piaget
Sociocultural Context	Strong emphasis		Little emphasis
Constructivism	Social constructivist		Cognitive constructivist
Stages	No general stages of development proposed		Strong emphasis on stages (sensorimotor, preoperational, concrete operational, and formal operational)
Key Processes	Zone of proximal development, language, dialogue, tools of the culture		Schema, assimilation, accommodation, operations, conservation, classification
Role of Language	A major role; language plays a powerful role in shaping thought		Language has a minimal role; cognition primarily directs language
View on Education	Education plays a central role, helping children learn the tools of the culture		Education merely refines the child's cognitive skills that have already emerged
Teaching Implications	Teacher is a facilitator and guide, not a director; establish many opportunities for children to learn with the teacher and more-skilled peers		Also views teacher as a facilitator and guide, not a director; provide support for children to explore their world and discover knowledge

cognitive development for Piaget is formal operational thought. For Vygotsky, the endpoint can differ depending on which skills are considered to be the most important in a particular culture. In Piaget's theory, children construct knowledge by transforming, organizing, and reorganizing previous knowledge. From Vygotsky's perspective, children construct knowledge through social interaction. The implication of Piaget's theory for teaching is that children need support to explore their world and discover knowledge. The main implication of Vygotsky's theory for teaching is that students need many opportunities to learn with the teacher and more-skilled peers. In both Piaget's and Vygotsky's theories, teachers serve as facilitators and guides, rather than as directors and molders of learning. Figure 10 compares Vygotsky's and Piaget's theories. As indicated in Figure 10, among the factors that Vygotsky emphasized more than Piaget are the sociocultural context, education, and language.

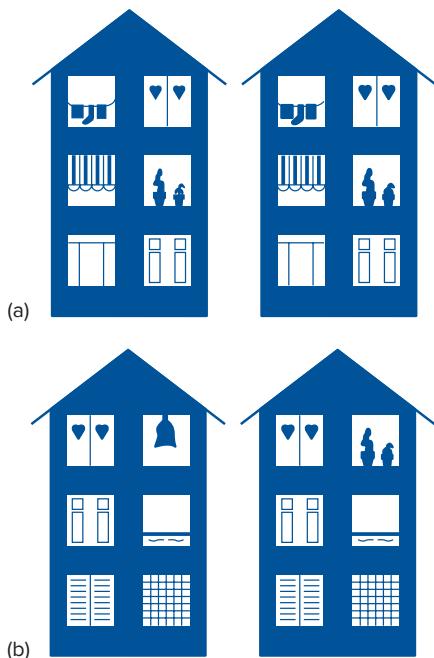

Criticisms of Vygotsky's theory also have surfaced. Some critics point out that Vygotsky was not specific enough about age-related changes. Another criticism is that Vygotsky did not adequately describe how changes in socioemotional capabilities contribute to cognitive development (Goncu & Gauvain, 2012). Yet another criticism is that he overemphasized the role of language in thinking. Also, his emphasis on collaboration and guidance has potential pitfalls. Might facilitators be too helpful in some cases, as when a parent becomes overbearing and controlling? Further, some children might become lazy and expect help when they could have done something on their own.

## INFORMATION PROCESSING

Piaget's and Vygotsky's theories provided important ideas about how young children think and how their thinking changes. More recently, the information-processing approach has generated research that illuminates how children process information during the preschool years (Siegler & Braithwaite, 2017). What are the limitations and advances in young children's ability to pay attention to the environment, to remember, to develop strategies and solve problems, and to understand their own mental processes and those of others?

What are some advances in children's attention in early childhood?

**FIGURE 11**

**THE PLANFULNESS OF ATTENTION.** In one study, children were given pairs of houses to examine, like the ones shown here (Vurpillot, 1968). For three pairs of houses, what was in the windows was identical (a). For the other three pairs, the windows had different items in them (b). By filming the reflection in the children's eyes, researchers could determine what they were looking at, how long they looked, and the sequence of their eye movements. Children under 6 examined only a fragmentary portion of each display and made their judgments on the basis of insufficient information. By contrast, older children scanned the windows in more detailed ways and were more accurate in their judgments of which windows were identical.

**executive attention** Involves action planning, allocating attention to goals, error detection and compensation, monitoring progress on tasks, and dealing with novel or difficult circumstances.

**sustained attention** Focused and extended engagement with an object, task, event, or other aspect of the environment.

**Attention** Recall that *attention* is defined as the focusing of mental resources on select information. The child's ability to pay attention improves significantly during the preschool years (Rothbart & Posner, 2015; Wu & Scerif, 2018). Toddlers wander around, shift attention from one activity to another, and seem to spend little time focusing on any one object or event. By comparison, the preschool child might be observed watching television for a half hour or longer.

Young children especially make advances in two aspects of attention—executive attention and sustained attention (Rothbart & Posner, 2015). **Executive attention** involves action planning, allocating attention to goals, error detection and compensation, monitoring progress on tasks, and dealing with novel or difficult circumstances (McClelland & others, 2017; Schmitt & others, 2017). **Sustained attention** is focused and extended engagement with an object, task, event, or other aspect of the environment. Sustained attention also is called *vigilance* (Benitez & others, 2017). Research indicates that although older children and adolescents show increases in vigilance, it is during the preschool years that individuals show the greatest increase in vigilance (Rothbart & Posner, 2015).

Mary Rothbart and Maria Gartstein (2008, p. 332) explained why advances in executive and sustained attention are so important in early childhood:

The development of the . . . executive attention system supports the rapid increases in effortful control in the toddler and preschool years. Increases in attention are due, in part, to advances in comprehension and language development. As children are better able to understand their environment, this increased appreciation of their surroundings helps them to sustain attention for longer periods of time.

In at least two ways, however, the preschool child's control of attention is still deficient:

- **Salient versus relevant dimensions.** Preschool children are likely to pay attention to stimuli that stand out, or are *salient*, even when those stimuli are not relevant to solving a problem or performing a task. For example, if a flashy, attractive clown presents the directions for solving a problem, preschool children are likely to pay more attention to the clown than to the directions. After the age of 6 or 7, children attend more efficiently to the dimensions of the task that are relevant, such as the directions for solving a problem. This change reflects a shift to cognitive control of attention, so that children behave less impulsively and reflect more.
- **Planfulness.** When experimenters ask children to judge whether two complex pictures are the same, preschool children tend to use a haphazard comparison strategy, not examining all of the details before making a judgment. By contrast, elementary-school-age children are more likely to systematically compare the details across the pictures, one detail at a time (Vurpillot, 1968) (see Figure 11).

In Central European countries such as Hungary, kindergarten children participate in exercises designed to improve their attention (Mills & Mills, 2000; Posner & Rothbart, 2007). For example, in one eye-contact exercise, the teacher sits in the center of a circle of children and each child is required to catch the teacher's eye before being permitted to leave the group. In other exercises created to improve attention, teachers have children participate in stop-go activities during which they have to listen for a specific signal, such as a drumbeat or an exact number of rhythmic beats, before stopping the activity.

Computer exercises recently have been developed to improve children's attention (Jaeggi, Berman, & Jonides, 2009; Rothbart & Posner, 2015). For example, one study revealed that five days of computer exercises that involved learning how to use a joystick, working memory, and conflict resolution skills improved the attention of 4- to 6-year-old children (Rueda, Posner, & Rothbart, 2005). Although not commercially available, further information about computer exercises for improving children's attention can be found at [www.teach-the-brain.org/learn/attention/index](http://www.teach-the-brain.org/learn/attention/index).

The ability of preschool children to control and sustain their attention is related to a number of positive academic outcomes. For example, a study of more than 1,000 children revealed that their ability to sustain their attention at 54 months of age was linked to their school readiness (which included achievement and language skills) (NICHD Early Child Care Research Network, 2005). In another study, the ability to focus attention better at age 5 was linked to a higher level of school achievement at age 9 (Razza, Martin, & Brooks-Gunn, 2012). Also, a recent study found that preschoolers' sustained attention was linked to a greater likelihood of completing college by 25 years of age (McClelland & others, 2013).

**Memory** Memory—the retention of information over time—is a central process in children’s cognitive development. Most of a young infant’s memories are fragile and, for the most part, short-lived—except for the memory of perceptual-motor actions, which can be substantial (Bauer, 2018). Thus, we saw that to understand the infant’s capacity to remember we need to distinguish *implicit memory* from *explicit memory*. Explicit memory itself, however, comes in many forms (Radavsky, 2018). One distinction occurs between relatively permanent or long-term memory and short-term memory.

**Short-Term Memory** In **short-term memory**, individuals retain information for up to 30 seconds if there is no rehearsal of the information. Using rehearsal (repeating information after it has been presented), we can keep information in short-term memory for a much longer period. One method of assessing short-term memory is the memory-span task. You hear a short list of stimuli—usually digits—presented at a rapid pace (one per second, for example). Then you are asked to repeat the digits.

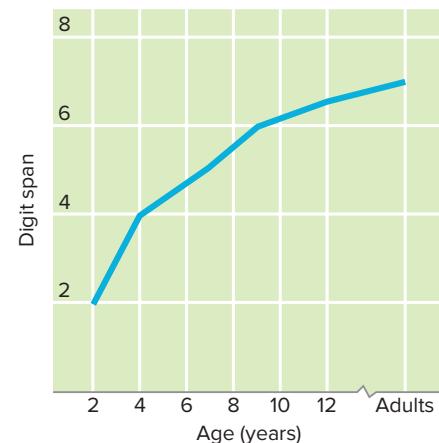

Research with the memory-span task suggests that short-term memory increases during early childhood. For example, in one investigation memory span increased from about 2 digits in 2- to 3-year-old children to about 5 digits in 7-year-old children, yet between 7 and 13 years of age memory span increased by only 2 more digits (Dempster, 1981) (see Figure 12). Keep in mind, though, that memory span varies from one individual to another.

Why does memory span change with age? Rehearsal of information is important; older children rehearse the digits more than younger children do. Speed—especially the speed with which memory items can be identified—and efficiency of processing information are important, too (Schneider, 2011).

The speed-of-processing explanation highlights a key point in the information-processing perspective: The speed with which a child processes information is an important aspect of the child’s cognitive abilities, and there is abundant evidence that the speed with which many cognitive tasks are completed improves dramatically across the childhood years (Rose, Feldman, & Jankowski, 2015). A recent study found that myelination (the process by which the sheath that encases axons helps electrical signals travel faster down the axon) in a number of brain areas was linked to young children’s processing speed (Chevalier & others, 2015).

**How Accurate Are Young Children’s Long-Term Memories?** While toddlers’ short-term memory span increases during the early childhood years, their memory also becomes more accurate. Young children can remember a great deal of information if they are given appropriate cues and prompts (Bruck & Ceci, 2012). Increasingly, young children are even being allowed to testify in court, especially if they are the sole witnesses to abuse, a crime, and so forth (Andrews, Ahern, & Lamb, 2017; Pantell & others, 2018). Several factors can influence the accuracy of a young child’s memory (Bruck & Ceci, 1999):

- *There are age differences in children’s susceptibility to suggestion.* Preschoolers are the most suggestible age group in comparison with older children and adults (Lehman & others, 2010). For example, preschool children are more susceptible to believing misleading or incorrect information given after an event (Ghetti & Alexander, 2004). Despite these differences among various age groups, there is still concern about the reaction of older children when they are subjected to suggestive interviews (Ahern, Kowalski, & Lamb, 2018; Peixoto & others, 2017).
- *There are individual differences in susceptibility.* Some preschoolers are highly resistant to interviewers’ suggestions, whereas others immediately succumb to the slightest suggestion (Ceci, Hritz, & Royer, 2016).
- *Interviewing techniques can produce substantial distortions in children’s reports about highly salient events.* Children are suggestible not just about peripheral details but also about the central aspects of an event (Cederborg & others, 2013). In some cases, children’s false reports can be tinged with sexual connotations. In laboratory studies, young children have made false claims about “silly events” that involved body contact (such as “Did the nurse lick your knee?” or “Did she blow in your ear?”). A significant number of preschool children have falsely reported that someone touched their private parts, kissed them, and hugged them, when these events clearly did not happen in the research. Nonetheless, young children are capable of recalling much that is relevant about an event (Lamb & others, 2015). Young children are more likely to accurately

**FIGURE 12**

### DEVELOPMENTAL CHANGES IN

**MEMORY SPAN.** In one study, from 2 years of age to 7 years of age children’s memory span increased from 2 digits to 5 digits (Dempster, 1981). Between 7 and 13 years of age, memory span had increased on average only another 2 digits, to 7 digits. *What factors might contribute to the increase in memory span during childhood?*

recall information about an event if the interviewer has a neutral tone, there is limited use of misleading questions, and there is no motivation for the child to make a false report (Principe, Greenhoot, & Ceci, 2014).

In sum, whether a young child's eyewitness testimony is accurate or not may depend on a number of factors such as the type, number, and intensity of the suggestive techniques the child has experienced (Lamb & others, 2015). It appears that the reliability of young children's reports has as much to do with the skills and motivation of the interviewer as with any natural limitations on young children's memory (Andrews & Lamb, 2018; Ceci, Hritz, & Royer, 2016).

**Autobiographical Memory** Another aspect of long-term memory that has been extensively studied in research on children's development is autobiographical memory (Bauer, 2018; Bauer & others, 2017).

*Autobiographical memory* involves memory of significant events and experiences in one's life. You are engaging in autobiographical memory when you answer questions such as: Who was your first-grade teacher and what was s/he like? What is the most traumatic event that happened to you as a child?

During the preschool years, young children's memories increasingly take on more autobiographical characteristics (Bauer, 2018; Bauer & Larkina, 2016). In some areas, such as remembering a story, a movie, a song, or an interesting event or experience, young children have been shown to have reasonably good memories. From 3 to 5 years of age, they (1) increasingly remember events as occurring at a specific time and location, such as "on my birthday at Chuck E. Cheese's last year" and (2) include more elements that are rich in detail in their narratives (Bauer, 2013). In one study, children went from including four descriptive items per event at 3½ years of age to 12 such items at 6 years of age (Fivush & Haden, 1997).

**Executive Function** Recently, increasing attention has been given to the development of children's **executive function**, an umbrella-like concept that consists of a number of higher-level cognitive processes linked to the development of the brain's prefrontal cortex (Bardikoff & Sabbagh, 2017; Knapp & Morton, 2017; McClelland & others, 2017; Perone, Almy, & Zelazo, 2017). Executive function involves managing one's thoughts to engage in goal-directed behavior and self-control (Hoskyn, Iarocci, & Young, 2017; Muller & others, 2017). Earlier in this chapter, we described the recent interest in *executive attention*, which comes under the umbrella of executive function.

In early childhood, executive function especially involves developmental advances in cognitive inhibition (such as inhibiting a strong tendency that is incorrect), cognitive flexibility (such as shifting attention to another item or topic), goal-setting (such as sharing a toy or mastering a skill like catching a ball), and delay of gratification (waiting longer to get a more attractive reward, for example) (Cheng & others, 2018; Groppe & Elsner, 2017; Semenov & Zelazo, 2017). During early childhood, the relatively stimulus-driven toddler is transformed into a child capable of flexible, goal-directed problem solving that characterizes executive function (Zelazo & Muller, 2011).

Researchers have found that advances in executive function during the preschool years are linked with math skills, language development, and school readiness (Blair, 2017; Hoskyn, Iarocci, & Young, 2017; Liu & others, 2018; Muller & others, 2017; Schmitt & others, 2017). A recent study revealed that executive function skills predicted mathematical gains in kindergarten (Fuhs & others, 2014). Another recent study of young children also revealed that executive function was associated with emergent literacy and vocabulary development (Becker & others, 2014). And a recent study found that young children who showed delayed development of executive function had a lower level of school readiness (Willoughby & others, 2017).

Walter Mischel and his colleagues (Berman & others, 2013; Mischel, 2014; Mischel, Cantor, & Feldman, 1996; Mischel & Moore, 1980; Mischel & others, 2011; Schlam & others, 2013; Zayas, Mischel, & Pandey, 2014) have conducted a number of studies involving delay of gratification among young children. One way they assess delay of gratification is to place a young child alone in a room with an alluring marshmallow that is within their reach. The children are told that they can either ring a bell at any time and eat the marshmallow or wait until the experimenter returns and then get two marshmallows. Among the young children who were able to wait for the experimenter to return, what did they do to help them wait? They engaged in a number of strategies to distract their attention from the marshmallows, including singing songs,

**executive function** An umbrella-like concept that consists of a number of higher-level cognitive processes linked to the development of the brain's prefrontal cortex. Executive function involves managing one's thoughts to engage in goal-directed behavior and to exercise self-control.

picking their noses, or doing other things to keep from looking at the marshmallows. Mischel and his colleagues labeled these strategies “cool thoughts” (that is, doing non-marshmallow-related thoughts and activities), whereas they said that young children who looked at the marshmallow were engaging in “hot thoughts.” The young children who engaged in cool thoughts were more likely to eat the marshmallow later or wait until the experimenter returned to the room.

In longitudinal research, Mischel and his colleagues have found that the preschool children who were able to delay gratification became more academically successful, had higher SAT scores and higher grade point averages at the end of college, and coped more effectively with stress as adolescents and emerging adults (Mischel, 2014). And as adults, they made more money in their career, were more law-abiding, were likely to have a lower body mass index, and were happier than individuals who were unable to delay gratification as preschoolers (Mischel, 2014; Moffitt, 2012; Moffitt & others, 2011; Schlam & others, 2013). Although the ability to delay gratification in preschool was linked to academic success and coping in adolescence and competence in adulthood, Mischel (2014) emphasizes that adolescents and adults can improve their ability to delay gratification.

What are some predictors of young children’s executive function? Parenting practices are linked to children’s development of executive function (Bernier & others, 2015; Cheng & others, 2018). For example, several studies have linked greater use of verbal scaffolding by parents (providing age-appropriate support during cognitive tasks) to children’s more advanced executive function (Bibok, Carpendale, & Muller, 2009; Hammond & others, 2012). A recent study revealed that secure attachment to mothers during the toddler years was linked to a higher level of executive function at 5 to 6 years of age (Bernier & others, 2015).

Other predictors of better executive function in children include higher socioeconomic status (Duncan, McClelland, & Acock, 2017); some aspects of language, including vocabulary size, verbal labeling, and bilingualism (Bell, Wolfe, & Adkins, 2007; Bialystok, 2010; Muller & others, 2008; Nesbitt, Farran, & Fuhs, 2015); imagination (generating novel ideas, for example) (White & Carlson, 2016); cultural background (Asian children, especially urban Chinese and Korean children, show better executive function than U.S. children) (Lan & others, 2011; Sabagh & others, 2006); and fewer sleep problems (Friedman & others, 2009).

Some developmental psychologists use their training in areas such as cognitive development to pursue careers in applied areas. To read about the work of Helen Hadani, an individual who has followed this path, see the *Connecting with Careers* profile.

**The Child’s Theory of Mind** Even young children are curious about the nature of the human mind (Birch & others, 2017; Devine & Hughes, 2018a, b; Oktay-Gur, Schultz, & Rakoczy, 2018; Wellman, 2011, 2015). They have a **theory of mind**, which refers to awareness of one’s own mental processes and the mental processes of others. Studies of theory of mind view the child as “a thinker who is trying to explain, predict, and understand people’s thoughts, feelings, and utterances” (Harris, 2006, p. 847).

**Developmental Changes** Children’s theory of mind changes as they develop through childhood (Wellman, 2015). Although whether infants have a theory of mind continues to be questioned by some (Rakoczy, 2012), the consensus is that some changes occur quite early in development, as we will see next (Scott & Baillargeon, 2017).

From 18 months to 3 years of age, children begin to understand three mental states:

- *Perceptions.* By 2 years of age, a child recognizes that another person will see what’s in front of her own eyes instead of what’s in front of the child’s eyes (Lempers, Flavell, & Flavell, 1977), and by 3 years of age, the child realizes that looking leads to knowing what’s inside a container (Pratt & Bryant, 1990).
- *Emotions.* The child can distinguish between positive (for example, happy) and negative (for example, sad) emotions. A child might say, “Tommy feels bad.”
- *Desires.* All humans have some sort of desires. But when do children begin to recognize that someone else’s desires may differ from their own? Toddlers recognize that if people want something, they will try to get it. For instance, a child might say, “I want my mommy.”

Two- to three-year-olds understand the way that desires are related to actions and to simple emotions. For example, they understand that people will search for what they want and that if they obtain it, they are likely to feel happy, but if they don’t, they will keep searching for it and are likely to feel sad or angry (Wellman & Woolley, 1990). ### Helen Hadani, Ph.D., Developmental Psychologist, Toy Designer, and Associate Director of Research for the Center for Childhood Creativity

Helen Hadani obtained a Ph.D. in developmental psychology from Stanford University. As a graduate student at Stanford, she worked part-time for Hasbro Toys and Apple testing children's software and other computer products for young children. Her first job after graduate school was with Zowie Entertainment, which was subsequently bought by LEGO. In her work as a toy designer there, Helen conducted experiments and focus groups at different stages of a toy's development, and she also studied the age-effectiveness of each toy. In Helen's words, "Even in a toy's most primitive stage of development . . . you see children's creativity in responding to challenges, their satisfaction when a problem is solved or simply their delight in having fun" (Schlegel, 2000, p. 50).

More recently, she began working with the Bay Area Discovery Museum's Center for Childhood Creativity (CCC) in Sausalito, California, an education-focused think tank that pioneers new research, thought-leadership, and teacher training programs that advance creative thinking in all children. Helen is currently the Associate Director of Research for the CCC.

Helen Hadani has worked as a toy designer and currently holds a museum position that involves thinking of ways to increase children's creative thinking.

**DEVELOPMENTAL CHANGES IN FALSE-BELIEF PERFORMANCE.** False-belief performance—the child's understanding that a person may have a false belief that contradicts reality—dramatically increases from 2½ years of age through the middle of the elementary school years. In a summary of the results of many studies, 2½-year-olds gave incorrect responses about 80 percent of the time (Wellman, Cross, & Watson, 2001). At 3 years, 8 months, they were correct about 50 percent of the time, and after that, they gave increasingly correct responses.

desires earlier and more frequently than they refer to cognitive states such as thinking and knowing (Bartsch & Wellman, 1995; Wellman, 2015).

One of the landmark developments in understanding others' desires is recognizing that someone else may have different desires from one's own (Doherty, 2008; Wellman, 2015). Eighteen-month-olds understand that their own food preferences may not match the preferences of others—they will give an adult the food to which she says "Yummy!" even if the food is something that the infants detest (Repacholi & Gopnik, 1997). As they get older, they can verbalize that they themselves do not like something but an adult might (Flavell & others, 1992).

Between the ages of 3 and 5, children come to understand that the mind can represent objects and events accurately or inaccurately (Rhodes & Brandone, 2014; Tompkins & others, 2017). The realization that people can have *false beliefs*—beliefs that are not true—develops in a majority of children by the time they are 5 years old (Wellman, Cross, & Watson, 2001) (see Figure 13). This point is often described as a pivotal one in understanding the mind—recognizing that beliefs are not just mapped directly into the mind from the surrounding world, but that different people can also have different, and sometimes incorrect, beliefs (Gelman, 2009). In a classic false-belief task, young children were shown a Band-Aids box and asked what was inside (Jenkins & Astington, 1996). To the children's surprise, the box actually contained pencils. When asked what a child who had never seen the box would think was inside, 3-year-olds typically responded, "Pencils." However, the 4- and 5-year-olds, grinning in anticipation of the false beliefs of other children who had not seen what was inside the box, were more likely to say "Band-Aids."

In a similar task, children are told a story about Sally and Anne: Sally places a toy in a basket and then leaves the room (see Figure 14). In her absence, Anne takes the toy from the basket and places it in a box. Children are asked where Sally will look for the toy when she returns. The major finding is that 3-year-olds tend to fail false-belief tasks, saying that Sally will look in the box (even though Sally could not have known that the toy had moved to this new location). Four-year-olds and older children tend to perform the task correctly, saying that Sally will have a "false belief"—she will think the object is in the basket, even though that belief is now false. The conclusion from these studies is that children younger than 4 years old do not understand that it is possible to have a false belief.

It is only beyond the preschool years—at approximately 5 to 7 years of age—that children have a deepening appreciation of the mind itself rather than just an understanding of mental

states (Lagattuta & others, 2015). For example, they begin to recognize that people's behaviors do not necessarily reflect their thoughts and feelings (Flavell, Green, & Flavell, 1993). Not until middle and late childhood do children see the mind as an active constructor of knowledge or a processing center (Flavell, Green, & Flavell, 1998) and move from understanding that beliefs can be false to realizing that the same event can be open to multiple interpretations (Carpendale & Chandler, 1996). For example, in one study, children saw an ambiguous line drawing (for example, a drawing that could be seen as either a duck or a rabbit); one puppet told the child she believed the drawing was a duck while another puppet told the child he believed the drawing was a rabbit (see Figure 15). Before the age of 7, children said that there was one right answer and that it was not okay for the two puppets to have different opinions.

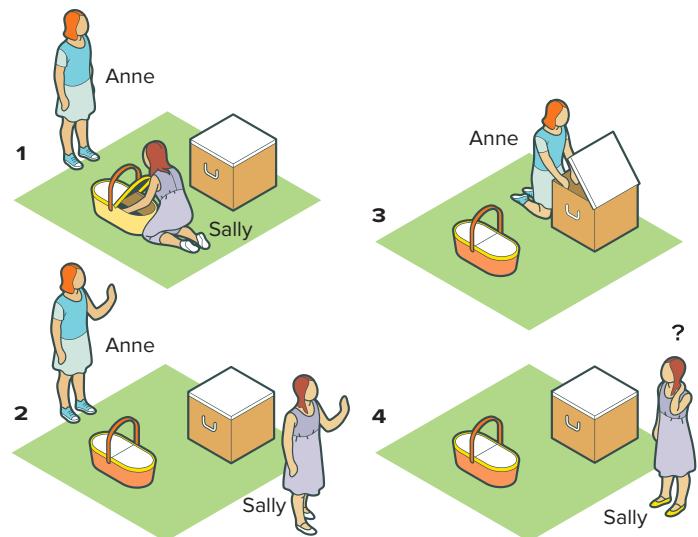

Although most research on children's theory of mind focuses on children around or before their preschool years, at 7 years of age and beyond there are important developments in the ability to understand the beliefs and thoughts of others (Apperly, 2012; Miller, 2012). Although it is important to understand that people may have different interpretations, it is also necessary to recognize that some interpretations and beliefs may be evaluated on the basis of the merits of arguments and evidence (Kuhn, Cheney, & Weinstock, 2000). In early adolescence, children begin to understand that people can have ambivalent feelings (Flavell & Miller, 1998). They start to recognize that the same person can feel both happy and sad about the same event. They also engage in more recursive thinking: thinking about what other people are thinking about.

**Individual Differences and Factors that Influence Theory of Mind** As in other developmental research, there are individual differences in the ages when children reach certain milestones in their theory of mind (Birch & others, 2017; Devine & Hughes, 2017). For example, *executive function*, which describes several functions discussed earlier in this chapter, such as planning and inhibition, that are important for flexible, future-oriented behavior, also is connected to theory of mind development (Benson & Sabbagh, 2017). Children who perform better at such executive function tasks show a better understanding of theory of mind (Benson & Sabbagh, 2017). For example, in one study of 3- to 5-year-old children, earlier development of executive function predicted theory of mind performance, especially on false belief tasks (Doenyas, Yavuz, & Selcuk, 2018).

Language development also likely plays a prominent role in the increasingly reflective nature of theory of mind as children go through the early childhood and middle and late childhood years (Meins & others, 2013). Researchers have found that differences in children's language skills predict performance on theory of mind tasks (Hughes & Devine, 2015).

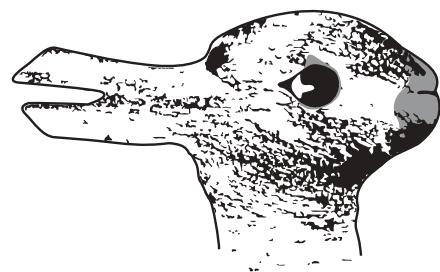

Among other factors that influence children's theory of mind development are advances in prefrontal cortex functioning (Powers, Chavez, & Heatherton, 2016), engaging in make-believe play (Kavanaugh, 2006), and various aspects of social interaction (Hughes, Devine, & Wang, 2017). Among the social interaction factors that advance children's theory of mind are being securely attached to parents who engage children in mental state talk ("That's a good thought you have" or "Can you tell what he's thinking?") (Laranjo & others, 2010), having older siblings and friends who engage in mental state talk (Hughes & others, 2010), and living in a higher socioeconomic status family (Devine & Hughes, 2018a). A recent study also found that parental mental state talk advanced preschool children's theory of mind (Devine & Hughes, 2018b). Further, researchers have found that children who have an advanced theory of mind are more popular with their peers and have better social skills in peer relations (Peterson & others, 2016; Slaughter & others, 2014).

Another individual difference in understanding the mind involves autism (Fletcher-Watson & others, 2014; Jones & others, 2018). Researchers have found that children with autism have difficulty developing a theory of mind, especially in relation to understanding others' beliefs and emotions (Berenguer & others, 2018; Garon, Smith, & Bryson, 2018). A recent study found that theory of mind predicted the severity of autism in children (Hoogenhout & Malcolm-Smith, 2017). Thus, it is not surprising that autistic children have difficulty in interactions with others.

**FIGURE 14**

**THE SALLY AND ANNE FALSE-BELIEF TASK.** In the false-belief task, the skit above in which Sally has a basket and Anne has a box is shown to children. Sally places a toy in her basket and then leaves. While Sally is gone and can't watch, Anne removes the toy from Sally's basket and places it in her box. Sally then comes back and the children are asked where they think Sally will look for her toy. Children are said to "pass" the false-belief task if they understand that Sally looks in her basket first before realizing the toy isn't there.

Toddlers move rather quickly from producing two-word utterances to creating three-, four-, and five-word combinations. Between 2 and 3 years of age, they begin the transition from saying simple sentences that express a single proposition to saying complex sentences.

As young children learn the special features of their own language, there are extensive regularities in how they acquire that particular language (Clark, 2017; Litz, Snyder, & Pater, 2017). For example, all children learn the prepositions *on* and *in* before other prepositions. Children learning other languages, such as Russian or Chinese, also acquire the particular features of those languages in a consistent order.

## UNDERSTANDING PHONOLOGY AND MORPHOLOGY

During the preschool years, most children gradually become more sensitive to the sounds of spoken words and become increasingly capable of producing all the sounds of their language (Goad, 2017; Kelly & others, 2018). By the time children are 3 years of age, they can produce all the vowel sounds and most of the consonant sounds (Menn & Stoel-Gammon, 2009). They recognize the sounds in word combinations such as “Merry go round” before they can produce them.

As children move beyond two-word utterances, they demonstrate a knowledge of morphology rules (Clark, 2017; Snyder, 2017). Children begin using the plural and possessive forms of nouns (such as *dogs* and *dog's*). They put appropriate endings on verbs (such as *-s* when the subject is third-person singular and *-ed* for the past tense). They use prepositions (such as *in* and *on*), articles (such as *a* and *the*), and various forms of the verb *to be* (such as “I was going to the store”). Some of the best evidence for changes in children’s use of morphological rules occurs in their overgeneralization of the rules, as when a preschool child says “foots” instead of “feet,” or “goed” instead of “went.”

In a classic experiment that was designed to study children’s knowledge of morphological rules, such as how to make a plural, Jean Berko (1958) presented preschool children and first-grade children with cards such as the one shown in Figure 16. Children were asked to look at the card while the experimenter read aloud the words on the card. Then the children were asked to supply the missing word. This task might sound easy, but Berko was interested in the children’s ability to apply the appropriate morphological rule—in this case to say “wugs” with the *z* sound that indicates the plural.

Although the children’s answers were not perfect, they were much better than chance. What makes Berko’s study impressive is that most of the words were made up for the

experiment. Thus, the children could not base their responses on remembering past instances of hearing the words. That they could make the plurals or past tenses of words they had never heard before was proof that they knew the morphological rules.

## CHANGES IN SYNTAX AND SEMANTICS

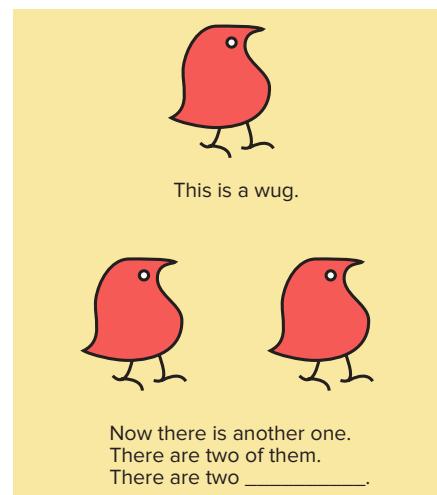

Preschool children also learn and apply rules of syntax (Clark, 2017; Tieu & others, 2018). They show a growing mastery of complex rules for how words should be ordered (Fletcher & Frizelle, 2017; Kyrtzis, 2017; Thornton, 2017). Consider *wh*- questions, such as “Where is Daddy going?” or “What is that boy doing?” To ask these questions properly, the child must know two important differences between *wh*-questions and affirmative statements (for instance, “Daddy is going to work” and “That boy is waiting for the school bus”). First, a *wh*-word must be added at the beginning of the sentence. Second, the auxiliary verb must be inverted—that is, exchanged with the subject of the sentence. Young children learn quite early where to put the *wh*-word, but they take much longer to learn the auxiliary-inversion rule. Thus, preschool children might ask, “Where Daddy is going?” and “What that boy is doing?”

Gains in semantics also characterize early childhood. Vocabulary development is dramatic (Thornton, 2017). Some experts have concluded that between 18 months and 6 years of age, young children learn approximately one new word every waking hour (Gelman & Kalish, 2006). By the time they enter first grade, it is estimated that children know about 14,000 words (Clark, 1993).

Why can children learn so many new words so quickly? One possibility is **fast mapping**, which involves children’s ability to make an initial connection between a word and its referent after only limited exposure to the word (McGregor, 2017; van Hout, 2017). Researchers have found that exposure to words on multiple occasions over several days results in more successful word learning than the same number of exposures in a single day (Childers & Tomasello, 2002). Recent research using eye-tracking found that even 15-month-old infants fast map words (Puccini & Liszkowski, 2012). Also, fast mapping promotes deeper understanding of word meaning, such as learning where the word can apply and its nuances.

What are some important aspects of how word learning optimally occurs? Following are six key principles in young children’s vocabulary development (Harris, Golinkoff, & Hirsh-Pasek, 2011):

1. *Children learn the words they hear most often.* They learn the words that they encounter when interacting with parents, teachers, siblings, and peers, as well as words that they hear when books are read aloud to them. They especially benefit from encountering words that they do not know.
2. *Children learn words for things and events that interest them.* Parents and teachers can direct young children to experience words in contexts that interest the children; playful peer interactions are especially helpful in this regard.
3. *Children learn words better in responsive and interactive contexts than in passive contexts.* Children who experience turn-taking opportunities, joint focusing experiences, and positive, sensitive socializing contexts with adults encounter the scaffolding necessary for optimal word learning. They learn words less effectively when they are passive learners.
4. *Children learn words best in contexts that are meaningful.* Young children learn new words more effectively when new words are encountered in integrated contexts rather than as isolated facts.
5. *Children learn words best when they access clear information about word meaning.* Children whose parents and teachers are sensitive to words the children might not understand and provide support and elaboration with hints about word meaning learn words better than those whose parents and teachers quickly state a new word and don’t monitor whether children understand its meaning.
6. *Children learn words best when grammar and vocabulary are considered.* Children who experience a large number of words and diversity in verbal stimulation develop a richer vocabulary and better understanding of grammar. In many cases, vocabulary and grammar development are connected.

### STIMULI IN BERKO'S STUDY OF YOUNG CHILDREN'S UNDERSTANDING OF MORPHOLOGICAL RULES.

In Jean Berko's (1958) study, young children were presented cards, such as this one with a “wug” on it. Then the children were asked to supply the missing word; in supplying the missing word, they had to say it correctly, too. “Wugs” is the correct response here.

## ADVANCES IN PRAGMATICS

Changes in pragmatics, the appropriate use of language in different contexts, also characterize young children's language development (Fujiki & Brinton, 2017). A 6-year-old is simply a much better conversationalist than a 2-year-old is. What are some of the improvements in pragmatics during the preschool years?

Young children begin to engage in extended discourse (Akhtar & Herold, 2008). For example, they learn culturally specific rules of conversation and politeness and become sensitive to the need to adapt their speech in different settings. Their developing linguistic skills and increasing ability to take the perspective of others contribute to their generation of more competent narratives.

As children get older, they become increasingly able to talk about things that are not here (Grandma's house, for example) and not now (what happened to them yesterday or might happen tomorrow, for example). A preschool child can tell you what she wants for lunch tomorrow, something that would not have been possible at the two-word stage of language development.

Around 4 to 5 years of age, children learn to change their speech style to suit the situation. For example, even 4-year-old children speak to a 2-year-old differently from the way they speak to a same-aged peer; they use shorter sentences with the 2-year-old. They also speak differently to an adult and to a same-aged peer, using more polite and formal language with the adult (Shatz & Gelman, 1973).

## YOUNG CHILDREN'S LITERACY

Concern about the ability of U.S. children to read and write has led to a careful examination of preschool and kindergarten children's experiences, with the hope that a positive orientation toward reading and writing can be developed early in life (Temple & others, 2018; Tompkins, 2017, 2019). Parents and teachers need to provide young children with a supportive environment for developing literacy skills (Tompkins, 2017, 2019). Children should be active participants and be immersed in a wide range of interesting situations involving listening, talking, writing, and reading (Reutzel & Cooter, 2019; Vukelich & others, 2016). One study revealed that children whose mothers had more education acquired more advanced emergent literacy levels than children whose mothers had less education (Korat, 2009). Another study found that literacy experiences (such as how often the child was read to), the quality of the mother's engagement with her child (such as attempts to cognitively stimulate the child), and provision of learning materials (such as age-appropriate books) were important home literacy experiences in low-income families that were linked to the children's language development in positive ways (Rodriguez & others, 2009). Instruction should be built on what children already know about oral language, reading, and writing. Further, early precursors of literacy and academic success include language skills, phonological and syntactic knowledge, letter identification, and conceptual knowledge about print and its conventions and functions (Jalongo, 2014). Also, a recent study found that 60 minutes of physical activity per day in preschool academic contexts improved early literacy (Kirk & Kirk, 2016).

Books can be valuable in enhancing children's communication skills (Reutzel & Cooter, 2019; Temple & others, 2018). What are some strategies for using books effectively with preschool children? Ellen Galinsky (2010) suggests the following strategies:

- *Use books to initiate conversation with young children.* Ask them to put themselves in the book characters' places and imagine what they might be thinking or feeling.
- *Use what and why questions.* Ask young children what they think is going to happen next in a story and then to see if it occurs.
- *Encourage children to ask questions about stories.*
- *Choose some books that play with language.* Creative books on the alphabet, including those with rhymes, often interest young children.

## 4 Early Childhood Education

**LG4**

Evaluate different approaches to early childhood education.

Variations in Early Childhood Education

Education for Young Children Who Are Disadvantaged

Controversies in Early Childhood Education

To the teachers in a Reggio Emilia program (described in the chapter opening), preschool children are active learners who are engaged in exploring the world with their peers, constructing their knowledge of the world in collaboration with their community, and aided but not directed by their teachers. In many ways, the Reggio Emilia approach applies ideas consistent with the views of Piaget and Vygotsky that were discussed earlier in this chapter. Our exploration of early childhood education focuses on variations in programs, education for young children who are disadvantaged, and some controversies in early childhood education.

### VARIATIONS IN EARLY CHILDHOOD EDUCATION

Attending preschool is rapidly becoming the norm for U.S. children. There are many variations in the way young children are educated (Bredekamp, 2017; Feeney, Moravcik, & Nolte, 2019; Henniger, 2017). The foundation of early childhood education has been the child-centered kindergarten.

**The Child-Centered Kindergarten** Nurturing is a key aspect of the **child-centered kindergarten**, which emphasizes the education of the whole child and concern for his or her physical, cognitive, and socioemotional development (Gordon, Williams, & Brown, 2017; Morrison, 2017, 2018). Instruction is organized around the child's needs, interests, and learning styles. Emphasis is on the process of learning, rather than what is learned (Follari, 2019; Gestwicki, 2017). The child-centered kindergarten honors three principles: (1) each child follows a unique developmental pattern; (2) young children learn best through firsthand experiences with people and materials; and (3) play is extremely important in the child's total development. *Experimenting, exploring, discovering, trying out, restructuring, speaking, and listening* are frequent activities in excellent kindergarten programs. Such programs are closely attuned to the developmental status of 4- and 5-year-old children.

**The Montessori Approach** Montessori schools are patterned after the educational philosophy of Maria Montessori (1870–1952), an Italian physician-turned-educator who at the beginning of the twentieth century crafted a revolutionary approach to young children's education. The **Montessori approach** is a philosophy of education in which children are given considerable freedom and spontaneity in choosing activities. They are allowed to move from one activity to another as they desire. The teacher acts as a facilitator rather than a director. The

**child-centered kindergarten** Education that involves the whole child by considering both the child's physical, cognitive, and socioemotional development and the child's needs, interests, and learning styles.

**Montessori approach** An educational philosophy in which children are given considerable freedom and spontaneity in choosing activities and are allowed to move from one activity to another as they desire.

Larry Page and Sergey Brin, founders of the highly successful Internet search engine Google, said that their early years at Montessori schools were a major factor in their success (International Montessori Council, 2006). During an interview with Barbara Walters, they said they learned how to be self-directed and self-starters at Montessori (ABC News, 2005). Montessori experiences encouraged them to think for themselves and allowed them the freedom to develop their own interests.

teacher shows the child how to perform intellectual activities, demonstrates interesting ways to explore curriculum materials, and offers help when the child requests it (Bahmaee, Saadatmand, & Yarmohammadian, 2016). “By encouraging children to make decisions from an early age, Montessori programs seek to develop self-regulated problem solvers who can make choices and manage their time effectively” (Hyson, Copple, & Jones, 2006, p. 14). The number of Montessori schools in the United States has expanded dramatically in recent years, from 1 school in 1959 to 355 schools in 1970 and more than 4,000 today. A recent study found that Latino children in low-income communities who began the school year having at-risk pre-academic and behavioral skills benefited from a Montessori public school pre-K program, ending the year scoring above national averages for school readiness (Ansari & Winsler, 2014).

Some developmentalists favor the Montessori approach, but others believe that it neglects children’s socioemotional development. For example, although Montessori fosters independence and the development of cognitive skills, it deemphasizes verbal interaction between the teacher and child and between peers. Montessori’s critics also argue that it restricts imaginative play and that its heavy reliance on self-corrective materials may not adequately allow for creativity and for a variety of learning styles.

**Developmentally Appropriate and Inappropriate Education** Many educators and psychologists conclude that preschool and young elementary school children learn best through active, hands-on teaching methods such as games and dramatic play. They know that children develop at varying rates and that schools need to allow for these individual differences (Gestwicki, 2017; Follari, 2019). They also argue that schools should focus on supporting children’s socioemotional development as well as their cognitive development. Educators refer to this type of schooling as **developmentally appropriate practice (DAP)**, which is based on knowledge of the typical development of children within an age span (age-appropriateness), as well as the uniqueness of the child (individual-appropriateness). DAP emphasizes the importance of creating settings that encourage active learning and reflect children’s interests and capabilities (Beaver, Wyatt, & Jackman, 2018; Bredekamp, 2017; Feeney, Moravcik, & Nolte, 2019). Desired outcomes for DAP include thinking critically, working cooperatively, solving problems, developing self-regulatory skills, and enjoying learning. The emphasis in DAP is on the process of learning rather than its content (Bredekamp, 2017).

Do developmentally appropriate educational practices improve young children’s development? Some researchers have found that young children in developmentally appropriate classrooms are likely to have less stress, be more motivated, be more skilled socially, have better work habits, be more creative, have better language skills, and demonstrate better math skills than children in developmentally inappropriate classrooms (Hart & others, 2003). However, not all studies show significant positive benefits for developmentally appropriate education (Hyson, Copple, & Jones, 2006). Among the reasons it is difficult to generalize about research on developmentally appropriate education is that individual programs often vary, and developmentally appropriate education is an evolving concept. Recent changes in the concept have given more attention to sociocultural factors, to the teacher’s active involvement and implementation of systematic intentions, and to the degree to which academic skills should be emphasized and how they should be taught.

**Project Head Start** A government-funded program that is designed to provide children from low-income families with the opportunity to acquire the skills and experiences important for school success.

## EDUCATION FOR YOUNG CHILDREN WHO ARE DISADVANTAGED

For many years, U.S. children from low-income families did not receive any education before they entered first grade. Often, they began first grade already several steps behind their classmates in their readiness to learn. In the summer of 1965, the federal government began an effort to break the cycle of poverty and substandard education for young children in the United States through **Project Head Start**. It is a compensatory program designed to provide children from low-income families the opportunity to acquire the skills and experiences important for success in school (Hustedt, Friedman, & Barnett, 2012; Miller, Farkas, & Duncan, 2016; Paschall & Mastgeorge, 2018). After almost half a century, Head Start continues to be the largest federally funded program for U.S. children, with almost 1 million U.S. children enrolled annually (Hagen & Lamb-Parker, 2008). In 2007, 3 percent of Head Start children were 5 years old, 51 percent were 4 years old, 36 percent were 3 years old, and 10 percent were under 3 years of age (Administration for Children & Families, 2008).

### **Yolanda Garcia, Head Start Director and College Dean**

Yolanda Garcia is the Director of WestEd's E3 Institute—Excellence in Early Education, a project for the Center for Child and Family Studies. She previously directed the Children's Services Department, Santa Clara County Office of Education. Her training includes two master's degrees, one in public policy and child welfare from the University of Chicago and another in education administration from San Jose State University.

Garcia has served on many national advisory committees that have resulted in

improvements in the staffing of Head Start programs. Most notably, she served on the Head Start Quality Committee that recommended the development of Early Head Start and revised performance standards for Head Start programs.

Yolanda went on to obtain a doctorate from the University of San Francisco in 2011 in Leadership and Organizational Development. Currently, she is Dean of Child Development and Teacher Education for the Sonoma County College District in northern California.

*Early Head Start* was established in 1995 to serve children from birth to 3 years of age. In 2007, half of all new funds appropriated for Head Start programs were used for the expansion of Early Head Start (Burgette & others, 2017). Researchers have found positive effects for Early Head Start (Hoffman & Ewen, 2007). A recent study revealed that Early Head Start had a protective effect on risks young children might experience related to parenting stress, language development, and self-control (Ayoub, Vallotton, & Mastergeorge, 2011). Another recent study revealed language benefits for Early Head Start children (Love & others, 2013).

Head Start programs are not all created equal. One estimate is that 40 percent of the 1,400 Head Start programs are of questionable quality (Zigler & Styfco, 1994). More attention needs to be given to developing consistently high-quality Head Start programs (Hillemeier & others, 2013). One individual who is strongly motivated to make Head Start a valuable learning experience for young children from disadvantaged backgrounds is Yolanda Garcia. To read about her work, see *Connecting with Careers*.

Evaluations support the positive influence of quality early childhood programs on both the cognitive and social worlds of disadvantaged young children (Bierman & others, 2014; Chor, 2018; McCoy & others, 2016). A national evaluation of Head Start revealed that the program had a positive influence on the language and cognitive development of 3- and 4-year-olds (Puma & others, 2010). However, by the end of the first grade, there were few lasting outcomes. One exception was a larger vocabulary for those who went to Head Start as 4-year-olds and better oral comprehension for those who went to Head Start as 3-year-olds. And two recent studies found that improved parenting engagement and skills were linked to the success of children in Head Start programs (Ansari & Gershoff, 2016; Roggman & others, 2016).

One-fourth of Head Start children have mothers who also participated in Head Start. In a multigenerational study, a positive influence on cognitive and socioemotional development (assessed in the third grade) occurred for Head Start children whose mothers had also attended Head Start programs (when compared with Head Start children whose mothers were not in Head Start) (Chor, 2018). This result likely occurred because of improved family resources and home learning environments.

One high-quality early childhood education program (although not a Head Start program) is the Perry Preschool program in Ypsilanti, Michigan, a two-year preschool program that includes weekly home visits from program personnel. In analyses of the long-term effects of the program, adults who had been in the Perry Preschool program were compared with a control group of adults from the same background who had not received the enriched early childhood education (Schweinhart & others, 2005; Weikert, 1993). Those who had been in the Perry Preschool program had fewer teen pregnancies and higher rates of high school graduation, and at age 40 the former preschool students were more likely to be employed, own a home, and have a savings account, and less likely to have been arrested than adults in the control group.

What is the curriculum controversy in early childhood education?

©Ronnie Kaufman/Corbis/Getty Images

## CONTROVERSIES IN EARLY CHILDHOOD EDUCATION

Two current controversies in early childhood education involve (1) what the curriculum for early childhood education should be and (2) whether preschool education should be universal in the United States.

**Curriculum Controversy** A current controversy in early childhood education involves what the curriculum for early childhood education should be (Bredekamp, 2017; Follari, 2019; Gordon, Williams, & Browne, 2017; Morrison, 2018). On one side are those who advocate a child-centered, constructivist approach much like that emphasized by the National Association for the Education of Young Children (NAEYC), along the lines of developmentally appropriate practice. On the other side are those who advocate an academic, direct-instruction approach.

In reality, many high-quality early childhood education programs include both academic and constructivist approaches. Many education experts like Lilian Katz (1999), though, worry about academic approaches that place too much pressure on young children to achieve and don't provide any opportunities to actively construct knowledge. Competent early childhood programs also should focus on cognitive development and socioemotional development, not exclusively on cognitive development (Feeney, Moravcik, & Nolte, 2019; Follari, 2019; Gestwicki, 2017).

**Universal Preschool Education** Another early childhood education controversy focuses on whether preschool education should be instituted for all U.S. 4-year-old children. Publicly funded preschool programs now are present in 42 states and the District of Columbia (National Institute for Early Education Research, 2016).

Edward Zigler and his colleagues (2011) have argued that the United States should have universal preschool education. They emphasize that quality preschools prepare children for school readiness and academic success. Zigler and his colleagues (2006) cite research that shows quality preschool programs decrease the likelihood that once children go to elementary and secondary school they will be retained in a grade or drop out of school. They also point to analyses indicating that universal preschool would bring cost savings on the order of billions of dollars because of a diminished need for remedial and justice services (Karoly & Bigelow, 2005).

Critics of universal preschool education argue that the gains attributed to preschool and kindergarten education are often overstated. They especially stress that research has not proven that nondisadvantaged children benefit from attending a preschool. Thus, the critics say it is more important to improve preschool education for young children who are disadvantaged than to fund preschool education for all 4-year-old children. Some critics, especially home-schooling advocates, emphasize that young children should be educated by their parents, not by schools. Thus, controversy continues to surround questions about whether universal preschool education should be implemented.

In the next chapter, you will read about the many advances that take place during the socioemotional development of young children. The cognitive advances we discussed in this chapter, combined with the socioemotional experiences young children have in interacting with others, pave the way for social cognitive advances in understanding the self and others. Next, you will read about the continuing changes in children's physical and cognitive development in middle and late childhood. In terms of physical development, their motor skills become smoother and more coordinated. The development of their brain—especially the prefrontal cortex—provides the foundation for a number of cognitive advances, including the development of learning strategies and reading skills.

### 1 Physical Changes

Body Growth and Change

Motor and Perceptual Development

Sleep

Nutrition and Exercise

Illness and Death

**LG1** Identify physical changes in early childhood.

- The average child grows 2½ inches in height and gains 5 to 10 pounds a year during early childhood. Growth patterns vary individually, though. Some of the brain's interior changes in early childhood are due to myelination. From 3 to 6 years of age, the most rapid growth in the brain occurs in the frontal lobes.
- Gross motor skills increase dramatically during early childhood. Children become increasingly adventuresome as their gross motor skills improve. Fine motor skills also improve substantially during early childhood. Young children also make advances in perceptual development.
- Experts recommend that young children get 11 to 13 hours of sleep each night. Most young children sleep through the night and have one daytime nap. Helping the young child slow down before bedtime often leads to less resistance in going to bed. Sleep problems in young children are linked to other problems, such as being overweight and being depressed. Disruptions in sleep in early childhood are related to less optimal adjustment in preschool.
- Too many young children in the United States are being raised on diets that are too high in fat. The child's life should be centered on activities, not meals. Other nutritional concerns include malnutrition in early childhood and the inadequate diets of many children living in poverty. Young children are not getting as much exercise as they need.
- In recent decades, vaccines have virtually eradicated many diseases that once resulted in the deaths of many young children. The disorders still most likely to be fatal for young children in the United States are cancer and cardiovascular disease, but accidents are the leading cause of death in young children. A special concern is the poor health status of many young children in low-income families. There has been a dramatic increase in HIV/AIDS in young children in developing countries in the last decade.

### 2 Cognitive Changes

Piaget's Preoperational Stage

**LG2** Describe three views of the cognitive changes that occur in early childhood.

- According to Piaget, in the preoperational stage children cannot yet perform operations, which are reversible mental actions, but they begin to represent the world with symbols, to form stable concepts, and to reason. During the symbolic function substage, which occurs

between about 2 and 4 years of age, children begin to mentally represent an object that is not present, but their thought is limited by egocentrism and animism. During the intuitive thought substage, which stretches from about 4 to 7 years of age, children begin to reason and to bombard adults with questions. Thought at this substage is called intuitive because children seem so sure about their knowledge yet are unaware of how they know what they know. Centration and a lack of conservation also characterize the preoperational stage.

#### Vygotsky's Theory

- Vygotsky's theory represents a social constructivist approach to development. According to Vygotsky, children construct knowledge through social interaction, and they use language not only to communicate with others but also to plan, guide, and monitor their own behavior and to help them solve problems. His theory suggests that adults should assess and use the child's zone of proximal development (ZPD), which is the range of tasks that are too difficult for children to master alone but that can be learned with the guidance and assistance of adults or more-skilled children. The theory also suggests that adults and peers should teach through scaffolding, which involves changing the level of support over the course of a teaching session, with the more-skilled person adjusting guidance to fit the student's current performance level.
- The child's ability to attend to stimuli dramatically improves during early childhood. Advances in executive attention and sustained attention are especially important in early childhood, but young children still attend to the salient rather than the relevant features of a task.
- Significant improvement in short-term memory occurs during early childhood. With good prompts, young children's long-term memories can be accurate, although young children can be led into developing false memories.
- Advances in executive function, an umbrella-like concept that consists of a number of higher-level cognitive processes linked to the development of the prefrontal cortex, occur in early childhood. Executive function involves managing one's thoughts to engage in goal-directed behavior and to exercise self-control.
- Young children express curiosity about the human mind, and this has been studied under the topic of theory of mind. A number of developmental changes characterize children's theory of mind, including those involved in false beliefs. Individual variations also are involved in theory of mind. For example, autistic children have difficulty developing such a theory.

## 3 Language Development

**LG3** Summarize how language develops in early childhood.

#### Understanding Phonology and Morphology

- Young children increase their grasp of language's rule systems. In terms of phonology, most young children become more sensitive to the sounds of spoken language. Berko's classic experiment demonstrated that young children understand morphological rules.
- Preschool children learn and apply rules of syntax and of how words should be ordered. In terms of semantics, vocabulary development increases dramatically during early childhood.
- Young children's conversational skills improve, they increase their sensitivity to the needs of others in conversation, and they learn to change their speech style to suit the situation.
- Parents and teachers need to provide young children with a supportive environment in which to develop literacy skills. Children should be active participants and be immersed in a wide range of interesting experiences that involve listening, talking, writing, and reading.

## 4 Early Childhood Education

**LG4** Evaluate different approaches to early childhood education.

#### Variations in Early Childhood Education

- The child-centered kindergarten emphasizes educating the whole child, with particular attention to individual variation, the process of learning, and the importance of play in development. The Montessori approach allows children to choose from a range of activities while teachers serve as facilitators.

- Developmentally appropriate practice focuses on the typical patterns of children (age-appropriateness) and the uniqueness of each child (individual-appropriateness). Such practice contrasts with developmentally inappropriate practice, which ignores the concrete, hands-on approach to learning.
- The U.S. government has tried to break the poverty cycle with programs such as Head Start. The Early Head Start program began in 1995. Model programs have been shown to have positive effects on children who live in poverty.
- Controversy characterizes early childhood education curricula. On one side are the child-centered, constructivist advocates; on the other are those who advocate an academic, direct-instruction approach. Another controversy focuses on whether preschool education makes a difference, especially for children who are not disadvantaged.

## **L**ike many children, Sarah Newland loves animals.

During a trip to the zoo when she was 4 years old, Sarah learned about an animal that was a member of an endangered species and became motivated to help. With her mother's guidance, she baked lots of cakes and cookies, then sold them on the sidewalk outside her home. She was excited about making \$35 from the cake and cookie sales, donating it to the World Wildlife Fund. Several weeks later, the fund wrote back to Sarah requesting more money. Sarah was devastated because she thought she had taken care of the animal problem. Her mother consoled her and told her that the endangered animal problem and many others are so big that it takes ongoing help from many people to solve them. Her mother's guidance when Sarah was a young child must have worked because by the end of elementary school, Sarah had begun helping out at a child care center and working with her mother to provide meals to the homeless.

As Sarah's mother did, sensitive parents can make a difference in encouraging young children's sense of morality. Just as parents support and guide their children to become good readers, musicians, or athletes, they also play key roles in young children's socioemotional development (Source: Kantrowitz, 1991).

### **topical connections** *looking back*

During infancy, children's socioemotional development makes considerable progress as their caregivers (especially their parents) socialize them and they develop more sophisticated ways of initiating social interactions with others. Development of a secure attachment is a key aspect of infant development, and the development of autonomy in the second year of life also signals an important accomplishment. As children move through infancy, it is important for caregivers to guide them in regulating their emotions. Temperament also is a central characteristic of the infant's profile, and some temperament styles are more adaptive than others. The use of child care has become increasingly common in recent years, and the quality of this care varies considerably. Parents continue to play key roles in children's development in the early childhood period, but peers begin to play more important roles as well.

# preview

In early childhood, children's emotional lives and personalities develop in significant ways, and their small worlds widen. In addition to the continuing influence of family relationships, peers take on a more significant role in children's development, and play as well as media and screen time fill the days of many young children's lives.

Many changes characterize young children's socioemotional development in early childhood. Their developing minds and social experiences produce remarkable advances in the development of their self, emotional maturity, moral understanding, and gender awareness.

### THE SELF

During the second year of life, children make considerable progress in self-recognition. In the early childhood years, young children develop in many ways that enable them to enhance their self-understanding.

**Initiative Versus Guilt** You have read about Erik Erikson's (1968) eight developmental stages that are encountered during certain time periods in the life span. Erikson's first two stages—trust versus mistrust, and autonomy versus shame and doubt—describe what he considers to be the main developmental tasks of infancy. Erikson's psychosocial stage associated with early childhood is initiative versus guilt. By now, children have become convinced that they are persons in their own right; during early childhood, they begin to discover what kind of person they will become. They identify intensely with their parents, who most of the time appear to them to be powerful and beautiful, although often unreasonable, disagreeable, and sometimes even dangerous. During early childhood, children use their perceptual, motor, cognitive, and language skills to make things happen. They have a surplus of energy that permits them to forget failures quickly and to approach new areas that seem desirable—even if dangerous—with undiminished zest and often an increased sense of direction. On their own initiative, then, children at this stage exuberantly move out into a wider social world.

The great governor of initiative is conscience. Young children's initiative and enthusiasm may bring them not only rewards but also guilt, which lowers self-esteem.

**Self-Understanding and Understanding Others** Recent research studies have revealed that young children are more psychologically aware—of themselves and others—than used to be thought (Thompson, 2015). This psychological awareness reflects expanding psychological sophistication.

**Self-Understanding** In Erikson's portrait of early childhood, the young child clearly has begun to develop **self-understanding**, which is the representation of self, the substance and content of self-conceptions (Harter, 2012, 2016). Though not the whole of personal identity, self-understanding provides its rational underpinnings. Mainly through interviews, researchers have probed children's conceptions of many aspects of self-understanding.

Early self-understanding involves self-recognition. In early childhood, young children think that the self can be described by material characteristics such as size, shape, and color. They distinguish themselves from others through physical and material attributes. Says 4-year-old Sandra, "I'm different from Jennifer because I have brown hair and she has blond hair." Says 4-year-old Ralph, "I am different from Hank because I am taller, and I am different from my sister because I have a bicycle." Physical activities are also a central component of the self in

**self-understanding** The child's cognitive representation of self, the substance and content of the child's self-conceptions.

early childhood (Keller, Ford, & Meacham, 1978). For example, preschool children often describe themselves in terms of activities such as play. In sum, during early childhood, children often provide self-descriptions that involve bodily attributes, material possessions, and physical activities.

Although young children mainly describe themselves in terms of concrete, observable features and action tendencies, at about 4 to 5 years of age as they hear others use words describing psychological traits and emotions, they begin to include these in their own self-descriptions (Marsh, Ellis, & Craven, 2002). Thus, in a self-description, a 4-year-old might say, "I'm not scared. I'm always happy." Young children's self-descriptions are typically unrealistically positive, as reflected in the comment of this 4-year-old who says he is always happy, which he is not (Harter, 2012). They express this optimism because they don't yet distinguish between their desired competence and their actual competence, tend to confuse ability and effort (thinking that differences in ability can be changed as easily as can differences in effort), don't engage in spontaneous social comparison of their abilities with those of others, and tend to compare their present abilities with what they could do at an earlier age (which usually makes their abilities look quite good). This overestimation of their attributes helps to protect young children from negative self-evaluations.

However, as in virtually all areas of human development, there are individual variations in young children's self-conceptions, and there is increasing evidence that some children are vulnerable to negative self-attributions (Thompson, 2015). For example, one study revealed that insecurely attached preschool children whose mothers reported a high level of parenting stress and depressive symptoms had a lower self-concept than other young children in more positive family circumstances (Goodvin & others, 2008). This research indicates that young children's generally optimistic self-ascriptions do not buffer them from adverse, stressful family conditions (Thompson, 2011).

Researchers have found that young children's ability to understand their own and others' emotions precedes advances in their theory of mind (Nelson & others, 2013a; O'Brien & others, 2011). These studies indicate that a better basic understanding of emotions in early childhood enables young children to develop a more advanced understanding of others' perspectives.

**Understanding Others** Young children also make advances in their understanding of others and their capacity to learn from others (Fu & others, 2015; Harter, 2012, 2016; Ma & others, 2018; Landrum, Pflaum & Mills, 2016; Thompson, 2015). Young children's theory of mind includes understanding that other people have emotions and desires (Devine & Hughes, 2018a, b; Rizzo & Killen, 2018). And, at about 4 to 5 years, children not only start describing themselves in terms of psychological traits, but they also begin to perceive others in terms of psychological traits. Thus, a 4-year-old might say, "My teacher is nice."

As they mature, young children need to develop an understanding that people don't always give accurate reports of their beliefs (Mills & Elashi, 2014). Researchers have found that even 4-year-olds understand that people may make statements that aren't true to obtain what they want or to avoid trouble (Lee & others, 2002). For example, one study revealed that 4- and 5-year-olds were increasingly skeptical of another child's claim to be sick when the children were informed that the child wanted to avoid having to go to camp (Gee & Heyman, 2007).

Another important aspect of understanding others involves understanding joint commitments. As children approach their third birthday, their collaborative interactions with others increasingly involve obligations to the partner (Tomasello & Hamann, 2012).

Young children also learn extensively through observing others' behavior. For example, a recent study found that young children who observed a peer be rewarded for confessing to cheating on a task were more likely to be more honest in the future themselves (Ma & others, 2018).

Both the extensive theory of mind research and the recent research on young children's social understanding underscore that young children are not

Young children are more psychologically aware of themselves and others than used to be thought. as egocentric as Jean Piaget envisioned (Decety, Meidenbauer, & Cowell, 2018; Devine & Hughes, 2018a, b). Piaget's concept of egocentrism has become so ingrained in people's thinking about young children that too often the current research on social awareness in infancy and early childhood has been overlooked. Research increasingly shows that young children are more socially sensitive and perceptive than was previously envisioned, suggesting that parents and teachers can influence children's development by interacting with them in ways that help them to better understand and navigate the social world (Thompson 2015, 2016). If young children are seeking to better understand various mental and emotional states (intentions, goals, feelings, desires) that underlie people's actions, then talking with them about these internal states can improve young children's understanding of them (Thompson, 2015, 2016).

However, debate continues to surround the question of whether young children are socially sensitive or basically egocentric (Birch & others, 2017). Ross Thompson (2015, 2016) comes down on the side of viewing young children as socially sensitive, while Susan Harter (2012, 2013, 2016) argues that there is still evidence to support the conclusion that young children are essentially egocentric.

## EMOTIONAL DEVELOPMENT

The young child's growing awareness of self is linked to the ability to feel an expanding range of emotions. Young children, like adults, experience many emotions during the course of a day. Their emotional development in early childhood allows them to try to make sense of other people's emotional reactions and to begin to control their own emotions (Blair, 2017; Morris & others, 2018).

**Expressing Emotions** Recall that even young infants experience emotions such as joy and fear, but to experience *self-conscious emotions* children must be able to refer to themselves and be aware of themselves as distinct from others (Lewis, 2015, 2016). Pride, shame, embarrassment, and guilt are examples of self-conscious emotions. Self-conscious emotions do not appear to develop until self-awareness occurs at approximately 15 to 18 months of age. In a recent study, the broad capacity for self-evaluative emotion was present in the preschool years and was linked to young children's empathetic concern (Ross, 2017). In this study, young children's moral pride and pride in response to achievement and resilience to shame were linked to a greater tendency to engage in spontaneous helping.

During the early childhood years, emotions such as pride and guilt become more common. They are especially influenced by parents' responses to children's behavior. For example, a young child may experience shame when a parent says, "You should feel bad about biting your sister." One study revealed that young children's emotional expression was linked to their parents' own expressive behavior (Nelson & others, 2012). In this study, mothers who expressed a high incidence of positive emotions and a low incidence of negative emotions at home had children who were observed to use more positive emotion words during mother-child interactions than mothers who expressed few positive emotions at home.

**Understanding Emotions** One of the most important advances in emotional development in early childhood is an increased understanding of emotion (Kuhnert & others, 2017; O'Kearney & others, 2107; Perry & Calkins, 2018). During early childhood, young children increasingly understand that certain situations are likely to evoke particular emotions, facial expressions indicate specific emotions, emotions affect behavior, and emotions can be used to influence others' emotions (Cole & others, 2009).

Between 2 and 4 years of age, children considerably increase the number of terms they use to describe emotions. During this time, they are also learning about the causes and consequences of feelings (Denham & others, 2011).

When they are 4 to 5 years of age, children show an increased ability to reflect on emotions. They also begin to understand that the same event can elicit different feelings in different people. Moreover, they show a growing awareness that they need to manage their emotions to meet social standards.

One program that is designed to improve young children's understanding of emotions is the Emotion-Based Prevention program (EBP) (Izard & others, 2008). This program consists of a teacher-conducted emotions course in the classroom, emotion tutoring and coaching teacher dialogues, and weekly parent messages that reinforce the lessons taught in the

classroom. In the classroom component, teachers ask children to label or demonstrate emotional expressions, share ideas about what causes them to feel the emotions they described, compare expressions of different emotions and their intensities, and draw out or act out emotion expressions for their classmates. Researchers found that EBP was effective in improving Head Start children's emotion knowledge and that the children who participated in the program showed a decrease in their expression of negative emotions and internalizing behaviors (Finion & others, 2015).

**Regulating Emotions** Emotion regulation is an important aspect of development. Emotion regulation especially plays a key role in children's ability to manage the demands and conflicts they face in interacting with others (Blair, 2016, 2017; Perry & Calkins, 2018; Eisenberg, Spinrad, & Valiente, 2016).

Many researchers consider the growth of emotion regulation in children as fundamental to becoming socially competent (Blair, 2017; Cole & Hollenstein, 2018; Cole, Lougheed, & Ram, 2018; Perry & Calkins, 2018; Thompson, 2015). Emotion regulation can be conceptualized as an important component of self-regulation or of executive function. Recall that executive function is increasingly thought to be a key concept in describing the young child's higher-level cognitive functioning (Cheng & others, 2018; Liu & others, 2018; Muller & others, 2017; Perry & Calkins, 2018; Schmitt & others, 2017).

Cybele Raver and her colleagues (Blair, 2017; Blair & Raver, 2012, 2015; Blair, Raver, & Finegood, 2016; Raver & others, 2011, 2012, 2013; Zhai, Raver, & Jones, 2012) have conducted a number of studies that explore the role of emotion regulation in young children's development. They use various interventions, such as increasing caregiver emotional expressiveness, to improve young children's emotion regulation and reduce behavior problems in children growing up in poverty conditions. To read in greater detail about one of Cybele Raver's studies, see *Connecting Through Research*.

**Emotion-Coaching and Emotion-Dismissing Parents** Parents can play an important role in helping young children regulate their emotions (Bendeuz & others, 2018; Morris & others, 2018; Norona & Baker, 2017; Quinones-Camacho & Davis, 2018). Depending on how they talk with their children about emotion, parents can be described as taking an *emotion-coaching* or an *emotion-dismissing* approach (Gottman, 2018). The distinction between these approaches is most evident in the way the parent deals with the child's negative emotions (anger, frustration, sadness, and so on). *Emotion-coaching parents* monitor their children's emotions, view their children's negative emotions as opportunities for teaching, assist them in labeling emotions, and coach them in how to deal effectively with emotions. In contrast, *emotion-dismissing parents* view their role as to deny, ignore, or change negative emotions. Emotion-coaching parents interact with their children in a less rejecting manner, use more scaffolding and praise, and are more nurturant than are emotion-dismissing parents. Moreover, the children of emotion-coaching parents are better at soothing themselves when they get upset, more effective in regulating their negative affect, focus their attention better, and have fewer behavior problems than the children of emotion-dismissing parents (Gottman, 2018). Researchers have found that fathers' emotion coaching is related to children's social competence (Baker, Fenning, & Crnic, 2011) and that mothers' emotion coaching is linked to less oppositional behavior (Dunsmore, Booker, & Ollendick, 2013).

Parents' knowledge of their children's emotional world can help them guide their children's emotional development and teach their children how to cope effectively with problems (Bendeuz & others, 2018; Morris & others, 2018). One study found that mothers' knowledge about what distresses and comforts their children predicted the children's coping, empathy, and prosocial behavior (Vinik, Almas, & Grusec, 2011).

A challenge parents face is that young children typically don't want to talk about difficult emotional topics, such as being distressed or engaging in negative behaviors. Among the strategies young children use to avoid these conversations is to not talk at all, change the topic, push away, or run away. In one study, young children were more likely to openly discuss difficult emotional circumstances when they were securely attached to their mother and when their mother conversed with them in a way that validated and accepted the child's views (Thompson & others, 2009).

**Emotion Regulation and Peer Relations** Emotions play a strong role in determining the success of a child's peer relationships (Smetana & Ball, 2018). Specifically, the ability to

### Caregivers' Emotional Expressiveness, Children's Emotion Regulation, and Behavior Problems in Head Start Children

A study by Dana McCoy and Cybele Raver (2011) explored links between caregivers' reports of their positive and negative emotional expressiveness, observations of young children's emotion regulation, and teachers' reports of the children's internalizing and externalizing behavior problems. The participants were 97 mostly African American and Latino children whose mean age was 4 years and 3 months, along with their primary caregivers (90 mothers, 5 fathers, and 2 grandmothers).

To assess caregiver expressiveness, caregivers were asked to provide ratings from 1 (never/rarely) to 9 (very frequently) on 7 items that reflect caregiver expressiveness, such as "telling family members how happy you are" and "expressing anger at someone's carelessness." Children's emotion regulation was assessed with (a) the emotion regulation part of the PSRA (preschool self-regulation assessment) in which observers rated young children's behavior on 4 delay tasks, 3 executive function tasks, and 3 compliance tasks; (b) an assessment report on children's emotion and emotion regulation; and (c) observations of the children's real-time emotion regulation related to positive emotion (expressions of happiness, for example) and negative emotion (expressions of anger or irritability, for example). Children's internalizing and externalizing behaviors were rated by their teachers on the extent to which the children had shown such behavioral problems in the last 3 months.

The researchers found that a higher level of caregiver negativity and a lower level of children's emotion regulation independently

were linked to more internalizing behavior problems in the young Head Start children. Also, caregivers' reports of their positive emotional expressiveness were associated with a lower level of young children's externalizing behavior problems. The findings demonstrate the importance of family emotional climate and young children's emotion regulation in the development of young children.

modulate one's emotions is an important skill that benefits children in their relationships with peers. Moody and emotionally negative children are more likely to experience rejection by their peers, whereas emotionally positive children are more popular. A recent study found that young children with higher emotion regulation were more popular with their peers (Nakamichi, 2018).

## MORAL DEVELOPMENT

**Moral development** involves thoughts, feelings, and behaviors regarding rules and conventions about what people should do in their interactions with other people. Major developmental theories have focused on different aspects of moral development (Gray & Graham, 2018; Hoover & others, 2018; Killen & Dahl, 2018; Narváez, 2017a, b, 2018; Turiel & Gingo, 2017).

**Moral Feelings** Feelings of anxiety and guilt are central to the account of moral development provided by Sigmund Freud's psychoanalytic theory. According to Freud, children attempt to reduce anxiety, avoid punishment, and maintain parental affection by identifying with parents and internalizing their standards of right and wrong, thus forming the superego—the moral element of personality.

Freud's ideas are not backed by research, but guilt certainly can motivate moral behavior. Other emotions, however, also contribute to the child's moral development, including positive feelings. One important example is empathy, which involves responding to another person's feelings with an emotion that echoes the other's feelings (Denham, Bassett, & Wyatt, 2015).

#### Theories

Freud theorized that individuals go through five psychosexual stages. Connect to "Introduction."

**moral development** Development that involves thoughts, feelings, and behaviors regarding rules and conventions about what people should do in their interactions with other people.

Infants have the capacity for some purely empathic responses, but empathy often requires the ability to discern another's inner psychological states, which is also known as perspective taking. Learning how to identify a wide range of emotional states in others and to anticipate what kinds of action will improve another person's emotional state helps to advance children's moral development (Thompson, 2015).

Today, many child developmentalists believe that both positive feelings—such as empathy, sympathy, admiration, and self-esteem—and negative feelings—such as anger, outrage, shame, and guilt—contribute to children's moral development (Eisenberg, Spinrad, & Morris, 2013; Kim & Kochanska, 2017; Ross, 2017). When these emotions are strongly experienced, they influence children to act in accord with standards of right and wrong. *Sympathy*—an other-oriented emotional response in which an observer experiences emotions that are similar or identical to what the other person is feeling—often motivates prosocial behavior (Eisenberg, Spinrad, & Knafo-Noam, 2015). In one study, young children's sympathy predicted whether they would share or not (Ongley & Malti, 2014).

Connections between emotions can occur, and these connections may influence children's development. For example, in a recent study, participants' guilt proneness combined with their empathy predicted an increase in prosocial behavior (Torstveit, Sutterlin, & Lugo, 2016).

**Moral Reasoning** Interest in how children think about moral issues was stimulated by Piaget (1932), who extensively observed and interviewed children between the ages of 4 and 12. Piaget watched children play marbles to learn how they applied and thought about the game's rules. He also asked children about ethical issues—theft, lies, punishment, and justice, for example. Piaget concluded that children go through two distinct stages in how they think about morality.

- From about 4 to 7 years of age, children display **heteronomous morality**, the first stage of moral development in Piaget's theory. Children think of justice and rules as unchangeable properties of the world, removed from the control of people.
- From 7 to 10 years of age, children are in a transition showing some features of the first stage of moral reasoning and some stages of the second stage, autonomous morality.
- At about 10 years of age and older, children show **autonomous morality**. They become aware that rules and laws are created by people, and in judging an action they consider the actor's intentions as well as the consequences.

Because young children are heteronomous moralists, they judge the rightness or goodness of behavior by considering its consequences, not the intentions of the actor. For example, to the heteronomous moralist, breaking 12 cups accidentally is worse than breaking one cup intentionally. As children develop into moral autonomists, intentions become more important than consequences.

The heteronomous thinker also believes that rules are unchangeable and are handed down by all-powerful authorities. When Piaget suggested to young children that they use new rules in a game of marbles, they resisted. By contrast, older children—moral autonomists—accept change and recognize that rules are merely convenient conventions, subject to change.

The heteronomous thinker also believes in **immanent justice**, the concept that if a rule is broken, punishment will be meted out immediately. The young child believes that a violation is connected automatically to its punishment. Immanent justice also implies that if something unfortunate happens to someone, the person must have transgressed earlier. Older children, who are moral autonomists, recognize that punishment occurs only if someone witnesses the wrongdoing and that even then, punishment is not inevitable.

How do these changes in moral reasoning occur? Piaget concluded that the changes come about through the mutual give-and-take of peer relations. In the peer group, where others have power and status similar to the child's, plans are negotiated and coordinated, and disagreements are reasoned about and eventually settled. Parent-child relations, in which parents have the power and children do not, are less likely to advance moral reasoning, because rules are often handed down in an authoritarian way.

**Moral Behavior** The behavioral and social cognitive approaches initially described early in this edition focus on moral behavior rather than moral reasoning. Advocates of these perspectives hold that the processes of reinforcement, punishment, and imitation explain the

### Theories

What are the main themes of Bandura's social cognitive theory? Connect to the "Introduction" chapter.

development of moral behavior. When children are rewarded for behavior that is consistent with laws and social conventions, they are likely to repeat that behavior. When models who behave morally are provided, children are likely to adopt their actions. And, when children are punished for immoral behavior, those behaviors are likely to be reduced or eliminated. However, because punishment may have adverse side effects, as discussed later in this chapter, it should be used judiciously and cautiously.

In the moral behavior view, the situation also influences behavior. More than a half century ago, a comprehensive study of thousands of children in many situations—at home, at school, and at church, for example—found that the totally honest child was virtually nonexistent; so was the child who cheated in all situations (Hartshorne & May, 1928–1930). Behavioral and social cognitive researchers emphasize that what children do in one situation is often only weakly related to what they do in other situations. A child might cheat in class but not in a game; a child might steal a piece of candy when alone but not steal it when others are present.

And when children observe people behaving morally, they are likely to imitate their actions (Ma & others, 2018). In one study, 2-year-olds watched a video of an adult engaging in prosocial behavior in response to another person's distress (Williamson, Donohue, & Tully, 2013). Children who saw the prosocial video were more likely than children who did not see it to imitate the prosocial behavior in response to their own parents' distress.

Social cognitive theorists also stress that the ability to resist temptation is closely tied to the development of self-control. To achieve this self-control, children must learn to delay gratification. According to social cognitive theorists, cognitive factors are important in the child's development of self-control (Bandura, 2009, 2010a, b, 2012).

**Conscience** Conscience refers to an internal regulation of standards of right and wrong that involves an integration of all three components of moral development we have described so far—moral thought, feeling, and behavior (Kochanska & others, 2010). Reflecting the presence of a conscience in young children, researchers have found that young children are aware of right and wrong, have the capacity to show empathy toward others, experience guilt, indicate discomfort following a transgression, and are sensitive to violating rules (Kochanska & Aksan, 2007; Kochanska & others, 2009).

Recent research focuses on the role of guilt in young children's cooperation. For example, researchers have found that experiencing guilt motivates reparative behavior as early as 2 to 3 years of age and transgressors' displays of guilt motivate cooperative behavior in 4- to 5-year-olds (Vaish, 2018; Vaish Carpenter, & Tomasello, 2016).

A major interest regarding young children's conscience focuses on children's relationships with their caregivers (Kochanska & Kim, 2012, 2013). Especially important in this regard is the emergence of young children's willingness to embrace the values of their parents, an orientation that flows from a positive, close relationship (Kochanska & Aksan, 2007). For example, children who are securely attached are more likely to internalize their parents' values and rules (Kim & Kochanska, 2017; Kochanska & Kim, 2012, 2013; Thompson, 2014, 2015).

**Parenting and Young Children's Moral Development** In Ross Thompson's (2006, 2009, 2012) view, young children are moral apprentices, striving to understand what is moral. Among the most important aspects of the relationship between parents and children that contribute to children's moral development are relational quality, parental discipline, proactive strategies, and conversational dialogue.

Parent-child relationships introduce children to the mutual obligations of close relationships (Kim & Kochanska, 2017; Kim & others, 2014; Kochanska & Kim, 2012, 2013). Parents' obligations include engaging in positive caregiving and guiding children to become competent human beings. Children's obligations include responding appropriately to parents' initiatives and maintaining a positive relationship with parents.

An important parenting strategy involves proactively averting potential misbehavior by children before it takes place (Thompson, 2009). With younger children, being proactive means using diversion, such as distracting their attention or moving them to alternative activities. With older children, being proactive may involve talking with them about values that the parents deem important.

Conversations related to moral development can benefit children, regardless of whether they occur as part of a discipline encounter or outside the encounter in the everyday stream of parent-child interaction (Thompson & Newton, 2013). The conversations can be planned or spontaneous and can focus on topics such as past events (for example, a child's prior

misbehavior or positive moral conduct), shared future events (for example, going somewhere that may involve a temptation and will require positive moral behavior), and immediate events (for example, talking with the child about a sibling's tantrums).

Researchers have found that parents' talk about emotions is associated with toddlers' sharing and helping (Brownell & others, 2013). In this study, children who helped and shared more quickly and frequently, especially in tasks that required complex emotional understanding, had parents who more often asked them to label and explain emotions displayed in books. Importantly, it was the parents' elicitation of emotion talk rather than parents' own production of emotion labels and explanations that was linked to toddlers' prosocial behavior.

## GENDER

**Gender** refers to the characteristics of people as males and females. **Gender identity** involves a sense of one's own gender, including knowledge, understanding, and acceptance of being male or female (Brannon, 2017; Martin & others, 2017). One aspect of gender identity involves knowing whether you are a girl or boy, an awareness that most children develop by about 2½ years of age (Blakemore, Berenbaum, & Liben, 2009). **Gender roles** are sets of expectations that prescribe how females or males should think, act, and feel. During the preschool years, most children increasingly act in ways that match their culture's gender roles. **Gender typing** refers to acquisition of a traditional masculine or feminine role. For example, fighting is more characteristic of a traditional masculine role and crying is more characteristic of a traditional feminine role (Helgeson, 2017). One study revealed that sex-typed behavior (boys playing with cars and girls with jewelry, for example) increased during the preschool years and that children who engaged in the most sex-typed behavior during the preschool years still did so at 8 years of age (Golombok & others, 2008).

**Biological Influences** Biology clearly plays a role in gender development (Lickliter, 2018; Mason & others, 2018). Among the possible biological influences are chromosomes, hormones, and evolution (Li, Kung, & Hines, 2017).

**Chromosomes and Hormones** Biologists have learned a great deal about how sex differences develop. Recall that humans normally have 46 chromosomes arranged in pairs. The 23rd pair consists of a combination of X and Y chromosomes, usually two X chromosomes in a female and an X and a Y in a male. In the first few weeks of gestation, however, female and male embryos look alike.

Males start to differ from females when genes on the Y chromosome in the male embryo trigger the development of testes rather than ovaries; the testes secrete copious amounts of the class of hormones known as androgens. Low levels of androgens in the female embryo allow the normal development of female sex organs.

Thus, hormones play a key role in the development of sex differences (Li, Kung, & Hines, 2017). The two main classes of sex hormones, estrogens and androgens, are secreted by the *gonads* (ovaries in females, testes in males). *Estrogens*, such as estradiol, influence the development of female physical sex characteristics. *Androgens*, such as testosterone, promote the development of male physical sex characteristics. Sex hormones also can influence children's socioemotional development.

**The Evolutionary Psychology View** How might physical differences between the sexes give rise to psychological differences between males and females? Evolutionary psychology offers one answer. According to evolutionary psychology, adaptation during human evolution produced psychological differences between males and females (Antfolk, 2018; Buss, 2012, 2015). Because of their differing roles in reproduction, males and females faced differing pressures when the human species was evolving. In particular, because having multiple sexual liaisons improves the likelihood that males will pass on their genes, natural selection favored males who adopted short-term mating strategies (Hoefnagels, 2018; Johnson, 2017). These are strategies that allow a male to win the competition with other males for sexual access to females. Therefore, say evolutionary psychologists, males evolved dispositions that favor violence, competition, and risk taking.

In contrast, according to evolutionary psychologists, females' contributions to the gene pool were improved when they secured resources that ensured that their offspring would survive.

**gender identity** The sense of being male or female, which most children acquire by the time they are 3 years old.

**gender role** A set of expectations that prescribes how females or males should think, act, and feel.

**gender typing** Acquisition of a traditional masculine or feminine role.

First imagine that this is a photograph of a baby girl. *What expectations would you have of her?* Then imagine that this is a photograph of a baby boy. *What expectations would you have of him?*

As a consequence, natural selection favored females who devoted effort to parenting and chose successful, ambitious mates who could provide their offspring with resources and protection.

Critics of evolutionary psychology argue that its hypotheses are backed by speculations about prehistory, not evidence, and that in any event people are not locked into behavior that was adaptive in the evolutionary past. Critics also claim that the evolutionary view pays little attention to cultural and individual variations in gender differences (Hyde & DeLamater, 2017).

**Social Influences** Many social scientists do not locate the cause of psychological gender differences in biological dispositions. Rather, they argue that these differences reflect social experiences. Explanations for how gender differences come about through experience include both social and cognitive theories.

**Social Theories of Gender** Three main social theories of gender have been proposed—social role theory, psychoanalytic theory, and social cognitive theory. Alice Eagly (2001, 2010, 2012, 2013, 2016, 2017) proposed **social role theory**, which states that gender differences result from the contrasting roles of women and men. In most cultures around the world, women have less power and status than men, and they control fewer resources (UNICEF, 2018). Compared with men, women perform more domestic work, spend fewer hours in paid employment, receive lower pay, and are more thinly represented in the highest levels of organizations (Helgeson, 2017). In Eagly's view, as women adapted to roles with less power and less status in society, they showed more cooperative, less dominant profiles than men. Thus, the social hierarchy and division of labor are important causes of gender differences in power, assertiveness, and nurturing (Eagly & Wood, 2017).

The **psychoanalytic theory of gender** stems from Freud's view that the preschool child develops a sexual attraction to the opposite-sex parent. This is the process known as the Oedipus (for boys) or Electra (for girls) complex. At 5 or 6 years of age, the child renounces this attraction because of anxious feelings. Subsequently, the child identifies with the same-sex parent, unconsciously adopting the same-sex parent's characteristics. However, developmentalists have observed that gender development does not proceed as Freud proposed. Children become gender-typed much earlier than 5 or 6 years of age, and they become masculine or feminine even when the same-sex parent is not present in the family.

The social cognitive approach provides an alternative explanation of how children develop gender-typed behavior. According to the **social cognitive theory of gender**, children's gender development occurs through observing and imitating what other people say and do, and through being rewarded and punished for gender-appropriate and gender-inappropriate behavior (Bussey & Bandura, 1999). From birth onward, males and females are treated differently from one another. When infants and toddlers show gender-appropriate behavior, adults tend to reward them. Parents often use rewards and punishments to teach their daughters to be feminine ("Karen, you are being a good girl when you play gently with your doll") and their sons to be masculine ("Keith, a boy as big as you is not supposed to cry"). Parents, however, are only one of many sources through which children learn gender roles (Brown & Stone, 2018). Culture, schools, peers, the media, and other family members also provide gender role models (Chen, Lee, & Chen, 2018; Liben, 2017; Lever-Duffy & McDonald, 2018; Lord & others, 2017). For example, children also learn about gender by observing the behavior of other adults in the neighborhood and on television (Bugental & Grusec, 2006). As children get older, peers become increasingly important. Let's take a closer look at the influence of parents and peers.

**Parental Influences** Parents, by action and by example, influence their children's gender development (Brannon, 2017; Endendijk & others, 2017; Helgeson, 2017; Leaper & Bigler, 2018; Liben, 2017). Both mothers and fathers are psychologically important to their children's gender development (Leaper, 2015). Cultures around the world, however, tend to give mothers and fathers different roles (Chen, Lee, & Chen, 2018). A research review yielded the following conclusions (Bronstein, 2006):

- *Mothers' socialization strategies.* In many cultures, mothers socialize their daughters to be more obedient and responsible than their sons. They also place more restrictions on daughters' autonomy.
- *Fathers' socialization strategies.* Fathers show more attention to sons than to daughters, engage in more activities with sons, and put forth more effort to promote sons' intellectual development.

What role does gender play in children's peer relations?

(Left) ©altrendo images/Getty Images; (right) ©Cindy Charles/PhotoEdit

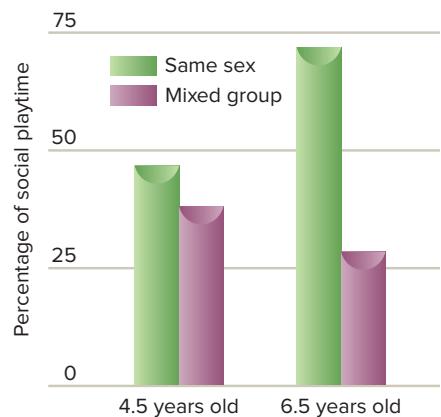

Thus, according to Bronstein (2006, pp. 269–270), “Despite an increased awareness in the United States and other Western cultures of the detrimental effects of gender stereotyping, many parents continue to foster behaviors and perceptions that are consonant with traditional gender role norms.”

**Peer Influences** Parents provide the earliest discrimination of gender roles, but peers soon join the process of responding to and modeling masculine and feminine behavior (Martin, Fabes, & Hanish, 2018; Rose & Smith, 2018; Zosuls & others, 2016). In fact, peers become so important to gender development that the playground has been called “gender school” (Luria & Herzog, 1985).

Peers extensively reward and punish gender behavior (Rubin, Bukowski, & Bowker, 2015). For example, when children play in ways that the culture says are sex-appropriate, their peers tend to reward them. But peers often reject children who act in a manner that is considered more characteristic of the other gender (Handrinós & others, 2012). A little girl who brings a doll to the park may find herself surrounded by new friends; a little boy who does the same thing might be jeered at. However, there is greater pressure for boys to conform to a traditional male role than for girls to conform to a traditional female role (Fagot, Rogers, & Leinbach, 2000). For example, a preschool girl who wants to wear boys’ clothing receives considerably more approval than a boy who wants to wear a dress. The very term “tomboy” implies broad social acceptance of girls’ adopting traditional male behaviors. In a recent study of 9- to 10-year-olds in Great Britain, gender nonconforming boys were at highest risk for peer rejection (Braun & Davidson, 2017). In this study, gender non-conforming girls were preferred more than gender-conforming girls, with children most often citing masculine activities as the reason for this choice.

Gender molds important aspects of peer relations (Rose & Smith, 2018). It influences the composition of children’s groups, the size of groups, and interactions within a group (Maccoby, 1998, 2002):

- *Gender composition of children’s groups.* Around the age of 3, children already show a preference to spend time with same-sex playmates. From 4 to 12 years of age, this preference for playing in same-sex groups increases, and during the elementary school years children spend a large majority of their free time with children of their own sex (see Figure 1). One study found that when preschool children select a playmate, both the sex of the playmate and the playmate’s level of gender-typed activity are important but sex of the playmate is more important (Martin & others, 2013).
- *Group size.* From about 5 years of age onward, boys are more likely to associate together in larger clusters than girls are. Boys are also more likely to participate in organized group games than girls are. In one study, same-sex groups of six children were permitted to use play materials in any way they wished (Benenson, Apostolaris, & Parnass, 1997). Girls were more likely than boys to play in dyads or triads, while boys were more likely to interact in larger groups and seek to attain a group goal.
- *Interaction in same-sex groups.* Boys are more likely than girls to engage in rough-and-tumble play, competition, conflict, ego displays, risk taking, and quests for dominance. By contrast, girls are more likely to engage in “collaborative discourse,” in which they talk and act in a more reciprocal manner.

**FIGURE 1**  
**DEVELOPMENTAL CHANGES IN PERCENTAGE OF TIME SPENT IN SAME-SEX AND MIXED-GROUP SETTINGS.** Observations of children show that they are more likely to play in same-sex than mixed-sex groups. This tendency increases between 4 and 6 years of age.

**gender schema theory** The theory that gender typing emerges as children develop gender schemas of their culture's gender-appropriate and gender-inappropriate behavior.

**Cognitive Influences** One influential cognitive theory is **gender schema theory**, which states that gender typing emerges as children gradually develop gender schemas of what is gender-appropriate and gender-inappropriate in their culture (Liben & others, 2018; Martin & Cook, 2017; Martin, Fabes, & Hanish, 2018; Miller & others, 2013). A *schema* is a cognitive structure, a network of associations that guides an individual's perceptions. A *gender schema* organizes the world in terms of female and male. Children are internally motivated to perceive the world and to act in accordance with their developing schemas. Bit by bit, children pick up what is gender-appropriate and gender-inappropriate in their culture, and develop gender schemas that shape how they perceive the world and what they remember (Conry-Murray, Kim, & Turiel, 2012; Liben, 2017). Children are motivated to act in ways that conform to these gender schemas. Thus, gender schemas fuel gender typing.

Attachment to a caregiver is a key social relationship during infancy; however, some experts maintain that secure attachment and other aspects of the infant years have been overdramatized as determinants of life-span development. Social and emotional development is also shaped by other relationships and by temperament, contexts, and social experiences during early childhood and later. In this section, we will discuss social relationships in early childhood beyond attachment. We will explore different types of parenting, sibling relationships, and variations in family structures.

### PARENTING

Media accounts sometimes portray parents as unhappy, feeling little joy in caring for their children. However, one study found that parents were more satisfied with their lives than were nonparents, felt relatively better on a daily basis than did nonparents, and had more positive feelings related to caring for their children than toward doing other daily activities (Nelson & others, 2013b).

Juggling work and child care can be challenging for families with young children. A survey of American parents found that approximately half of fathers and one-fourth of mothers reported feeling that they weren't spending enough time with their children (Pew Research, 2013). Nonetheless, this survey found that both mothers and fathers were spending more time with their children than parents did a generation earlier.

Good parenting takes time and effort (Hutchings & Williams, 2019; Morris & others, 2018; Serrano-Villar, Huang, & Calzada, 2017). You can't do it in a minute here and a minute there.

You can't do it with CDs or DVDs. Of course, it's not just the quantity of time parents spend with children that is important for children's development—the quality of the parenting is clearly important (Grusec, 2017; Lindsay & others, 2018; Orth, 2018; Taylor & Workman, 2018). To understand variations in parenting, let's consider the styles parents use when they interact with their children, how they discipline their children, and the dynamics of coparenting.

**Baumrind's Parenting Styles** Diana Baumrind (1971, 2012) argues that parents should be neither punitive nor aloof. Rather, they should develop rules for their children and be affectionate with them. She has described four types of parenting styles:

- **Authoritarian parenting** is a restrictive, punitive style in which parents exhort the child to follow their directions and respect their work and effort. The authoritarian parent places firm limits and controls on the child and allows little verbal exchange. For example, an authoritarian parent might say, "You will do it my way or else." Authoritarian parents also might spank the child frequently, enforce rules rigidly but not explain them, and show rage toward the child. Children of authoritarian parents are often unhappy, fearful, and anxious about comparing themselves with others, fail to initiate activity, and have weak communication skills. A recent research review of a large number of studies concluded that authoritarian parenting is linked to a higher level of externalizing problems (acting out, high levels of aggression, for example) (Pinquart, 2017). Also, a recent study of young children found that an authoritarian parenting style, as well as pressuring the child to eat, were linked to increased risk that children would be overweight or obese (Melis Yavuz & Selcuk, 2018).
- **Authoritative parenting** encourages children to be independent but still places limits and controls on their actions. Extensive verbal give-and-take is allowed, and parents are warm and nurturing toward the child. An authoritative parent might put his arm around the child in a comforting way and say, "You know you should not have done that. Let's talk about how you can handle the situation better next time." Authoritative parents show pleasure and support in response to children's constructive behavior. They also expect mature, independent, and age-appropriate behavior from their children. Children whose parents are authoritative are often cheerful, self-controlled and self-reliant, and achievement-oriented; they tend to maintain friendly relations with peers, cooperate with adults, and cope well with stress. As was just indicated, authoritative parents do exercise some direction and control over their children. The children of authoritative parents who engage in behavioral or psychological control without being coercive or punitive often show positive developmental outcomes (Baumrind, Larzelere, & Owens, 2010). In a recent study, children of authoritative parents engaged in more prosocial behavior than their counterparts whose parents used the other parenting styles described in this section (Carlo & others, 2018). Also, in a recent research review, authoritative parenting was the most effective parenting style in predicting which children and adolescents would be less likely to be overweight or obese later in their development (Sokol, Qin, & Poti, 2017).
- **Neglectful parenting** is a style in which the parent is uninvolved in the child's life. Children whose parents are neglectful develop the sense that other aspects of the parents' lives are more important than they are. These children tend to be socially incompetent. Many have poor self-control and don't handle independence well. They frequently have low self-esteem, are immature, and may be alienated from the family. In adolescence, they may show patterns of truancy and delinquency. In the recent research review of studies described under authoritarian parenting, the review also found that neglectful parenting was associated with a higher level of externalizing problems (Pinquart, 2017).
- **Indulgent parenting** is a style in which parents are highly involved with their children but place few demands or controls on them. Such parents let their children do what they want. As a result, the children never learn to control their own behavior and always expect to get their way. Some parents deliberately rear their children in this way because they believe the combination of warm involvement and few restraints will produce a creative, confident child. However, children whose parents are indulgent rarely learn respect for others and have difficulty controlling their behavior. They might be domineering, egocentric, and noncompliant, and have difficulties in peer relations.

These four classifications of parenting involve combinations of acceptance and responsiveness on the one hand and demand and control on the other (Maccoby & Martin, 1983). How

**CLASSIFICATION OF PARENTING STYLES.** The four types of parenting styles (authoritative, authoritarian, indulgent, and neglectful) involve the dimensions of acceptance and responsiveness, on the one hand, and demand and control on the other. For example, authoritative parenting involves being both accepting/responsive and demanding/controlling.

these dimensions combine to produce authoritarian, authoritative, neglectful, and indulgent parenting is shown in Figure 2.

**Parenting Styles in Context** Do the benefits of authoritative parenting transcend the boundaries of ethnicity, socioeconomic status (SES), and household composition? Although occasional exceptions have been found, evidence linking authoritative parenting with competence on the part of the child occurs in research across a wide range of ethnic groups, social strata, cultures, and family structures (Steinberg, 2014).

Nonetheless, researchers have found that in some ethnic groups, aspects of the authoritarian style may be associated with more positive child outcomes than Baumrind predicts (Clarke-Stewart & Parke, 2014; Pinquart & Kauser, 2018). Elements of the authoritarian style may take on different meanings and have different effects depending on the context. For example, Asian American parents often continue aspects of traditional Asian child-rearing practices that have sometimes been described as authoritarian. The parents exert considerable control over their children's lives. However, Ruth Chao (2001, 2005, 2007; Chao & Otsuki-Clutter, 2011; Chao & Tseng, 2002) argues that the style of parenting used by many Asian American parents is distinct from the domineering control of the authoritarian style. Instead, Chao argues, this type of parental control reflects concern and involvement in their children's lives and is best conceptualized as a type of training. The high academic achievement of Asian American children may be a consequence of their "training" parents (Stevenson & Zusho, 2002). In research involving Chinese American adolescents and their parents, parental control was endorsed, as were the Confucian parental goals of perseverance, self-discipline in schoolwork, obedience, and sensitiveness to parents' wishes (Russell, Crockett, & Chao, 2010).

An emphasis on requiring respect and obedience is also associated with the authoritarian style, but in Latino child rearing this focus may be positive rather than punitive. Rather than suppressing the child's development, it may encourage the development of a self and an identity that are embedded in the family and require respect and obedience (Dixon, Graber, & Brooks-Gunn, 2008). In these circumstances, emphasizing respect and obedience may be part of maintaining a harmonious family and important in shaping the child's identity (Umana-Taylor & others, 2014).

**Further Thoughts on Parenting Styles** Several caveats about parenting styles are in order. First, the parenting styles do not capture the important themes of reciprocal socialization and synchrony. Keep in mind that children socialize parents, just as parents socialize children (Klein & others, 2018).

Second, many parents use a combination of techniques rather than a single technique, although one technique may be dominant. Although consistent parenting is usually recommended, the wise parent may sense the importance of being more permissive in certain situations, more authoritarian in others, and more authoritative in yet other circumstances. In addition, parenting styles often are talked about as if both parents have the same style, although this may not be the case.

Third, some critics argue that the concept of parenting style is too broad and that more research needs to be conducted to "unpack" parenting styles by studying various components that compose the styles (Grusec, 2011, 2017; Grusec & others). For example, is parental monitoring more important than warmth in predicting child and adolescent outcomes?

Fourth, much of the parenting style research has involved mothers, not fathers. In many families, mothers will use one style, fathers another style. Especially in traditional cultures, fathers have an authoritarian style and mothers a more permissive, indulgent style. It has often been said that it is beneficial for parents to engage in a consistent parenting style; however, if fathers are authoritarian and aren't willing to change, children benefit when mothers use an authoritative style.

**Punishment** For centuries, corporal (physical) punishment, such as spanking, has been considered a necessary and even desirable method of disciplining children. Use of corporal punishment is legal in every state in America. A national survey of U.S. parents with 3- and 4-year-old children found that 26 percent of parents reported spanking their children frequently, and 67 percent of the parents reported yelling at their children frequently (Regalado & others, 2004). A study of more than 11,000 U.S. parents indicated that 80 percent of the parents reported spanking their children by the time they reached kindergarten (Gershoff & others, 2012). A recent research review concluded that there is widespread approval of corporal punishment by U.S. parents (Chiocca, 2017). A cross-cultural comparison found that individuals in the United States were among those with the most favorable attitudes toward corporal punishment and were the most likely to remember it being used by their parents (Curran & others, 2001) (see Figure 3). Physical punishment is outlawed in 41 countries, with an increasing number of countries banning physical punishment mainly to protect children from abuse and exploitation (Committee on the Rights of the Child, 2014).

What are some reasons for avoiding spanking or similar harsh punishments? The reasons include the following:

- When adults punish a child by yelling, screaming, or spanking, they are presenting children with out-of-control models for handling stressful situations. Children may imitate this aggressive, out-of-control behavior.
- Punishment can instill fear, rage, or avoidance. For example, spanking the child may cause the child to avoid being around the parent and to fear the parent.
- Punishment tells children what not to do rather than what to do. Children should be given feedback, such as “Why don’t you try this?”
- Punishment can be abusive. Parents might unintentionally become so angry when they are punishing the child that they injure the child physically or emotionally (Knox, 2010).

Most child psychologists recommend handling misbehavior by reasoning with the child, especially explaining the consequences of the child’s actions for others. Time out, in which the child is removed from a setting that offers positive reinforcement, can also be effective. For example, when the child has misbehaved, a parent might take away TV viewing for a specified time.

Debate about the effects of punishment on children’s development continues (Deater-Deckard, 2013; Ferguson, 2013; Gershoff, 2013; Gershoff & Grogan-Kaylor, 2016; Gershoff, Lee, & Durrant, 2017; Grusec & others, 2013; Holden & others, 2017; Knox, 2010; Laible, Thompson, & Froimson, 2015; Lansford & others, 2012). Several longitudinal studies have found that physical punishment of young children is associated with higher levels of aggression later in childhood and adolescence (Berlin & others, 2009; Gershoff & others, 2012; Lansford & others, 2014; Taylor & others, 2010; Thompson & others, 2017). In one longitudinal study, harsh physical punishment in childhood was linked to a higher incidence of intimate partner violence in adulthood (Afifi & others, 2017b).

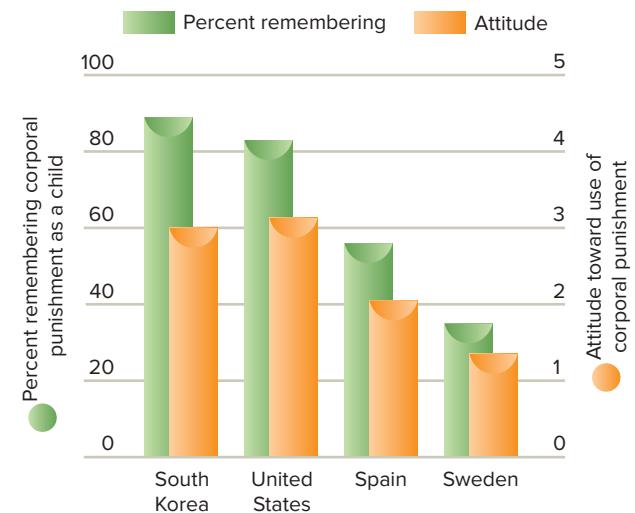

However, a meta-analysis that focused on longitudinal studies revealed that the negative outcomes of punishment on children’s internalizing and externalizing problems were minimal (Ferguson, 2013). A research review of 26 studies also concluded that only severe or predominant use of spanking, not mild spanking, compared unfavorably with alternative discipline practices (Larzelere & Kuhn, 2005). Nonetheless, in a recent meta-analysis, when physical punishment was not abusive it still was linked to detrimental child outcomes (Gershoff & Grogan-Kaylor, 2016). And in a recent Japanese study, occasional spanking at 3 years of age was associated with a higher level of behavioral problems at 5 years of age (Okusono & others, 2017).

Some experts (including Diana Baumrind) argue that much of the evidence for the negative effects of physical punishment is based on studies in which parents acted in an abusive manner (Baumrind, Larzelere, & Cowan, 2002). She concludes from her research that when parents use punishment in a calm, reasoned manner (which she says characterized most of the authoritative parents in her studies), children’s development benefits. In sum, she emphasizes that physical punishment does not need to present children with an out-of-control adult who is yelling and screaming, as well as spanking.

**FIGURE 3**

**CORPORAL PUNISHMENT IN DIFFERENT COUNTRIES.** A five-point scale was used to assess attitudes toward corporal punishment, with scores closer to 1 indicating an attitude against its use and scores closer to 5 suggesting an attitude favoring its use. *Why are studies of corporal punishment correlational studies, and how does that affect their usefulness?*

Thus, in the view of some experts, it is still difficult to determine whether the effects of physical punishment are harmful to children's development, although such a view might be distasteful to some individuals (Ferguson, 2013; Grusec & others, 2013). And as with other research on parenting, research on punishment is correlational in nature, making it difficult to discover causal factors. Also, consider the concept of reciprocal socialization, discussed in the chapter on "Socioemotional Development in Infancy," which emphasizes bidirectional child and parent influences. Researchers have found links between children's early behavioral problems and parents' greater use of physical punishment over time (Laible, Thompson, & Froimson, 2015; Sheehan & Watson, 2015).

In one research review, Elizabeth Gershoff (2013) concluded that the defenders of spanking have not produced any evidence that spanking produces positive outcomes for children, and she noted that negative outcomes of spanking have been replicated in many studies. Also, one thing that is clear regarding research on punishment of children is that if physical punishment is used, it needs to be mild, infrequent, age-appropriate, and used in the context of a positive parent-child relationship (Grusec, 2011). It is also clear that when physical punishment involves abuse, it can be very harmful to children's development (Almy & Cicchetti, 2018; Cicchetti, 2017). And an increasing majority of leading experts on parenting conclude that physical punishment has harmful effects on children and should not be used (Afifi & others, 2017a; Gershoff, Lee, & Durrant, 2017; Holden & others, 2017).

What characterizes coparenting?  
©Shutterstock/ESB Professional

**Coparenting** The support that parents provide one another in jointly raising a child is called **coparenting**. Poor coordination between parents, undermining of the other parent, lack of cooperation and warmth, and disconnection by one parent are conditions that place children at risk for problems (Pruett & others, 2017; Reader, Teti, & Cleveland, 2017). For example, one study revealed that coparenting influenced young children's effortful control above and beyond maternal and paternal parenting by themselves (Kareman & others, 2008). Another study found that greater father involvement in young children's play was linked to an increase in supportive coparenting (Jia & Schoppe-Sullivan, 2011). Researchers also have found that unmarried African American parents who were instructed in coparenting techniques during the prenatal period and also one month after the baby was born had higher levels of rapport, communication, and problem-solving skills when the baby was 3 months old (McHale, Salman-Engin, & Coovert, 2015).

## CHILD MALTREATMENT

Unfortunately, punishment sometimes leads to the abuse of infants and children (Cicchetti, 2017; Doyle & Cicchetti, 2018). In 2013, 679,000 U.S. children were found to be victims of child abuse at least once during that year (U.S. Department of Health and Human Services, 2015). Ninety-one percent of these children were abused by one or both parents. Laws in many states now require physicians and teachers to report suspected cases of child abuse, yet many cases go unreported, especially those involving battered infants.

Whereas the public and many professionals use the term *child abuse* to refer to both abuse and neglect, developmentalists increasingly use the term *child maltreatment* (Almy & Cicchetti, 2018; Cicchetti & Toth, 2017). This term does not have quite the emotional impact of the term *abuse* and acknowledges that maltreatment includes diverse conditions.

**Types of Child Maltreatment** The four main types of child maltreatment are physical abuse, child neglect, sexual abuse, and emotional abuse (Jackson, Kissoon, & Greene, 2015; National Clearinghouse on Child Abuse and Neglect, 2013):

- *Physical abuse* is characterized by the infliction of physical injury as a result of punching, beating, kicking, biting, burning, shaking, or otherwise harming a child. The parent or other person may not have intended to hurt the child; the injury may have resulted from excessive physical punishment (Lo & others, 2017; Smith & others, 2018).
- *Child neglect* is characterized by failure to provide for the child's basic needs (Naughton & others, 2017). Neglect can be physical (abandonment, for example), educational (allowing chronic truancy, for example), or emotional (marked inattention to

Child maltreatment involves grossly inadequate and destructive aspects of parenting.

### Darla Botkin, Marriage and Family Therapist

Darla Botkin is a marriage and family therapist who teaches, conducts research, and engages in marriage and family therapy. She is on the faculty of the University of Kentucky. Botkin obtained a bachelor's degree in elementary education with a concentration in special education and then went on to receive a master's degree in early childhood education. She spent the next six years working with children and their families in a variety of settings, including child care, elementary school, and Head Start. These experiences led Botkin to recognize the interdependence of the developmental settings that children and their parents experience (such as home, school, and work). She returned to graduate school and obtained a Ph.D. in family studies from the University of Tennessee. She then became a faculty member in the Family Studies program at the University of Kentucky. Completing further coursework and clinical training in marriage and family therapy, she became certified as a marriage and family therapist.

Botkin's current interests include working with young children in family therapy, addressing gender and ethnic issues in family therapy, and exploring the role of spirituality in family wellness.

the child's needs, for example). Child neglect is by far the most common form of child maltreatment. In every country where relevant data have been collected, neglect occurs up to three times as often as abuse (O'Hara & others, 2018). A recent research review of risk factors for engaging in child neglect found that most risks involved parent factors, including a history of antisocial behavior/criminal offending, having mental/physical problems, and experiencing abuse in their own childhood (Mulder & others, 2018).

- *Sexual abuse* includes fondling a child's genitals, intercourse, incest, rape, sodomy, exhibitionism, and commercial exploitation through prostitution or the production of pornographic materials (Daigneault & others, 2017; Oates, 2018; Prino, Longobardi, & Settanni, 2018).
- *Emotional abuse (psychological/verbal abuse/mental injury)* includes acts or omissions by parents or other caregivers that have caused, or could cause, serious behavioral, cognitive, or emotional problems (Hagborg, Tidefors, & Fahlke, 2017).

Although any of these forms of child maltreatment may be found separately, they often occur in combination. Emotional abuse is almost always present when other forms are identified.

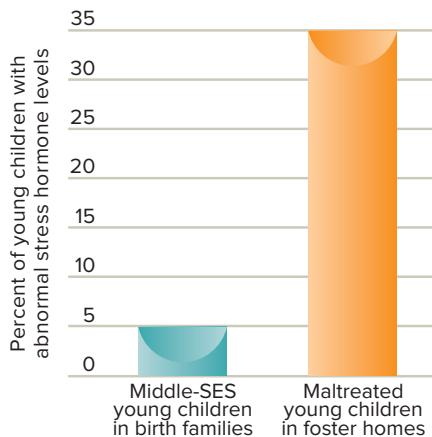

**The Contexts of Abuse** No single factor causes child maltreatment (Almy & Cicchetti, 2018; Cicchetti & Toth, 2017; Doyle & Cicchetti, 2018). A combination of factors, including the culture, family, and developmental characteristics of the child, likely contribute to child maltreatment.

The extensive violence that takes place in American culture, including TV violence, is reflected in the occurrence of violence in the family (Leppakoski, Flinck, & Paavilainen, 2015). The family itself is obviously a key part of the context of abuse (Cicchetti, 2017; McCarroll & others, 2017). Among the family and family-associated characteristics that may contribute

**ABNORMAL STRESS HORMONE LEVELS IN YOUNG CHILDREN IN DIFFERENT TYPES OF REARING CONDITIONS**

to child maltreatment are parenting stress, substance abuse, social isolation, single parenting, and socioeconomic difficulties (especially poverty) (Doyle & Cicchetti, 2018). The interactions of all family members need to be considered, regardless of who performs the violent acts against the child. For example, even though the father may be the one who physically abuses the child, the behavior of the mother, the child, and siblings also should be evaluated.

Were parents who abuse children abused by their own parents? A 30-year longitudinal study found that offspring of parents who engaged in child maltreatment and neglect are at risk for engaging in child neglect and sexual maltreatment themselves (Widom, Czaja, & DuMont, 2015). It is estimated that about one-third of parents who were abused themselves when they were young go on to abuse their own children (Cicchetti & Toth, 2006). Thus, some, but not a majority, of parents are involved in an intergenerational transmission of abuse.

**Developmental Consequences of Abuse** Among the consequences of child maltreatment in childhood and adolescence are poor emotion regulation, attachment problems, problems in peer relations, difficulty in adapting to school, and other psychological problems such as depression and delinquency (Bell & others, 2018; Doyle & Cicchetti, 2018). As shown in Figure 4, maltreated young children in foster care were more likely to show abnormal stress hormone levels than middle-SES young children living with their birth family (Gunnar, Fisher, & The Early Experience, Stress, and Prevention Network, 2006). In this study, the abnormal stress hormone levels were mainly present in the foster children who were neglected, best described as “institutional neglect” (Fisher, 2005). Abuse also may have this effect on young children (Gunnar & others, 2006). A recent study also found that physical abuse was linked to lower levels of cognitive development and school engagement in children (Font & Cage, 2018). Adolescents who experienced abuse or neglect as children are more likely than adolescents who were not maltreated as children to engage in violent romantic relationships, delinquency, sexual risk taking, and substance abuse (Trickett, Negriff, & Peckins, 2011). And a recent study found that exposure to either physical or sexual abuse in childhood and adolescence was linked to an increase in 13- to 18-year-olds’ suicidal ideation, plans, and attempts (Gomez & others, 2017).

Later, during the adult years, individuals who were maltreated as children are more likely to experience physical ailments, mental problems, and sexual problems (Lacelle & others, 2012). In a longitudinal study, people who had experienced abuse and neglect in the first five years of life had higher rates of interpersonal problems and lower academic achievement from childhood through their thirties (Raby & others, 2018). Among these interpersonal problems, people who were maltreated as children often have difficulty establishing and maintaining healthy intimate relationships (Dozier, Stovall-McClough, & Albus, 2009). As adults, maltreated children are also at higher risk for violent behavior toward other adults—especially dating partners and marital partners—as well as substance abuse, anxiety, and depression (Miller-Perrin, Perrin, & Kocur, 2009). One study also revealed that adults who had experienced child maltreatment were at increased risk for financial and employment-related difficulties (Zielinski, 2009).

An important research agenda is to discover how to prevent child maltreatment or to intervene in children’s lives when they have been maltreated (Almy & Cicchetti, 2018; Cozza & others, 2018; Weiler & Taussig, 2018). In one study of maltreating mothers and their 1-year-olds, two treatments were effective in reducing child maltreatment: (1) home visitation that emphasized improved parenting, coping with stress, and increased support for the mother; and (2) parent-infant psychotherapy that focused on improving maternal-infant attachment (Cicchetti, Toth, & Rogosch, 2005).

## SIBLING RELATIONSHIPS AND BIRTH ORDER

How do developmentalists characterize sibling relationships? How extensively does birth order influence behavior?

**Sibling Relationships** Approximately 80 percent of American children have one or more siblings—that is, sisters and brothers (Dunn, 2015; Fouts & Bader, 2017). If you grew up with siblings, you probably have abundant memories of aggressive, hostile interchanges. Siblings in the presence of each other when they are 2 to 4 years of age, on average, have a conflict once every 10 minutes and then the conflicts go down somewhat from 5 to 7 years of age (Kramer, 2006). What do parents do when they encounter siblings having a verbal or physical confrontation? One study revealed that they do one of three things: (1) intervene and try to help their children resolve the conflict, (2) admonish or threaten them, or (3) do nothing at

all (Kramer & Perozynski, 1999). Of interest is that in families with two siblings 2 to 5 years of age, the most frequent parental reaction is to do nothing at all.

Laurie Kramer (2006), who has conducted a number of research studies on siblings, says that not intervening and letting sibling conflict escalate are not good strategies. She developed a program titled “More Fun with Sisters and Brothers” that teaches 4- to 8-year-old siblings social skills for developing positive interactions (Kramer & Radey, 1997). Among the social skills taught in the program are how to appropriately initiate play, how to accept and refuse invitations to play, how to take another person’s perspective, how to deal with angry feelings, and how to manage conflict.

However, conflict is only one of the many dimensions of sibling relations (McHale, Updegraff, & Whiteman, 2013; Pike & Oliver, 2017). Sibling relations also include helping, sharing, teaching, and playing, and siblings can act as emotional supports and communication partners as well as rivals for parental attention.

Do parents usually favor one sibling over others—and if so, does it make a difference in a child’s development? One study of 384 sibling pairs revealed that 65 percent of their mothers and 70 percent of their fathers showed favoritism toward one sibling (Aldercotte, White, & Hughes, 2016; Shebloski, Conger, & Widaman, 2005). When favoritism of one sibling occurred, it was linked to lower self-esteem and sadness in the less-favored sibling. Indeed, equality and fairness are major concerns of siblings’ relationships with each other and how they are treated by their parents (Campione-Barr, 2011; Campione-Barr, Greer, & Kruse, 2013).

Judy Dunn (2015), a leading expert on sibling relationships, recently described three important characteristics of sibling relationships:

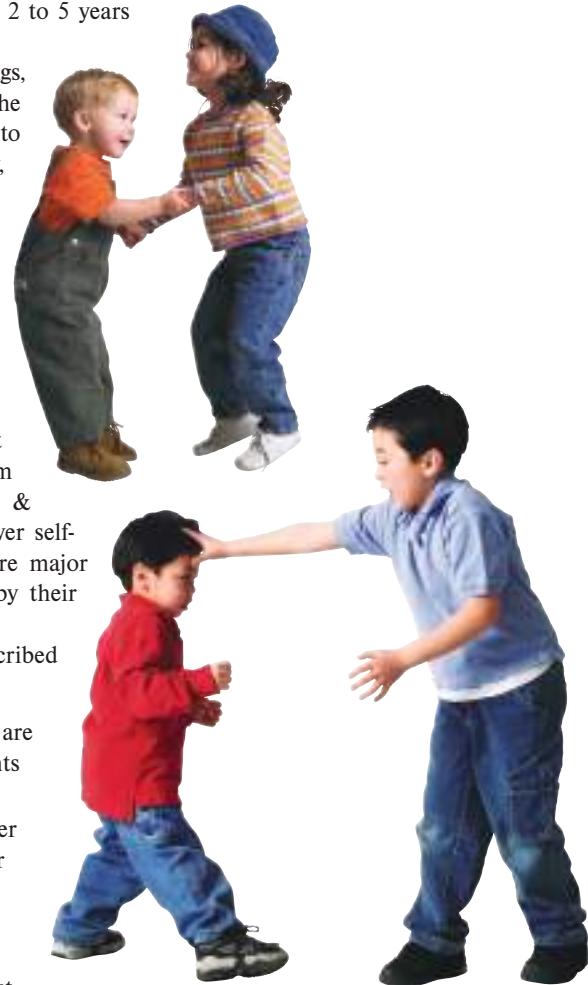

- *Emotional quality of the relationship.* Intense positive and negative emotions are often expressed by siblings toward each other. Many children and adolescents have mixed feelings toward their siblings.
- *Familiarity and intimacy of the relationship.* Siblings typically know each other very well, and this intimacy suggests that they can either provide support or tease and undermine each other, depending on the situation.
- *Variation in sibling relationships.* Some siblings describe their relationships more positively than others. Thus, there is considerable variation in sibling relationships. We just discussed that many siblings have mixed feelings about each other, but some children and adolescents mainly describe their siblings in warm, affectionate ways, whereas others primarily talk about how irritating and mean a sibling is. Research indicates that a high level of sibling conflict is linked to negative developmental outcomes (Fosco & others, 2012).

**Birth Order** Whether a child has older or younger siblings has been linked to development of certain personality characteristics. For example, one research review concluded that “first-borns are the most intelligent, achieving, and conscientious, while later-borns are the most rebellious, liberal, and agreeable” (Paulhus, 2008, p. 210). Compared with later-born children, firstborn children have also been described as more adult-oriented, helpful, conforming, and self-controlled. However, when such birth-order differences are reported, they often are small.

What accounts for differences related to birth order? Proposed explanations usually point to variations in interactions with parents and siblings associated with being in a particular position in the family. In one study, mothers became more negative, coercive, and restraining and played less with the firstborn following the birth of a second child (Dunn & Kendrick, 1982).

What is the only child like? The popular conception is that the only child is a “spoiled brat” with such undesirable characteristics as dependency, lack of self-control, and self-centered behavior. But researchers present a more positive portrayal of the only child. Only children often are achievement-oriented and display a desirable personality, especially in comparison with later-borns and children from large families (Falbo & Poston, 1993; Jiao, Ji, & Jing, 1996).

So far, our discussion suggests that birth order might be a strong predictor of behavior. However, an increasing number of family researchers stress that when all of the factors that influence behavior are considered, birth order by itself shows limited accuracy in predicting behavior. Think about some of the other important factors beyond birth order in children’s lives that influence their behavior. They include heredity, models of competency or incompetency that parents present to children on a daily basis, peer influences, school influences, socioeconomic

factors, sociohistorical factors, and cultural variations. When someone says firstborns are always like this but last-borns are always like that, the person is making overly simplistic statements that do not adequately take into account the complexity of influences on a child's development.

## THE CHANGING FAMILY IN A CHANGING SOCIETY

Beyond variations in the number of siblings, the families that children experience differ in many important ways (Hardy, Smeeding, & Ziliak, 2018; Hoffman & others, 2017; Lindsay & others, 2018; Parke, 2017; Patterson & others, 2018). The number of children growing up in single-parent families is staggering. As shown in Figure 5, the United States has one of the highest percentages of single-parent families in the world. Among two-parent families, there are those in which both parents work outside the home, one or both parents had a previous marriage that ended in divorce, or the parents are gay or lesbian. Differences in culture and socioeconomic status (SES) also influence families. How do these variations in families affect children?

**Working Parents** More than one of every two U.S. mothers with a child under the age of 5 is in the labor force; more than two of every three with a child from 6 to 17 years of age is employed. Maternal employment is a part of modern life, but its effects continue to be debated.

Most research on parental work has focused on the role of maternal employment on young children's development (O'Brien & others, 2014). However, the effects of working parents involve the father as well as the mother when such matters as work schedules, work-family stress, and unemployment are considered (Clarke-Stewart & Parke, 2014). For example, a study of almost 3,000 adolescents found a negative association between the father's, but not the mother's, unemployment and the adolescents' health (Bacikova-Sleskova, Benka, & Orosova, 2015).

Researchers have found that the nature of parents' work has more influence on children's development than whether a parent works outside the home (Han, 2009; O'Brien & others, 2014). And work can produce both positive and negative effects on parenting (Crouter & McHale, 2005). Ann Crouter (2006) described how parents bring their experiences at work into their homes. She concluded that parents who face poor working conditions such as long hours, overtime work, stressful work, and lack of autonomy on the job are likely to be more irritable at home and to engage in less effective parenting than their counterparts with better working conditions. A consistent finding is that children (especially girls) of working mothers engage in less gender stereotyping and have more egalitarian views of gender than children whose mothers are not employed outside the home (Goldberg & Lucas-Thompson, 2008).

**FIGURE 6**  
**DIVORCE AND CHILDREN'S EMOTIONAL PROBLEMS**

**PROBLEMS.** In Hetherington's research, 25 percent of children from divorced families showed serious emotional problems compared with only 10 percent of children from intact, never-divorced families. However, keep in mind that a substantial majority (75 percent) of the children from divorced families did not show serious emotional problems.

**Children in Divorced Families** It is estimated that 40 percent of children born to married parents in the United States will experience their parents' divorce (Hetherington & Stanley-Hagan, 2002). Let's examine some important questions about children in divorced families.

*Are children better adjusted in intact, never-divorced families than in divorced families?* Most researchers agree that children from divorced families show poorer adjustment than their counterparts in nondivorced families (Arkes, 2015; Hetherington, 2006; Lansford, 2012, 2013; Robbers & others, 2012; Weaver & Schofield, 2015) (see Figure 6). Those who have experienced multiple divorces are at greater risk. Children in divorced families are more likely than children in

nondivorced families to have academic problems, to show externalized problems (such as acting out and delinquency) and internalized problems (such as anxiety and depression), to be less socially responsible, to have less competent intimate relationships, to drop out of school, to become sexually active at an early age, to take drugs, to associate with antisocial peers, to have low self-esteem, and to be less securely attached as young adults (Lansford, 2012, 2013). In one study, individuals who had experienced their parents' divorce were more at risk for engaging in a suicide attempt (Alonzo & others, 2014). Nonetheless, keep in mind that a majority of children in divorced families do not have significant adjustment problems (Ahrons, 2007). One study found that 20 years after their parents had divorced when they were children, approximately 80 percent of adults concluded that their parents' decision to divorce had been a wise one (Ahrons, 2004).

Another study concluded that childhood divorce was linked to an increased number of cohabiting/marital partnerships and negative partner relationships the children had from 16 to 30 years of age (Fergusson, McLeod, & Horwood, 2014). An important point is that the outcomes just described for the life event of childhood divorce were explained by a variety of other factors and social contexts—parental history of illicit drug use, experience of childhood sexual abuse, lower-SES status at the time of the child's birth, and parental history of criminality. In another recent study, parental divorce, as well as child maltreatment, were linked to suicidal ideation in middle age (Stansfield & others, 2017).

*Should parents stay together for the sake of the children?* Whether parents should stay in an unhappy marriage for the sake of their children is one of the most commonly asked questions about divorce (Hetherington, 2006; Morrison, Fife, & Hertlien, 2017). If the stresses and disruptions in family relationships associated with an unhappy, conflictual marriage that erode the well-being of children are reduced by the move to a divorced, single-parent family, divorce can be advantageous. However, if the diminished resources and increased risks associated with divorce also are accompanied by inept parenting and sustained or increased conflict, not only within the divorced couple but also among the parents, children, and siblings, the best choice for the children would be for an unhappy marriage to be retained (Hetherington & Stanley-Hagan, 2002). It is difficult to determine how these “ifs” will play out when parents either remain together in an acrimonious marriage or become divorced.

Note that marital conflict may have negative consequences for children in the context of marriage or divorce (Cummings & others, 2017; Davies, Martin, & Sturge-Apple, 2016). And many of the problems that children from divorced homes experience begin during the predivorce period, a time when parents are often in active conflict with each other. Thus, when children from divorced homes show problems, the problems may not be due only to the divorce but also to the marital conflict that led to it.

E. Mark Cummings and his colleagues (Cummings & Miller, 2015; Cummings & others, 2017; Cummings & Valentino, 2015) have proposed *emotion security theory*, which has its roots in attachment theory and states that children appraise marital conflict in terms of their sense of security and safety in the family. These experts make a distinction between marital conflict that is negative for children (such as hostile emotional displays and destructive conflict tactics) and marital conflict that can be positive for children (such as marital disagreement that involves calmly discussing each person's perspective and then working together to reach a solution). In a recent study, interparental hostility was a stronger predictor of children's insecurity and externalizing problems than interparental disengagement and low levels of interparental cooperation (Davies & others, 2016). In another recent study, maladaptive marital conflict (destructive strategies, severity of arguments) when children were 2 years old was associated with an increase in internalizing problems eight years later due to an undermining of attachment security for girls, while negative emotional aftermath of conflict (unresolved, lingering tension) increased both boys' and girls' internalizing problems (Brock & Kochanska, 2016).

*How much do family processes matter in divorced families?* Family processes matter a great deal (Demby, 2016; Elam & others, 2016; Lansford, 2012; Luecken & others, 2016; Narayan & others, 2015; Warshak, 2014). For example, when divorced parents' relationship with each other is harmonious and when they use authoritative parenting, the adjustment of children improves (Hetherington, 2006). When the divorced parents can agree on child-rearing strategies and can maintain a cordial relationship with each other, frequent visits by the noncustodial parent usually benefit the child (Fabricius & others, 2010). Following a divorce, father involvement with children drops off more than mother involvement, especially if the children are girls. In one study, children were more likely to have behavior problems if their post-divorce home environment was less supportive and stimulating, their mother was less sensitive and more depressed, and if their

As marriage has become a more optional, less permanent institution in contemporary America, children and adolescents are encountering stresses and adaptive challenges associated with their parents' marital transitions.

household income was lower (Weaver & Schofield, 2015). Also, a study of divorced families revealed that an intervention focused on improving the mother-child relationship was linked to improvements in relationship quality that increased children's coping skills over the short term (6 months) and long term (6 years) (Velez & others, 2011). And a longitudinal study revealed that parental divorce experienced before age 7 was linked to a lower level of health through 50 years of age (Thomas & Hognas, 2015). Further, a recent study of noncustodial fathers in divorced families indicated that high father-child involvement and low interparental conflict were linked to positive child outcomes (Flam & others, 2016). Also, a recent research review concluded that coparenting (coparental support, cooperation, and agreement) following divorce was associated with positive child outcomes such as reduced anxiety and depression, as well as higher levels of self-esteem and academic performance (Lamela & Figueiredo, 2016).

*What factors influence an individual child's vulnerability to suffering negative consequences from living in a divorced family?* Among the factors involved in the child's risk and vulnerability is the child's adjustment prior to the divorce, as well as the child's personality and temperament, gender, and custody situation (Hetherington, 2006). Children whose parents later divorce often show poor adjustment before the breakup (Amato & Booth, 1996). Children who are socially mature and responsible, who show few behavioral problems, and who have an easy temperament are better able to cope with their parents' divorce. Children with a difficult temperament often have problems coping with their parents' divorce (Hetherington, 2000).

Earlier studies reported gender differences in response to divorce, with divorce being more negative for boys than girls in mother-custody families. However, more recent studies have shown that gender differences are less pronounced and consistent than was previously believed. Some of the inconsistency may be due to the increase in father custody, joint custody, and increased involvement of noncustodial fathers, especially in their sons' lives (Ziol-Guest, 2009).

Research on whether different types of custodial arrangements are better for children in divorced families has yielded inconsistent results (Parke, 2013). An analysis of studies found that children in joint-custody families were better adjusted than children in sole-custody families (Bauserman, 2002). However, joint custody works best for children when the parents can get along with each other (Clarke-Stewart & Parke, 2014).

*What role does socioeconomic status play in the lives of children in divorced families?* Custodial mothers experience the loss of about one-fourth to one-half of their predivorce income, in comparison with a loss of only one-tenth by custodial fathers. This income loss for divorced mothers is accompanied by increased workloads, high rates of job instability, and residential moves to less desirable neighborhoods with inferior schools (Braver & Lamb, 2013). One study found that children from families with higher incomes before the separation/divorce had fewer internalizing problems (Weaver & Schofield, 2015).

In sum, many factors are involved in determining how divorce influences a child's development (Hetherington, 2006; Lansford, 2012; Warshak, 2014). To read about some strategies for helping children cope with the divorce of their parents, see *Connecting Development to Life*.

**Gay and Lesbian Parents** Increasingly, gay and lesbian couples are creating families that include children (Farr, 2017; Oakley, Farr, & Scherer, 2017; Patterson, 2013, 2014; Patterson, Farr, & Hastings, 2015). Data indicate that approximately 20 percent of same-sex couples are raising children under the age of 18 in the United States (Gates, 2013).

Like heterosexual couples, gay and lesbian parents vary greatly. They may be single or they may have same-gender partners. Many lesbian mothers and gay fathers are noncustodial parents because they lost custody of their children to heterosexual spouses after a divorce. In addition, gays and lesbians are increasingly choosing parenthood through donor insemination or adoption (Simon & others, 2018). Researchers have found that the children conceived through new reproductive technologies—such as in vitro fertilization—are as well adjusted as their counterparts conceived by natural means (Golombok, 2011a, b).

Parenthood among lesbians and gays is controversial. Opponents claim that being raised by gay or lesbian parents harms the child's development. But researchers have found few differences between children growing up with lesbian mothers or gay fathers on the one hand, and children growing up with heterosexual parents on the other (Patterson, Farr, & Hastings, 2015). For example, children growing up in gay or lesbian families are just as popular with their peers, and no differences are found in the adjustment and mental health of children in these families compared with children in heterosexual families (Hyde & DeLamater, 2017). For example, in a recent study, the adjustment of school-aged children adopted during infancy by gay, lesbian, and heterosexual

## Communicating with Children About Divorce

Ellen Galinsky and Judy David (1988) developed a number of guidelines for communicating with children about divorce.

- **Explain the separation.** As soon as daily activities in the home make it obvious that one parent is leaving, tell the children. If possible, both parents should be present when children are told about the separation to come. The reasons for the separation are very difficult for young children to understand. No matter what parents tell children, children can find reasons to argue against the separation. It is extremely important for parents to tell the children who will take care of them and to describe the specific arrangements for seeing the other parent.
- **Explain that the separation is not the child's fault.** Young children often believe their parents' separation or divorce is their own fault. Therefore, it is important to tell children that they are not the cause of the separation. Parents need to repeat this statement a number of times.
- **Explain that it may take time to feel better.** Tell young children that it's normal to not feel good about what is happening and that many other children feel this way when their parents become separated. It is also okay for divorced parents to share some of their emotions with children by saying something like "I'm having a hard time since the separation just like you, but I know it's going to get better after a while." Such statements are best kept brief and should not criticize the other parent.

- **Keep the door open for further discussion.** Tell your children to come to you anytime they want to talk about the separation. It is healthy for children to express their pent-up emotions in discussions with their parents and to learn that the parents are willing to listen to their feelings and fears.
- **Provide as much continuity as possible.** The less children's worlds are disrupted by the separation, the easier their transition to a single-parent family will be. Thus, parents should maintain the rules already in place as much as possible. Children need parents who care enough not only to give them warmth and nurturance but also to set reasonable limits.
- **Provide support for your children and yourself.** After a divorce or separation, parents are as important to children as before the divorce or separation. Divorced parents need to provide children with as much support as possible. Parents function best when other people are available to give them support as adults and as parents. Divorced parents can find people who provide practical help and with whom they can talk about their problems.

parents showed no differences (Farr, 2017). Rather, children's behavior patterns and family functioning were predicted by earlier child adjustment issues and parental stress. In another recent study of lesbian and gay adoptive parents, 98 percent of the adoptive parents reported that their children had adjusted well to school (Farr, Oakley, & Ollen, 2016). Another study revealed more positive parenting in adoptive gay father families and fewer child externalizing problems in these families than in heterosexual families (Golombok & others, 2014). Contrary to the once-popular expectation that being raised by a gay or lesbian parent would result in the child growing up to be gay or lesbian, in reality the overwhelming majority of children from gay or lesbian families have a heterosexual orientation (Golombok & Tasker, 2010; Tasker & Golombok, 1997).

Researchers have compared the incidence of coparenting in adoptive heterosexual, lesbian, and gay couples with preschool-aged children (Farr & Patterson, 2013). Both self-reports and observations found that lesbian and gay couples shared child care more than heterosexual couples, with lesbian couples being more supportive than gay couples.

**Cultural, Ethnic, and Socioeconomic Variations** Parenting can be influenced by culture, ethnicity, and socioeconomic status (Nieto & Bode, 2018). Recall from Bronfenbrenner's ecological theory (see the "Introduction" chapter) that a number of social contexts influence the child's development. In Bronfenbrenner's theory, culture, ethnicity, and socioeconomic status are classified as part of the macrosystem because they represent broader, societal contexts.

**Cross-Cultural Studies** Different cultures often give different answers to basic questions such as what the father's role in the family should be, what support systems are

available to families, and how children should be disciplined (Gaskins, 2016). There are important cross-cultural variations in parenting and the value placed on children (Eo & Kim, 2018; Matsumoto & Juang, 2017; Suh & others, 2017). In some cultures, such as rural areas of many countries, authoritarian parenting is widespread (Smetana & Ball, 2018).

Cultural change, brought about by factors such as increasingly frequent international travel, access to the Internet and electronic communications, and economic globalization, is coming to families in many countries around the world. There are trends toward greater family mobility, migration to urban areas, separation as some family members work in cities or countries far from their homes, smaller families, fewer extended-family households, and increased maternal employment (Brown & Larson, 2002). These trends can change the resources that are available to children. For example, when several generations no longer live near each other, children may lose support and guidance from grandparents, aunts, and uncles. On the positive side, smaller families may produce more openness and communication between parents and children.

**Ethnicity** Families within different ethnic groups in the United States differ in their typical size, structure, composition, reliance on kinship networks, and levels of income and education (Gollnick & Chinn, 2017; Nieto & Bode, 2018). Large and extended families are more common among minority groups than among the non-Latino White majority. For example, 19 percent of Latino families have three or more children, compared with 14 percent of African American and 10 percent of White families. African American and Latino children interact more with grandparents, aunts, uncles, cousins, and more distant relatives than do White children.

Single-parent families are more common among African Americans and Latinos than among non-Latino White Americans. In comparison with two-parent households, single parents often have more limited resources of time, money, and energy (Evans, Li, & Sepanski Whipple, 2013). Ethnic minority parents also are less educated and more likely to live in low-income circumstances than their non-Latino White counterparts. Still, many impoverished ethnic minority families manage to find ways to raise competent children (Hurst, 2013; Nieto & Bode, 2018).

A major change in families in the last several decades has been the dramatic increase in the immigration of Latino and Asian families into the United States (Bas-Sarmiento & others, 2017; Giuntella, 2017; Koppelman, 2017; Non & others, 2018; Umana-Taylor & Douglass, 2017). Immigrant families often experience stressors uncommon to or less prominent among longtime residents, such as language barriers, dislocations and separations from support networks, the dual struggle to preserve identity and to acculturate, changes in SES status, and health (Anguiano, 2018; Cano & others, 2017; Chaudry & others, 2017; Wang & Palacios, 2017).

Further, an increasing number of children are growing up in transnational families, who move back and forth between the United States and Mexico or China (Solheim, Zaid, & Ballard, 2016). In some cases these children are left behind in their home country, and in other cases (especially in China), they are sent back to China to be raised by grandparents during their early childhood years. Such children might benefit from economic remittances but suffer emotionally from prolonged separation from their parents (Mazzucato, 2015).

Of course, individual families vary, and how ethnic minority families deal with stress depends on many factors (Anguiano, 2018; Cano & others, 2017; Chaudry & others, 2017; Non & others, 2018). Whether the parents are native-born or immigrants, how long the family has been in this country, and their socioeconomic status and national origin all make a difference (Gangamma & Shipman, 2018; Yoshikawa & others, 2016). The characteristics of the family's social context also influence its adaptation. What are the attitudes toward the family's ethnic group within its neighborhood or city? Can the family's children attend good schools? Are there community groups that welcome people from the family's ethnic group? Do members of the family's ethnic group form community groups of their own?

Ethnic minority/immigrant children and their parents are expected to move beyond their own cultural background and identify with aspects of the dominant culture. They undergo varying degrees of acculturation, which refers to cultural changes that occur when one culture comes in contact with another. Asian American parents, for example, may feel pressed to modify the traditional training style of parental control discussed earlier as they encounter the more permissive parenting typical of the dominant culture.

Researchers have found that many members of families that have recently immigrated to the United States adopt a bicultural orientation, selecting characteristics of the U.S. culture that help them to survive and advance, while retaining some aspects of their culture of origin (Moro, 2014). In adopting characteristics of the U.S. culture, Latino families are increasingly embracing its emphasis on education (Cooper, 2011). Although their school dropout rates have remained higher than those of other ethnic groups, toward the end of the first decade of the twenty-first century they declined considerably (National Center for Education Statistics, 2013). However, while many ethnic/immigrant families adopt a bicultural orientation, parenting in many ethnic minority families also focuses on issues associated with promoting children's ethnic pride, knowledge of their ethnic group, and awareness of discrimination (Gampe & Daum, 2018; Nieto & Bode, 2018; Umana-Taylor & Douglass, 2017).

**Socioeconomic Status** Low-income families have less access to resources than higher-income families do (Yoshikawa & others, 2017). The differential in access to resources encompasses nutrition, health care, protection from danger, and enriching educational and socialization opportunities such as tutoring and lessons in various activities (Hardy, Smeeding, & Ziliak, 2018). These differences are compounded in low-income families characterized by long-term poverty (Chaudry & others, 2017; Coley & others, 2018). One study found that persistent economic hardship and very early poverty were linked to lower cognitive functioning in children at 5 years of age (Schoon & others, 2012). And in another study, poverty-related adversity in family and school contexts in early childhood was linked to less effective executive function in second- and third-graders (Raver & others, 2013). A longitudinal study found that a multi-component (school-based educational enrichment and comprehensive family services) preschool to third grade intervention with low-income minority children in Chicago was effective in increasing their rate of high school graduation, as well as their undergraduate and graduate school success (Reynolds, Qu, & Temple, 2018).

In the United States and most Western cultures, differences have been found in child rearing among families with different socioeconomic statuses (SES) (Hoff, Laursen, & Tardif, 2002, p. 246):

- “Lower-SES parents (1) are more concerned that their children conform to society’s expectations, (2) create a home atmosphere in which it is clear that parents have authority over children,” (3) use physical punishment more in disciplining their children, and (4) are more directive and less conversational with their children.
- “Higher-SES parents (1) are more concerned with developing children’s initiative” and delay of gratification, “(2) create a home atmosphere in which children are more nearly equal participants and in which rules are discussed as opposed to being laid down” in an authoritarian manner, (3) are less likely to use physical punishment, and (4) “are less directive and more conversational” with their children.

## PEER RELATIONS

As children grow older, they spend an increasing amount of time with their *peers*—children of about the same age or maturity level.

**Peer Group Functions** What are the functions of a child's peer group? One of its most important functions is to provide a source of information and comparison about the world outside the family. Children receive feedback about their abilities from their peer group. Children evaluate what they do in terms of whether it is better than, as good as, or worse than what other children do. It is hard to make these judgments at home because siblings are usually older or younger.

Good peer relations promote normal socioemotional development (Bukowski, Laursen, & Rubin, 2018; Prinstein & others, 2018). Special concerns in peer relations focus on children who are withdrawn or aggressive (Coplan & others, 2018; Rubin & Barstead, 2018). Withdrawn children who are rejected by peers or are victimized and feel lonely are at risk for depression (Rubin & others, 2018). Children who are aggressive with their peers are at risk for a number of problems, including delinquency and dropping out of school (Nesi & others, 2017; Vitaro, Boivin, & Poulin, 2018).

**Developmental Changes** Recall from our discussion of gender that, by about the age of 3, children already prefer to spend time with same-sex rather than opposite-sex playmates, and this preference increases in early childhood. During these same years the frequency of peer interaction, both positive and negative, picks up considerably (Cillessen & Bukowski, 2018). Many preschool children spend considerable time in peer interaction conversing with playmates about such matters as “negotiating roles and rules in play, arguing, and agreeing” (Rubin, Bukowski, & Parker, 2006). And during early childhood children's interactions with peers become more coordinated and involve longer turns and sequences (Coplan & Arbeau, 2009).

**Friends** In early childhood, children distinguish between friends and nonfriends (Howes, 2009). For most young children, a friend is someone to play with. Young preschool children are more likely than older children to have friends who are of a different gender and ethnicity (Howes, 2009).

**The Connected Worlds of Parent-Child and Peer Relations** Parents may influence their children's peer relations in many ways, both directly and indirectly (Booth-Laforce & Groh, 2018). Parents affect such relations through their interactions with their children, how they manage their children's lives, and the opportunities they provide to their children (Brown & Bakken, 2011). For example, one study found that when mothers coached their preschool daughters about the negative aspects of peer conflicts involving relational aggression (harming someone by manipulating a relationship), the daughters engaged in lower rates of relational aggression (Werner & others, 2014).

Basic lifestyle decisions by parents—their choices of neighborhoods, churches, schools, and their own friends—largely determine the pool from which their children select possible friends. These choices in turn affect which children their children meet, their purpose in interacting, and eventually which children become their friends.

Researchers also have found that children's peer relations are linked to attachment security and parents' marital quality (Booth-LaForce & Groh, 2018). Early attachments to caregivers provide a connection to children's peer relations not only by creating a secure base from which children can explore social relationships beyond the family but also by conveying a

working model of relationships (Hartup, 2009). Researchers have found that when mothers coach their preschool daughters about the negative aspects of peer conflicts involving relational aggression (harming someone by manipulating a relationship), the daughters engage in lower rates of relational aggression (Werner & others, 2014).

Do these results indicate that children's peer relations always are wedded to parent-child relationships? Although parent-child relationships influence children's subsequent peer relations, children also learn other modes of relating through their relationships with peers. For example, rough-and-tumble play occurs mainly with other children, not in parent-child interaction. In times of stress, children often turn to parents rather than peers for support. In parent-child relationships, children learn how to relate to authority figures. With their peers, children are likely to interact on a much more equal basis and to learn a mode of relating based on mutual influence. We will have much more to say about peer relations later.

## PLAY

An extensive amount of peer interaction during childhood involves play, but social play is only one type of play. Play is a pleasurable activity in which children engage for its own sake, and its functions and forms vary (Hirsh-Pasek & Golinkoff, 2014).

**Play's Functions** Play is an important aspect of children's development (Bergen, 2015; Clark, 2016; Johnson & others, 2015; Taggart, Eisen, & Lillard, 2018). Theorists have focused on different aspects of play and highlighted a long list of functions (Henricks, 2015a, b).

According to Freud and Erikson, play helps children master anxieties and conflicts (Demanchick, 2015). Because tensions are relieved in play, children can cope more effectively with life's problems. Play permits children to work off excess physical energy and to release pent-up tensions. Therapists use *play therapy* both to allow children to work off frustrations and to analyze children's conflicts and ways of coping with them. Children may feel less threatened and be more likely to express their true feelings in the context of play (Clark, 2015, 2016; Demanchick, 2015).

Play also is an important context for cognitive development (Taggart, Eisen, & Lillard, 2018). Both Jean Piaget and Lev Vygotsky concluded that play is a child's work. Piaget (1962) maintained that play advances children's cognitive development. At the same time, he said, children's cognitive development *constrains* the way they play. Play permits children to practice their competencies and acquired skills in a relaxed, pleasurable way (Hirsh-Pasek & Golinkoff, 2014). Piaget thought that cognitive structures need to be exercised, and play provides the perfect setting for this exercise (DeLisi, 2015).

Vygotsky (1962) also considered play to be an excellent setting for cognitive development. He was especially interested in the symbolic and make-believe aspects of play, as when a child substitutes a stick for a horse and rides the stick as if it were a horse. For young children, the imaginary situation is real (Bodrova & Leong, 2015). Parents should encourage such imaginary play, because it advances the child's cognitive development, especially creative thought.

Daniel Berlyne (1960) described play as exciting and pleasurable in itself because it satisfies our exploratory drive. This drive involves curiosity and a desire for information about something new or unusual. Play encourages exploratory behavior by offering children the possibilities of novelty, complexity, uncertainty, surprise, and incongruity.

Let us play, for it is yet day  
And we cannot go to sleep;  
Besides, in the sky the little

**sensorimotor play** Behavior engaged in by infants that lets them derive pleasure from exercising their existing sensorimotor schemas.

**practice play** Play that involves repetition of behavior when new skills are being learned or when physical or mental mastery and coordination of skills are required for games or sports.

**pretense/symbolic play** Play in which the child transforms the physical environment into a symbol.

More recently, play has been described as an important context for the development of language and communication skills (Taggart, Eisen, & Lillard, 2018). Language and communication skills may be enhanced through discussions and negotiations regarding roles and rules in play as young children practice various words and phrases. These types of social interactions during play can benefit young children’s literacy skills (Bredekamp, 2017). Play is a central focus of the child-centered kindergarten and is thought to be an essential aspect of early childhood education (Feeney, Moravcik, & Nolte, 2019; Follari, 2019; Henniger, 2017; Morrison, 2018).

**Types of Play** The contemporary perspective on play emphasizes both the cognitive and the social aspects of play (Loizou, 2017; Sim & Xu, 2017). Among the most widely studied types of children’s play today are sensorimotor and practice play, pretense/symbolic play, social play, constructive play, and games.

**Sensorimotor and Practice Play** **Sensorimotor play** is behavior by infants that lets them derive pleasure from exercising their sensorimotor schemes. The development of sensorimotor play follows Piaget’s description of sensorimotor thought. Infants initially engage in exploratory and playful visual and motor transactions in the second quarter of the first year of life. At about 9 months of age, infants begin to select novel objects for exploration and play, especially responsive objects such as toys that make noise or bounce.

**Practice play** involves the repetition of behavior when new skills are being learned or when physical or mental mastery and coordination of skills are required for games or sports. Sensorimotor play, which often involves practice play, is primarily confined to infancy, whereas practice play can be engaged in throughout life. During the preschool years, children often engage in practice play.

**Pretense/Symbolic Play** **Pretense/symbolic play** occurs when the child transforms the physical environment into a symbol (Taggart, Eisen, & Lillard, 2018). Between 9 and 30 months of age, children increase their use of objects in symbolic play. They learn to transform objects—substituting them for other objects and acting toward them as if they were those other objects. For example, a preschool child treats a table as if it were a car and says, “I’m fixing the car,” as he grabs a leg of the table.

Many experts on play consider the preschool years the “golden age” of symbolic/pretense play that is dramatic or sociodramatic in nature. This type of make-believe play often appears at about 18 months of age and reaches a peak at 4 to 5 years of age, then gradually declines.

Some child psychologists conclude that pretend play is an important aspect of young children’s development and often reflects advances in their cognitive development, especially as an indication of symbolic understanding (Edmiston, 2017; Hakkarainen, Bredikyte, & Safarov, 2017; Taggart, Eisen, & Lillard, 2018). For example, Catherine Garvey (2000) and Angeline Lillard (2006) emphasize that hidden in young children’s pretend play narratives are remarkable capacities for role-taking, balancing of social roles, metacognition (thinking about thinking), testing of the reality-pretense distinction, and numerous nonegocentric capacities that reveal the remarkable cognitive skills of young children. A major accomplishment in early childhood is the development of children’s ability to share their pretend play with peers (Coplan & Arbeau, 2009). And researchers have found that pretend play contributes to young children’s self-regulation, mainly because of the self-monitoring and social sensitivity that is required in creating and enacting a sociodramatic narrative in cooperation with other children (Diamond & others, 2007).

**Social Play** **Social play** involves interaction with peers. Social play increases dramatically during the preschool years. For many children, social play is the main context for young children’s social interactions with peers (Solovieva & Quintanar, 2017).

**Constructive Play** **Constructive play** combines sensorimotor/practice play with symbolic representation. It occurs when children engage in the self-regulated creation of a product or a solution. Constructive play increases in the preschool years as symbolic play increases and sensorimotor play decreases. It also becomes a frequent form of play in the elementary school years, both within and outside of the classroom.

**Games** Games are activities that children engage in for pleasure and that have rules. Often they involve competition. Preschool children may begin to participate in social games that involve simple rules of reciprocity and turn taking. However, games take on a much stronger role in the lives of elementary school children. In one study, the highest incidence of game

playing occurred between 10 and 12 years of age (Eiferman, 1971). After age 12, games decline in popularity (Bergen, 1988).

**Trends in Play** Kathy Hirsh-Pasek, Roberta Golinkoff, and Dorothy Singer (Hirsh-Pasek & others, 2009; Singer, Golinkoff, & Hirsh-Pasek, 2006) are concerned about the small amount of time for free play that young children have today, reporting that it has declined considerably in recent decades. They especially are worried about young children's playtime being restricted at home and school so they can spend more time on academic subjects. They also point out that many schools have eliminated recess. And it is not just the declining time for free play that bothers them. They underscore that learning in playful contexts captivates children's minds in ways that enhance their cognitive and socioemotional development—Singer, Golinkoff, and Hirsh-Pasek's (2006) first book on play was titled *Play = Learning*. Among the cognitive benefits of play they described are skills in the following areas: creativity; abstract thinking; imagination; attention, concentration, and persistence; problem-solving; social cognition, empathy, and perspective taking; language; and mastery of new concepts. Among the socioemotional experiences and development they believe play promotes are enjoyment, relaxation, and self-expression; cooperation, sharing, and turn-taking; anxiety reduction; and self-confidence. With so many positive cognitive and socioemotional outcomes of play, clearly it is important that we find more time for play in young children's lives (Taggart, Eisen, & Lillard, 2018).

What are some of the benefits of play for children, according to Hirsh-Pasek and her colleagues?

## MEDIA/SCREEN TIME

Few developments in society in the second half of the twentieth century had a greater impact on children than television (Lever-Duffy & McDonald, 2018; Maloy & others, 2017). Television continues to have a strong influence on children's development, but children's use of other media and information/communication devices has led to the use of the term *screen time* to describe the amount of time individuals spend with television, DVDs, computers, video games, and hand-held electronic devices such as smartphones (Gebremariam & others, 2017; Goh & others, 2016; Li & others, 2017). A national survey found that there was a dramatic increase in young children's use of mobile devices in just two years from 2011 to 2013 (Common Sense Media, 2013). In this survey, playing games was children's most common activity on mobile devices, followed by using apps, watching videos, and watching TV shows or movies.

Despite the move to mobile devices, television is still the elephant in young children's media life, with 2- to 4-year-old children watching TV approximately 2 to 4 hours per day (Common Sense Media, 2013). In the U.S. national survey, 50 percent of children's screen time was spent

**social play** Play that involves social interactions with peers.

**constructive play** Play that combines sensorimotor and repetitive activity with symbolic representation of ideas. Constructive play occurs when children engage in self-regulated creation or construction of a product or a solution.

**games** Activities engaged in for pleasure that include rules and often involve competition with one or more individuals.

What are some concerns about the increase in children's media and screen time?

in front of TV sets (Common Sense Media, 2013). Compared with their counterparts in other developed countries, children in the United States watch television for considerably longer periods. The American Academy of Pediatrics (2016) recommends that 2- to 5-year olds watch no more than one hour of TV a day. The Academy also recommends that they only should be exposed to high-quality programs, such as *Sesame Street* and other PBS shows for young children.

Some types of TV shows are linked to positive outcomes for children. For example, a meta-analysis of studies in 14 countries found that watching the TV show *Sesame Street* produced positive outcomes in three areas: cognitive skills, learning about the world, and social reasoning and attitudes toward outgroups (Mares & Pan, 2013).

However, too much screen time can have a negative influence on children by making them passive learners, distracting them from doing homework, teaching them stereotypes, providing them with violent models of aggression, and presenting them with unrealistic views of the world (Calvert, 2015; Picherot & others, 2018). Among other concerns about young children having so much screen time are decreased time spent in play, less time interacting with peers, higher rates of aggression, decreased physical activity, lower cognitive development, poor sleep habits, and increased risk of being overweight or obese (Berglind & others, 2018). One research review concluded that greater amounts of screen time (mostly involving TV viewing) were associated with a lower level of cognitive development in early childhood (Carson & others, 2015). Also, a recent study of preschool children found that each additional hour of screen time was linked to less nightly sleep, later bedtimes, and reduced likelihood of sleeping 10 or more hours per night (Xu & others, 2016). Further, researchers have found that a high level of TV viewing is linked to a greater incidence of obesity in children and adolescents (Berglind & others, 2018). For example, a recent study of 2- to 6-year-olds found that increased TV viewing time on weekends was associated with a higher risk of being overweight or obese (Kondolot & others, 2017). Indeed, viewing as little as one hour of television daily was associated with an increase in body mass index (BMI) between kindergarten and the first grade (Peck & others, 2015).

A higher degree of parental monitoring of children's media use was linked to a number of positive outcomes in children's lives (more sleep, better school performance, less aggressive behavior, and more prosocial behavior) (Gentile & others, 2014). Researchers also have found that parental reductions in their own screen time were associated with decreased screen time for their children (Sanders, Parent, & Forehand, 2018; Xu, Wen, & Rissel, 2014).

**Effects of Television on Children's Aggression** The extent to which children are exposed to violence and aggression on television raises special concerns (Calvert, 2015). For example, Saturday morning cartoon shows average more than 25 violent acts per hour. One study revealed that spending increased time viewing TV violence, video game violence, and music video violence was independently associated with a higher level of physical aggression in children (Coker & others, 2015). Also, in one experiment, preschool children were randomly assigned to one of two groups: One group watched television shows taken directly from violent Saturday morning cartoons on 11 days; the second group watched television cartoon shows with all of the violence removed (Steur, Applefield, & Smith, 1971). The children were then observed during play at their preschool. The preschool children who had seen the TV cartoon shows with violence kicked, choked, and pushed their playmates more than did the preschool children who had watched nonviolent TV cartoon shows. Because the children were randomly assigned to the two conditions (TV cartoons with violence versus nonviolent TV cartoons), we can conclude that exposure to TV violence caused the increased aggression in the children in this investigation.

In addition to television violence, there is increased concern about children who play violent video games, especially those that are highly realistic (DeWall & others, 2013). Research reviews have concluded that playing violent video games is linked to aggression in both males and females (Gentile, 2011).

**Effects of Television on Children's Prosocial Behavior** Television can have a positive influence on children's development by presenting motivating educational programs, providing information about the world beyond their immediate environment, and displaying models of prosocial behavior (Maloy & others, 2017). A recent meta-analysis found that children's exposure to prosocial media is linked to higher levels of prosocial behavior and empathetic concern (Coyne & others, 2018). For example, researchers have found that when children watch positive social interchanges on the TV show *Sesame Street*, they subsequently are likely to imitate these positive social behaviors (Truglio & Kotler, 2014).

The middle and late childhood years bring further changes in children's socioemotional development. Development of self-understanding and understanding of others becomes more sophisticated, emotional understanding improves, and moral reasoning advances. Children now spend less time with parents, but parents continue to play very important roles in children's lives, especially in guiding their academic achievement and managing their opportunities. Peer status and friendship become more important in children's peer relations, and school takes on a stronger academic focus.

# Socioemotional Development in Early Childhood

## 1 Emotional and Personality Development

The Self

Emotional Development

**LG1**

Discuss emotional and personality development in early childhood.

- In Erikson's theory, early childhood is a period when development involves resolving the conflict of initiative versus guilt. The toddler's rudimentary self-understanding develops into the preschooler's representation of the self in terms of body parts, material possessions, and physical activities. At about 4 to 5 years of age, children also begin to use trait-like self-descriptions. Young children display more sophisticated self-understanding and understanding of others than was previously thought.
- Advances in young children's emotional development involve expressing emotions, understanding emotions, and regulating emotions. Young children's range of emotions expands during early childhood as they increasingly experience self-conscious emotions such as pride, shame, and guilt. Between 2 and 4 years old, children use an increasing number of terms to describe emotion and learn more about the causes and consequences of feelings. At 4 to 5 years of age, children show an increased ability to reflect on emotions and understand that a single event can elicit different emotions in different people. They also show a growing awareness of the need to manage emotions to meet social standards.
- Emotion-coaching parents have children who engage in more effective self-regulation of their emotions than do emotion-dismissing parents. Emotion regulation plays an important role in successful peer relations.

## Moral Development

- Moral development involves thoughts, feelings, and behaviors regarding rules and conventions about what people should do in their interactions with others. Freud's psychoanalytic theory emphasizes the importance of feelings in the development of the superego, the moral branch of personality. Positive emotions, such as empathy, also contribute to the child's moral development.
- Piaget analyzed moral reasoning and concluded that children from about 4 to 7 years of age display heteronomous morality, judging behavior by its consequences; then, at about 10 years of age and older, they develop autonomous morality.
- According to behavioral and social cognitive theorists, moral behavior develops as a result of reinforcement, punishment, and imitation, and there is considerable situational variability in moral behavior. Conscience refers to an internal regulation of standards of right and wrong that involves an integration of moral thought, feeling, and behavior.
- Young children's conscience emerges out of relationships with parents. Parents influence young children's moral development through the quality of parent-child relationships, by being proactive in helping children avert misbehavior, and by engaging children in conversational dialogue about moral issues.
- Gender refers to the social and psychological dimensions of being male or female. Gender identity is acquired by 2½ years of age for most children. A gender role is a set of expectations that prescribes how females or males should think, act, and feel. Gender typing refers to the acquisition of a traditional masculine or feminine role.
- Biological influences on gender development include chromosomes and hormones. However, biology does not completely dictate destiny in gender development; children's socialization experiences matter a great deal. Social role theory, psychoanalytic theory, and social cognitive theory emphasize various aspects of social experiences in the development of gender characteristics. Parents influence children's gender development, and peers are especially adept at rewarding gender-appropriate behavior. Gender schema theory emphasizes the role of cognition in gender development.

## 2 Families

### Parenting

**LG2**

Explain how families can influence young children's development.

- Authoritarian, authoritative, neglectful, and indulgent are four main parenting styles. Authoritative parenting is the most widely used style around the world and is the style most often associated with children's social competence. However, ethnic variations in parenting styles suggest that in Asian American families, some aspects of control may benefit children.
- Physical punishment is widely used by U.S. parents, but some experts conclude that there are a number of reasons it should not be used with children. However, there currently is controversy about the effects of physical punishment on children, with few studies making a distinction between abusive and mild physical punishment.
- Coparenting has positive effects on children's development.
- Child maltreatment may take the form of physical abuse, child neglect, sexual abuse, and emotional abuse. Child maltreatment places the child at risk for academic, emotional, and social problems. Adults who suffered child maltreatment are also vulnerable to a range of problems.
- Siblings interact with each other in positive and negative ways. Birth order is related in certain ways to personality characteristics—for example, firstborns are more adult-oriented and self-controlled than later-born children. Only children often are achievement-oriented. By itself, however, birth order is not a good predictor of behavior.
- In general, having both parents employed full-time outside the home has not been shown to have negative effects on children. However, the nature of parents' work can affect their parenting quality.
- Divorce can have negative effects on children's adjustment, but so can an acrimonious relationship between parents who stay together for their children's sake. If divorced parents develop a harmonious relationship and practice authoritative parenting, children's adjustment improves.
- Researchers have found few differences between children growing up in gay or lesbian families and children growing up in heterosexual families.

### Child Maltreatment

### Sibling Relationships and Birth Order

### The Changing Family in a Changing Society

- Cultures vary on a number of issues regarding families. African American and Latino children are more likely than White American children to live in single-parent families and larger families and to have extended family connections.
- Low-income families have less access to resources than higher-income families do. Lower-SES parents create a home atmosphere with more parental authority and greater use of physical punishment, while higher-SES parents are more concerned about developing children's initiative and ability to delay gratification.

### 3 Peer Relations, Play, and Media/Screen Time

LG3

Describe the roles of peers, play, and media/screen time in young children's development.

Peer Relations

Play

Media/Screen Time

- Peers are powerful socialization agents. Peers provide a source of information and comparison about the world outside the family. In early childhood, children distinguish between friends and nonfriends, with a friend often described as someone to play with.
- Parent-child and peer relationships are often connected. Parents influence their children's peer relations by how they manage children's lives and the opportunities they provide for interacting with peers. Rough-and-tumble play is more likely to occur in peer relations, whereas in times of stress children often turn to parents rather than peers for support.
- Play's functions include affiliation with peers, tension release, advances in cognitive development, exploration, and provision of a safe haven. The contemporary perspective on play emphasizes both the cognitive and the social aspects of play.
- Among the most widely studied types of children's play are sensorimotor play, practice play, pretense/symbolic play, social play, constructive play, and games.
- There is concern about the decreasing number of hours children spend in free play and in recess at school. Because play is a powerful positive context for the development of children's cognitive and socioemotional skills, it is important that we find more time for play in children's lives.
- Young children watch 2 to 4 hours of TV per day on average, but experts recommend that they watch 1 hour or less. Young children increasingly are spending time with other media and information/communication devices such as computers, DVDs, video games, and iPhones, which has given rise to the term *screen time*. Screen time can have both negative influences (such as turning children into passive learners, presenting them with aggressive models, and decreasing time spent with peers and in play and physical activity) and positive influences (such as providing models of prosocial behavior) on children's development. Both watching TV violence and playing violent video games have been linked to children's aggressive behavior. Watching prosocial behavior on TV can teach children positive social skills.

## Middle and Late Childhood

In middle and late childhood, children are on a different plane, belonging to a generation and feeling all their own. It is the wisdom of the human life span that at no time are children more ready to learn than during the period of expansive imagination at the end of early childhood. Children develop a sense of wanting to make things—and not just to make them, but to make them well and even perfectly. They seek to know and to understand. They are remarkable for their intelligence and for their curiosity. Their parents continue to be important influences in their lives, but their growth also is shaped by peers and friends. They don't think much about the future or about the past, but they enjoy the present moment. This section consists of two chapters: "Physical and Cognitive Development in Middle and Late Childhood" and "Socioemotional Development in Middle and Late Childhood."

## The following comments were made by Angie, an elementary-school-aged girl:

When I was 8 years old, I weighed 125 pounds. My clothes were the size that large teenage girls wear. I hated my body, and my classmates teased me all the time. I was so overweight and out of shape that when I took a P.E. class my face would get red and I had trouble breathing. I was jealous of the kids who played sports and weren't overweight like I was.

I'm 9 years old now and I've lost 30 pounds. I'm much happier and proud of myself. How did I lose the weight? My mom said she had finally decided enough was enough. She took me to a pediatrician who specializes in helping children lose weight and keep it off. The pediatrician counseled my mom about my eating and exercise habits, then had us join a group that he had created for overweight children and their parents. My mom and I go to the group once a week and we've now been participating in the program for 6 months. I no longer eat fast food meals and my mom is cooking more healthy meals. Now that I've lost weight, exercise is not as hard for me and I don't get teased by the kids at school. My mom's pretty happy too because she's lost 15 pounds herself since we've been in the counseling program.

Not all overweight children are as successful as Angie at reducing their weight. Indeed, being overweight or obese in childhood has become a major national concern in the United States. Later in this chapter, we will further explore being overweight and obese in childhood, including obesity's causes and outcomes.

### topical connections *looking back*

Children grow more slowly in early childhood than in infancy, but they still grow an average of 2.5 inches and gain 4 to 7 pounds a year. In early childhood, the most rapid growth in the brain occurs in the prefrontal cortex. The gross and fine motor skills of children also become smoother and more coordinated. In terms of cognitive development, early childhood is a period in which young children increasingly engage in symbolic thought. Young children's information-processing skills also improve considerably—executive and sustained attention advance, short-term memory gets better, executive function increases, and their understanding of the human mind makes considerable progress. Young children also increase their knowledge of language's rule systems, and their literacy benefits from active participation in a wide range of language experiences. Most young children attend an early childhood education program, and there are many variations in these programs.

# preview

During the middle and late childhood years, children grow taller, heavier, and stronger. They become more adept at using their physical skills, and they develop new cognitive skills. This chapter is about physical and cognitive development in middle and late childhood. To begin, we will explore aspects of physical development.

## 1 Physical Changes and Health

LG1

Describe physical changes and health in middle and late childhood.

Body Growth and Change

The Brain

Motor Development

Exercise

Health, Illness, and Disease

Continued change characterizes children's bodies during middle and late childhood, and their motor skills improve. As children move through the elementary school years, they gain greater control over their bodies and can sit and keep their attention focused for longer periods of time. Regular exercise is one key to making these years a time of healthy growth and development.

### BODY GROWTH AND CHANGE

The period of middle and late childhood involves slow, consistent growth (Hockenberry, Wilson, & Rodgers, 2017). This is a period of calm before the rapid growth spurt of adolescence. During the elementary school years, children grow an average of 2 to 3 inches a year until, at the age of 11, the average girl is 4 feet, 10 inches tall, and the average boy is 4 feet, 9 inches tall. During the middle and late childhood years, children gain about 5 to 7 pounds a year. The weight increase is due mainly to increases in the size of the skeletal and muscular systems, as well as the size of some body organs.

Proportional changes are among the most pronounced physical changes in middle and late childhood. Head circumference and waist circumference decrease in relation to body height (Kliegman & others, 2016; Perry & others, 2018). A less noticeable physical change is that bones continue to ossify during middle and late childhood but yield to pressure and pull more than mature bones.

### THE BRAIN

The development of brain-imaging techniques such as magnetic resonance imaging (MRI) has led to increased research on changes in the brain during middle and late childhood and links between these brain changes and cognitive development (Khundrakpam & others, 2018; Mah, Geeraert, & Lebel, 2017). Total brain volume stabilizes by the end of late childhood, but significant changes in various structures and regions of the brain continue to occur. In particular, the brain pathways and circuitry involving the prefrontal cortex, the highest level in the brain, continue to increase during middle and late childhood (see Figure 1). These advances in the prefrontal cortex are linked to children's improved attention, reasoning, and cognitive control (de Haan & Johnson, 2016; Wendelken & others, 2016, 2017).

Leading developmental neuroscientist Mark Johnson and his colleagues (2009) proposed that the prefrontal cortex likely orchestrates the functions of many other brain regions during development. As part of this neural leadership role, the prefrontal cortex may provide an advantage to neural networks and connections that include the prefrontal cortex. In their view, the prefrontal cortex coordinates the best neural connections for solving a problem at hand.

Changes also occur in the thickness of the cerebral cortex (cortical thickness) in middle and late childhood (Thomason & Thompson, 2011). One study used brain scans to assess cortical thickness in 5- to 11-year-old children (Sowell & others, 2004). Cortical thickening across a two-year time period was observed in the temporal and frontal lobe areas that function in language, which may reflect improvements in language abilities such as reading. Figure 6 in "Physical Development in Infancy" shows the locations of the temporal and frontal lobes in the brain.

#### Brain Development

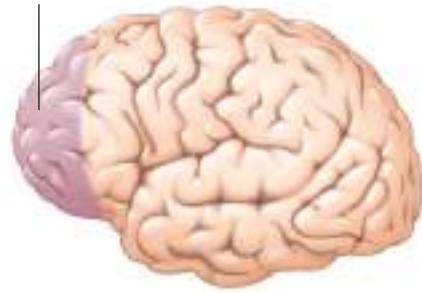

Synaptic pruning is an important aspect of the brain's development, and the pruning varies by brain region across children's development. Connect to "Physical Development in Infancy."

Prefrontal cortex

**FIGURE 1**

**THE PREFRONTAL CORTEX.** The brain pathways and circuitry involving the prefrontal cortex (shaded in purple) show significant advances in development during middle and late childhood. *What cognitive processes are linked to these changes in the prefrontal cortex?*

As children develop, some brain areas become more active while others become less so (Denes, 2016). One shift in activation that occurs as children develop is from diffuse, larger areas to more focal, smaller areas (Turkeltaub & others, 2003). This shift is characterized by synaptic pruning, a process in which areas of the brain that are not being used lose synaptic connections and areas that are used show increased connections. In one study, researchers found less diffusion and more focal activation in the prefrontal cortex from 7 to 30 years of age (Durston & others, 2006).

Increases in connectivity between brain regions also occurs as children develop (Faghiri & others, 2018). In a longitudinal study of individuals from 6 to 22 years of age, connectivity between the prefrontal and parietal lobes in childhood was linked to better reasoning ability later in development (Wendelken & others, 2017).

## MOTOR DEVELOPMENT

During middle and late childhood, children's motor skills become much smoother and more coordinated than they were in early childhood (Hockenberry, Wilson, & Rodgers, 2017). For example, only one child in a thousand can hit a tennis ball over the net at the age of 3, yet by the age of 10 or 11 most children can learn to play the sport. Running, climbing, skipping rope, swimming, bicycle riding, and skating are just a few of the many physical skills elementary school children can master. In gross motor skills involving large muscle activity, boys usually outperform girls.

Increased myelination of the central nervous system is reflected in the improvement of fine motor skills during middle and late childhood. Children can more adroitly use their hands as tools. Six-year-olds can hammer, paste, tie shoes, and fasten clothes. By 7 years of age, children's hands have become steadier. At this age, children prefer a pencil to a crayon for printing, and reversal of letters is less common. Printing becomes smaller. At 8 to 10 years of age, the hands can be used independently with more ease and precision. Fine motor coordination develops to the point at which children can write rather than print words. Cursive letter size becomes smaller and more even. At 10 to 12 years of age, children begin to show manipulative skills similar to the abilities of adults. They can master the complex, intricate, and rapid movements needed to produce fine-quality crafts or to play a difficult piece on a musical instrument. Girls usually outperform boys in their use of fine motor skills.

#### Exercise

Experts recommend that preschool children engage in two hours of physical activity per day. Connect to "Socioemotional Development in Early Childhood."

## EXERCISE

American children and adolescents are not getting enough exercise (Powers & Dodd, 2017; Powers & Howley, 2018). Increasing children's exercise levels has a number of positive outcomes (Dumuid & others, 2017; Walton-Fisette & Wuest, 2018).

An increasing number of studies document the importance of exercise in children's physical development (Dowda & others, 2017; Martin & others, 2018; Pan & others, 2017; Yan & others, 2018). A recent study of more than 6,000 elementary school children revealed that 55 minutes or more of moderate-to-vigorous physical activity daily was associated with a lower incidence of obesity (Nemet, 2016). Further, a research review concluded that exercise programs with a frequency of three weekly sessions lasting longer than 60 minutes were effective in lowering both systolic and diastolic blood pressure (Garcia-Hermoso, Saavedra, & Escalante, 2013).

Aerobic exercise also is linked to children's cognitive skills (Best, 2010; Lind & others, 2018; Martin & others, 2018). Researchers have found that aerobic exercise benefits children's processing speed, attention, memory, effortful and goal-directed thinking and behavior, and creativity (Chu & others, 2017; Davis & Cooper, 2011; Davis & others, 2011; Khan & Hillman, 2014; Lind & others, 2018; Ludyga & others, 2018; Monti, Hillman, & Cohen, 2012; Pan & others, 2017).

A recent meta-analysis concluded that sustained physical activity programs were linked to improvements in children's attention, executive function, and academic achievement (de Greeff & others, 2018). Also, a recent study found that a 6-week high-intensity exercise program with 7- to 13-year-olds improved their cognitive control and working memory (Moreau, Kirk, & Waldie, 2018). Further, in a recent fMRI study of physically unfit 8- to 11-year-old overweight children, a daily instructor-led aerobic exercise program that lasted eight months was effective in improving the efficiency of neural circuits that support better cognitive functioning (Kraft & others, 2014).

Parents and schools play important roles in determining children's exercise levels (Brusseau & others, 2018; de Heer & others, 2017; Lind & others, 2018; Lo & others, 2018; Solomon-Moore & others, 2018). Growing up with parents who exercise regularly provides positive models of exercise for children (Crawford & others, 2010). In addition, a research review found that school-based physical activity was successful in improving children's fitness and lowering their fat levels (Kriemler & others, 2011).

Screen time also is linked with low activity, obesity, and worse sleep patterns in children (Tanaka & others, 2017). A recent research review found that a higher level of screen time increased the risk of obesity for low- and high-activity children (Lane, Harrison, & Murphy, 2014). Also, a recent study of 8- to 12-year-olds found that screen time was associated with lower connectivity between brain regions, as well as lower levels of language skills and cognitive control (Horowitz-Kraus & Hutton, 2018). In this study, time spent reading was linked to higher levels of functioning in these areas.

Here are some ways to encourage children to exercise more:

- Offer more physical activity programs run by volunteers at school facilities.
- Improve physical fitness activities in schools.
- Have children plan community and school activities that interest them.
- Encourage families to focus more on physical activity, and encourage parents to exercise more.

## HEALTH, ILLNESS, AND DISEASE

For the most part, middle and late childhood is a time of excellent health. Disease and death are less prevalent at this time than during other periods in childhood and in adolescence. However, many children in middle and late childhood face health problems that harm their development.

**Accidents and Injuries** Injuries are the leading cause of death during middle and late childhood, and the most common cause of severe injury and death in this period is motor vehicle accidents, either as a pedestrian or as a passenger (Centers for Disease Control and Prevention, 2017c). For this reason, safety advocates recommend the use of safety-belt restraints and child booster seats in vehicles because they can greatly reduce the severity of motor vehicle injuries (Eberhardt & others, 2016; Shimony-Kanat & others, 2018). For example, one study found that child booster seats reduced the risk for serious injury by 45 percent for 4- to 8-year-old children (Sauber-Schatz & others, 2014). Other serious injuries involve bicycles, skateboards, roller skates, and other sports equipment (Perry & others, 2018).

**Overweight Children** Being overweight is an increasingly prevalent health problem in children (Blake, 2017; Donatelle, 2019; Smith & Collene, 2019). Recall that being overweight is defined in terms of body mass index (BMI), which is computed by a formula that takes into account height and weight—children at or above the 97th percentile are included in the obesity category, at or above the 95th percentile in the overweight category, and children at or above the 85th percentile are described as at risk for being overweight (Centers for Disease Control and Prevention, 2017b). Over the last three decades, the percentage of U.S. children who are at risk for being overweight has increased dramatically. Recently there has been a decrease in the percentage of 2- to 5-year-old children who are obese, which dropped from 12.1 percent in 2009–2010 to 9.4 percent in 2013–2014 (Ogden & others, 2016). In 2013–2014, 17.4 percent of 6- to 11-year-old U.S. children were classified as obese, essentially the same percentage as in 2009–2010 (Ogden & others, 2016).

It is not just in the United States that children are becoming more overweight (Thompson, Manore, & Vaughan, 2017). For example, a study found that general and abdominal obesity in Chinese children increased significantly from 1993 to 2009 (Liang & others, 2012). Further, a recent Chinese study revealed that high blood pressure in 23 percent of boys and 15 percent of girls could be attributed to being overweight or obese (Dong & others, 2015).

**Causes of Children Being Overweight** Heredity and environmental contexts are related to being overweight in childhood (Insel & Roth, 2018; Yanovski & Yanovski, 2018). Genetic analysis indicates that heredity is an important factor in children becoming overweight (Donatelle, 2019). Overweight parents tend to have overweight children (Pufal & others, 2012). For example, one study found that the greatest risk factor for being overweight at 9 years of age

was having an overweight parent (Agras & others, 2004). Parents and their children often have similar body types, height, body fat composition, and metabolism (Pereira-Lancha & others, 2012). In a 14-year longitudinal study, parental weight change predicted children's weight change (Andriani, Liao, & Kuo, 2015).

Environmental factors that influence whether children become overweight include the greater availability of food (especially food high in fat content), energy-saving devices, declining physical activity, parents' eating habits and monitoring of children's eating habits, the context in which a child eats, and heavy screen time (Ren & others, 2017). In a recent Japanese study, the family pattern that was linked to the highest risk of overweight/obesity in children was a combination of irregular mealtimes and the most screen time for both parents (Watanabe & others, 2016). Further, a recent study found that children were less likely to be obese or overweight when they attended schools in states that had a strong policy emphasis on healthy foods and beverages (Datar & Nicosia, 2017). Also, a behavior modification study of overweight and obese children made watching TV contingent on their engagement in exercise (Goldfield, 2012). The intervention markedly increased their exercise and reduced their TV viewing time.

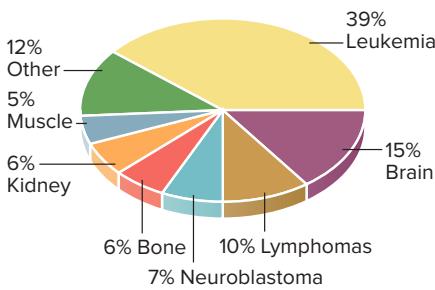

**Consequences of Being Overweight** The high percentage of overweight children in recent decades is cause for great concern because being overweight raises the risk for many medical and psychological problems (Powers & Dodd, 2017; Schiff, 2019; Song & others, 2018). Diabetes, hypertension (high blood pressure), and elevated blood cholesterol levels are common in children who are overweight (Chung, Onuzuruike, & Magge, 2018; Martin-Espinosa & others, 2017). Research reviews have concluded that obesity was linked with low self-esteem in children (Gomes & others, 2011; Moharei & others, 2018). And in one study, overweight children were more likely than normal-weight children to report being teased by their peers and family members (McCormack & others, 2011).

**Intervention Programs** A combination of diet, exercise, and behavior modification is often recommended to help children lose weight (Insel & Roth, 2018; Martin & others, 2018; Morgan & others, 2016). Intervention programs that emphasize getting parents to engage in healthier lifestyles themselves, as well as to feed their children healthier food and get them to exercise more, can produce weight reduction in overweight and obese children (Stovitz & others, 2014; Yacobovitch-Gavan & others, 2018). For example, one study found that a combination of a child-centered activity program and a parent-centered dietary modification program helped overweight children lose pounds over a two-year period (Collins & others, 2011).

**Cardiovascular Disease** Cardiovascular disease is uncommon in children. Nonetheless, environmental experiences and behavior during childhood can sow the seeds for cardiovascular disease in adulthood (Schaefer & others, 2017). Many elementary-school-aged children already possess one or more of the risk factors for cardiovascular disease, such as hypertension (high blood pressure) and obesity (Chung, Onuzuruike, & Magge, 2018; Zoller & others, 2017). In a recent study, the combination of a larger waist circumference and a higher body mass index (BMI) placed children at higher risk for developing cardiovascular disease (de Koning & others, 2015). A recent study found that high blood pressure in childhood was linked to high blood pressure and other heart abnormalities in adulthood (Fan & others, 2018). Also in a longitudinal study, high levels of body fat and elevated blood pressure beginning in childhood were linked to premature death from coronary heart disease in adulthood (Berenson & others, 2016). Further, one study found that high blood pressure went undiagnosed in 75 percent of children with the disease (Hansen, Gunn, & Kaelber, 2007).

**Cancer** Cancer is the second leading cause of death in U.S. children 5 to 14 years of age. One in every 330 children in the United States develops cancer before the age of 19. The incidence of cancer in children has increased slightly in recent years (National Cancer Institute, 2018).

Childhood cancers mainly attack the white blood cells (leukemia), brain, bone, lymph system, muscles, kidneys, and nervous system. All types of cancer are characterized by an uncontrolled proliferation of abnormal cells (Marcoux & others, 2018). As indicated in Figure 2,

Cancers in children have a different profile from adult cancers, which attack mainly the lungs, colon, breast, prostate, and pancreas.

## Sharon McLeod, Child Life Specialist

Sharon McLeod is a child life specialist who is senior clinical director in the Division of Child Life and Division of Integrative Care at the Children's Hospital Medical Center in Cincinnati.

Under McLeod's direction, the goals of her department are to promote children's optimal growth and development, reduce the stress of health care experiences, and provide support to child patients and their families. These goals are accomplished by facilitating therapeutic play and developmentally appropriate activities, educating and psychologically preparing children for medical procedures, and serving as a resource for parents and other professionals regarding children's development and health care issues.

McLeod says that human growth and development provides the foundation for her profession as a child life specialist. She also says her best times as a student were when she conducted fieldwork, had an internship, and experienced hands-on applications of the theories and concepts that she learned in her courses.

the most common cancer in children is leukemia, a cancer in which bone marrow manufactures an abundance of abnormal white blood cells that crowd out normal cells, making the child highly susceptible to bruising and infection (Kato & Manabe, 2018; Shago, 2017).

Because of advancements in cancer treatment, children with cancer are surviving longer than in the past (National Cancer Institute, 2018). Approximately 80 percent of children with acute lymphoblastic leukemia are cured with current chemotherapy treatment.

Child life specialists are among the health professionals who work to make the lives of children with diseases less stressful. To read about the work of child life specialist Sharon McLeod, see *Connecting with Careers*.

### U.S. CHILDREN WITH A DISABILITY WHO RECEIVE SPECIAL EDUCATION SERVICES

**SERVICES.** Figures are for the 2012–2013 school year and represent the five categories with the highest number and percentage of children. Both learning disability and attention deficit hyperactivity disorder are combined in the learning disabilities category (Condition of Education, 2016).

**learning disability** Difficulty in understanding or using spoken or written language or in doing mathematics. To be classified as a learning disability, the learning problem is not primarily the result of visual, hearing, or motor disabilities; intellectual disability; emotional disorders; or due to environmental, cultural, or economic disadvantage.

**dyslexia** A category of learning disabilities involving a severe impairment in the ability to read and spell.

**dysgraphia** A learning disability that involves difficulty in handwriting.

**dyscalculia** Also known as developmental arithmetic disorder; a learning disability that involves difficulty in math computation.

**attention deficit hyperactivity disorder (ADHD)** A disability in which children consistently show one or more of the following characteristics: (1) inattention, (2) hyperactivity, and (3) impulsivity.

## THE SCOPE OF DISABILITIES

Of all children in the United States, 12.9 percent from 3 to 21 years of age received special education or related services in 2012–2013, an increase of 3 percent since 1980–1981 (Condition of Education, 2016). Figure 3 shows the five largest groups of students with a disability who were served by federal programs during the 2012–2013 school year (Condition of Education, 2016). As indicated in Figure 3, students with a learning disability were by far the largest group of students with a disability to be given special education, followed by children with speech or hearing impairments, autism, intellectual disability, and emotional disturbance. Note that the U.S. Department of Education includes both students with a learning disability and students with ADHD in the category of learning disability.

**Learning Disabilities** The U.S. government created a definition of learning disabilities in 1997 and then reauthorized the definition with a few minor changes in 2004. Following is a summary of the government's definition of the characteristics that determine whether a child should be classified as having a learning disability. A child with a **learning disability** has difficulty in learning that involves understanding or using spoken or written language, and the difficulty can appear in listening, thinking, reading, writing, and spelling. A learning disability also may involve difficulty in doing mathematics (McCaskey & others, 2017, 2018). To be classified as a learning disability, the learning problem is not primarily the result of visual, hearing, or motor disabilities; intellectual disability; emotional disorders; or environmental, cultural, or economic disadvantage (Friend, 2018; Heward, Alber-Morgan, & Konrad, 2017).

About three times as many boys as girls are classified as having a learning disability. Among the explanations for this gender difference are a greater biological vulnerability among boys and *referral bias*. That is, boys are more likely to be referred by teachers for treatment because of troublesome behavior.

Approximately 80 percent of children with a learning disability have a reading problem (Shaywitz & Shaywitz, 2017). Three types of learning disabilities are dyslexia, dysgraphia, and dyscalculia:

- **Dyslexia** is a category reserved for individuals who have a severe impairment in their ability to read and spell (Shaywitz & Shaywitz, 2017).
- **Dysgraphia** is a learning disability that involves difficulty in handwriting (Hook & Haynes, 2017). Children with dysgraphia may write very slowly, their writing products may be virtually illegible, and they may make numerous spelling errors because of their inability to match sounds and letters.
- **Dyscalculia**, also known as developmental arithmetic disorder, is a learning disability that involves difficulty in math computation (McCaskey & others, 2017, 2018; Nelson & Powell, 2018).

The precise causes of learning disabilities have not yet been determined (Friend, 2018). Researchers have used brain-imaging techniques, such as magnetic resonance imaging, to explore whether specific regions of the brain might be involved in learning disabilities (Ramus & others, 2018; Shaywitz, Lyon, & Shaywitz, 2006) (see Figure 4). This research indicates that it is unlikely learning disabilities reside in a single, specific brain location. More likely, learning disabilities involve difficulty integrating information from multiple brain regions or subtle impairments in brain structures and functions.

Interventions with children who have a learning disability often focus on improving reading ability (Cunningham, 2017; Shaywitz & Shaywitz, 2017; Temple & others, 2018). Intensive instruction over a period of time by a competent teacher can help many children (Thompson & others, 2017).

**Attention Deficit Hyperactivity Disorder (ADHD)** **Attention deficit hyperactivity disorder (ADHD)** is a disability in which children consistently show one or more of the

following characteristics over a period of time: (1) inattention, (2) hyperactivity, and (3) impulsivity. Children who are inattentive have such difficulty focusing on any one thing that they may get bored with a task after only a few minutes—or even seconds. Children who are hyperactive show high levels of physical activity, seeming to be almost constantly in motion. Children who are impulsive have difficulty curbing their reactions; they do not do a good job of thinking before they act. Depending on the characteristics that children with ADHD display, they can be diagnosed as having (1) ADHD with predominantly inattention, (2) ADHD with predominantly hyperactivity/impulsivity, or (3) ADHD with both inattention and hyperactivity/impulsivity.

The number of children diagnosed and treated for ADHD has increased substantially in recent decades, by some estimates doubling in the 1990s. The American Psychiatric Association (2013) reported in the DSM-V that 5 percent of children have ADHD, although estimates are higher in community samples. For example, the Centers for Disease Control and Prevention (2016) estimates that ADHD has continued to increase in 4- to 17-year-old children from 8 percent in 2003 to 9.5 percent in 2007 and to 11 percent in 2016. According to the Centers for Disease Control and Prevention, 13.2 percent of U.S. boys and 5.6 of U.S. girls have ever been diagnosed with ADHD.

There is controversy, however, about the reasons for the increased diagnosis of ADHD (Friend, 2018; Hallahan, Kauffman, & Pullen, 2019). Some experts attribute the increase mainly to heightened awareness of the disorder; others are concerned that many children are being incorrectly diagnosed (Watson & others, 2014).

One study examined the possible misdiagnosis of ADHD (Bruchmiller, Margraf, & Schneider, 2012). In this study, child psychologists, psychiatrists, and social workers were given vignettes of children with ADHD. Some vignettes matched the diagnostic criteria for the disorder, while others did not. The child in each vignette was sometimes identified as male and sometimes as female. The researchers assessed whether the mental health professionals gave a diagnosis of ADHD to the child described in the vignette. The professionals overdiagnosed ADHD almost 20 percent of the time, and regardless of the symptoms described, boys were twice as likely as girls to be diagnosed as having ADHD.

Adjustment and optimal development are difficult for children who have ADHD, so it is important that the diagnosis be accurate (Hechtman & others, 2016; Hallahan, Kauffman, & Pullen, 2019). Children diagnosed with ADHD have an increased risk of lower academic achievement, problematic peer relations, school dropout, adolescent pregnancy, substance use problems, and antisocial behavior (Machado & others, 2018; Regnart, Truter, & Meyer, 2017). For example, a recent study found that childhood ADHD was associated with long-term underachievement in math and reading (Voigt & others, 2017). Also, a recent research review concluded that in comparison with typically developing girls, girls with ADHD had more problems in friendship, peer interaction, social skills, and peer victimization (Kok & others, 2016). Further, a recent research review concluded that ADHD in childhood was linked to the following long-term outcomes: failure to complete high school, other mental and substance use disorders, criminal activity, and unemployment (Erskine & others, 2016). And a recent study revealed that individuals with ADHD were more likely to become parents at 12 to 16 years of age (Ostergaard & others, 2017).

Definitive causes of ADHD have not been found. However, a number of possible causes have been proposed (Hallahan, Kauffman, & Pullen, 2019; Lewis, Wheeler, & Carter, 2017). Some children likely inherit a tendency to develop ADHD from their parents (Hess & others, 2018; Walton & others, 2017). Other children likely develop ADHD because of damage to their brain during prenatal or postnatal development (Bos & others, 2017). Among early possible contributors to ADHD are cigarette and alcohol exposure, as well as a high level of maternal stress during prenatal development and low birth weight (Scheinost & others, 2017).

As with learning disabilities, advances in brain-imaging technology are facilitating a better understanding of ADHD (Riaz & others, 2018; Sun & others, 2018). One study revealed that peak thickness of the cerebral cortex occurred three years later (at 10.5 years) in children with ADHD than in children without ADHD (at 7.5 years) (Shaw & others, 2007). The delay was more prominent in the prefrontal regions of the brain that are particularly

important in attention and planning (see Figure 5). Another study also found delayed development of the brain's frontal lobes in children with ADHD, likely due to delayed or decreased myelination (Nagel & others, 2011). Researchers also are exploring the roles that various neurotransmitters, such as serotonin and dopamine, might play in ADHD (Auerbach & others, 2017; Baptista & others, 2017).

The delays in brain development just described are in areas linked to executive function (Munro & others, 2018). An increasing focus of interest in the study of children with ADHD is their difficulty with tasks involving executive function, such as behavioral inhibition when necessary, use of working memory, and effective planning (Krieger & Amador-Campos, 2018; Toplak, West, & Stanovich, 2017). Researchers also have found deficits in theory of mind in children with ADHD (Maoz & others, 2018; Mary & others, 2016). Stimulant medication such as Ritalin or Adderall (which has fewer side effects than Ritalin) is effective in improving the attention of many children with ADHD, but it usually does not improve their attention to the levels seen in children who do not have ADHD (Wong & Stevens, 2012). A recent research review also concluded that stimulant medications are effective in treating ADHD during the short term but that longer-term benefits of stimulant medications are not clear (Rajeh & others, 2017). A meta-analysis concluded that behavior management treatments are useful in reducing the effects of ADHD (Fabiano & others, 2009). Researchers have often found that a combination of medication (such as Ritalin) and behavior management improves the behavior of some but not all children with ADHD better than medication alone or behavior management alone (Parens & Johnston, 2009).

The sheer number of ADHD diagnoses has prompted speculation that psychiatrists, parents, and teachers are in fact labeling normal childhood behavior as psychopathology (Mash & Wolfe, 2019; Molina & Pelham, 2014). One reason for concern about overdiagnosing ADHD is that the form of treatment in well over 80 percent of cases is psychoactive drugs, including stimulants such as Ritalin and Adderall (Garfield & others, 2012). Further, there is increasing concern that children who are given stimulant drugs such as Ritalin or Adderall are at risk for developing substance abuse problems, although evidence supporting this concern so far has been mixed (Erskine & others, 2016; Zulauf & others, 2014).

Recently, researchers have been exploring the possibility that neurofeedback might improve the attention of children with ADHD (Alegria & others, 2017; Gelade & others, 2018; Jiang, Abiri, & Zhao, 2017; Moreno-Garcia & others, 2018). Neurofeedback trains individuals to become more aware of their physiological responses so they can attain better control over their brain's prefrontal cortex, where executive control primarily occurs. Individuals with ADHD have higher levels of electroencephalogram (EEG) abnormalities, and neurofeedback produces audio-visual profiles of these abnormal brain waves so that individuals can learn how to achieve normal EEG functioning. In a recent study, 7- to 14-year-olds with ADHD were randomly assigned to either receive a neurofeedback treatment that consisted of 40 sessions or to take Ritalin (Meisel & others, 2013). Both groups showed a lower level of ADHD symptoms 6 months after the treatment, but only the neurofeedback group performed better academically.

Recently, mindfulness training also has been given to children and adolescents with ADHD (Edel & others, 2017; Evans & others, 2018; Sibalis & others, 2018). A recent meta-analysis concluded that mindfulness training significantly improved the attention of children with ADHD (Cairncross & Miller, 2018).

Exercise also is being investigated as a possible treatment for children with ADHD (Den Heijer & others, 2017; Grassman & others, 2017; Pan & others, 2018). For example, a recent study confirmed that an 8-week yoga program was effective in improving the sustained attention of children with ADHD (Chou & Huang, 2017). Also, a recent meta-analysis concluded that physical exercise is effective in reducing cognitive symptoms of ADHD in individuals 3 to 25 years of age (Tan, Pooley, & Speelman, 2016). And a second recent meta-analysis concluded that a short-term aerobic exercise program was effective in reducing symptoms such as inattention, hyperactivity, and impulsivity (Cerillo-Urbina & others, 2015). Also, a third recent meta-analysis indicated that exercise is associated with better executive function in children with ADHD (Vysniauske & others, 2018). Among the reasons that exercise might reduce ADHD symptoms in children are (1) better allocation of attention resources, (2) positive influence on prefrontal cortex functioning, and (3) exercise-induced dopamine release (Chang & others, 2012).

How can neurofeedback reduce the symptoms of ADHD in children?

©Jerilee Bennett/KRT/Newscom

Despite the encouraging results of recent studies involving the use of neurofeedback, mindfulness training, and exercise to improve the attention of children with ADHD, it still remains to be determined whether these non-drug therapies are as effective as stimulant drugs and/or whether they benefit children as add-ons to stimulant drugs to provide a combination treatment (Den Heijer & others, 2017).

**Emotional and Behavioral Disorders** Most children have minor emotional difficulties at some point during their school years. However, some children have problems so serious and persistent that they are classified as having an emotional or behavioral disorder (Mash & Wolfe, 2019). These problems may include internalized disorders such as depression or externalized disorders such as aggression.

**Emotional and behavioral disorders** consist of serious, persistent problems that involve relationships, aggression, depression, and fears associated with personal or school matters, as well as other inappropriate socioemotional characteristics (Lewis, Asbury, & Plomin, 2017; Weersing & others, 2017). Approximately 8 percent of children who have a disability and require an individualized education plan fall into this classification. Boys are three times as likely as girls to have these disorders.

**Autism Spectrum Disorders** **Autism spectrum disorders (ASD)**, also called pervasive developmental disorders, range from the severe disorder labeled autistic disorder to the milder disorder called Asperger syndrome. Autism spectrum disorders are characterized by problems in social interaction, problems in verbal and nonverbal communication, and repetitive behaviors (Boutot, 2017; Gerenser & Lopez, 2017). Children with these disorders may also show atypical responses to sensory experiences (National Institute of Mental Health, 2018). Intellectual disability is present in some children with autism; others show average or above-average intelligence (Bernier & Dawson, 2016).

Recent estimates of autism spectrum disorders indicate that they are dramatically increasing in occurrence (or are increasingly being detected). Once thought to affect only 1 in 2,500 children decades ago, they were estimated to be present in about 1 in 150 children in 2002 (Centers for Disease Control and Prevention, 2007). However, in the most recent survey, the estimated percentage of 8-year-old children with autism spectrum disorders had increased to 1 in 68 (Christensen & others, 2016). In the recent surveys, autism spectrum disorders were identified five times more often in boys than in girls, and 8 percent of individuals aged 3 to 21 with these disorders were receiving special education services (Centers for Disease Control and Prevention, 2017a).

Also, in recent surveys, only a minority of parents reported that their child's autistic spectrum disorder was identified prior to 3 years of age and that one-third to one-half of the cases were identified after 6 years of age (Sheldrick, Maye, & Carter, 2017). However, researchers are conducting studies that seek to identify earlier determinants of autism spectrum disorders (Reiersen, 2017).

**Autistic disorder** is a severe developmental autism spectrum disorder that has its onset during the first three years of life and includes deficiencies in social relationships, abnormalities in communication, and restricted, repetitive, and stereotyped patterns of behavior.

**Asperger syndrome** is a relatively mild autism spectrum disorder in which the child has relatively good verbal language skills, milder nonverbal language problems, and a restricted range of interests and relationships (Boutot, 2017). Children with Asperger syndrome often engage in obsessive, repetitive routines and preoccupations with a particular subject. For example, a child may be obsessed with baseball scores or specific videos on YouTube.

Children with autism have deficits in cognitive processing of information (Jones & others, 2018). For example, a recent study found that a lower level of working memory was the executive function most strongly associated with autism spectrum disorders (Ziermans & others, 2017). Children with these disorders may also show atypical responses to sensory experiences (National Institute of Mental Health, 2017). Intellectual disability is present in some children with autism; others show average or above-average intelligence (Volkmar & others, 2014).

In 2013, the American Psychiatric Association published the new edition (DSM-V) of its psychiatric classification of disorders. In the new classification, autistic disorder, Asperger's syndrome, and several other autistic variations were consolidated in the overarching category of autism spectrum disorder (Autism Research Institute, 2013). Distinctions are made in terms of the severity of problems based on amount of support needed due to challenges involving

social communication, restricted interests, and repetitive behaviors. Critics argue that the umbrella category proposed for autism spectrum disorder masks the heterogeneity that characterizes the subgroups of autism (Lai & others, 2013).

What causes autism spectrum disorders? The current consensus is that autism is a brain dysfunction characterized by abnormalities in brain structure and neurotransmitters (Ecker, 2017; Fernandez, Mollinedo-Gajate, & Penagarikano, 2018; Khundrakpam & others, 2017). Recent interest has focused on a lack of connectivity between brain regions as a key factor in autism (Abbott & others, 2018; Li, Karmath, & Xu, 2017; Nair & others, 2018; Nunes & others, 2018).

Genetic factors also are likely to play a role in the development of autism spectrum disorders (Valiente-Palleja & others, 2018; Wang & others, 2017; Yuan & others, 2017). One study revealed that mutations—missing or duplicated pieces of DNA on chromosome 16—can raise a child's risk of developing autism 100-fold (Weiss & others, 2008). There is no evidence that family socialization causes autism.

Children with autism benefit from a well-structured classroom, individualized teaching, and small-group instruction (Friend, 2018; Mastropieri & Scruggs, 2018). Behavior modification techniques are sometimes effective in helping autistic children learn (Alberto & Troutman, 2017; Zirpoli, 2016).

## EDUCATIONAL ISSUES

Until the 1970s most U.S. public schools either refused enrollment to children with disabilities or inadequately served them. This changed in 1975 when Public Law 94-142, the Education for All Handicapped Children Act, required that all students with disabilities be given a free, appropriate public education. In 1990, Public Law 94-142 was recast as the Individuals with Disabilities Education Act (IDEA). IDEA was amended in 1997 and then reauthorized in 2004 and renamed the Individuals with Disabilities Education Improvement Act.

IDEA spells out broad mandates for services to children with disabilities of all kinds (Smith & others, 2018). These services include evaluation and eligibility determination, appropriate education and an individualized education plan (IEP), and education in the least restrictive environment (LRE) (Cook & Richardson-Gibbs, 2018; Heward, Alber-Morgan, & Konrad, 2017).

An **individualized education plan (IEP)** is a written statement that spells out a program that is specifically tailored for the student with a disability. The **least restrictive environment (LRE)** is a setting that is as similar as possible to the one in which children who do not have a disability are educated. This provision of the IDEA has given a legal basis to efforts to educate children with a disability in the regular classroom. The term **inclusion** describes educating a child with special educational needs full-time in the regular classroom (Lewis, Wheeler, & Carter, 2017; Mastropieri & Scruggs, 2018). In a recent school year (2014), 61 percent of U.S. students with a disability spent more than 80 percent of their school day in a general classroom (compared with only 33 percent in 1990) (Condition of Education, 2015).

The outcomes of many legal changes regarding children with disabilities have been extremely positive (Hallahan, Kauffman, & Pullen, 2018; Smith & others, 2018). Compared with several decades ago, far more children today are receiving competent, specialized services. For many children, inclusion in the regular classroom, with modifications or supplemental services, is appropriate (Friend, 2018; Mastropieri & Scruggs, 2018). However, some leading experts on special education argue that in some cases the effort to educate children with disabilities in the regular classroom has become too extreme. For example, James Kauffman and his colleagues (Kauffman, McGee, & Brigham, 2004) state that inclusion too often has meant making accommodations in the regular classroom that do not always benefit children with disabilities. They advocate a more individualized approach that does not always involve full inclusion but allows options such as special education outside the regular classroom. Kauffman and his colleagues (2004, p. 620) acknowledge that children with disabilities “*do* need the services of specially trained professionals” and “*do* sometimes need altered curricula or adaptations to make their learning possible.” However, they believe “we sell students with disabilities short when we pretend that they are not different from typical students. We make the same error when we pretend that they must *not* be expected to put forth extra effort if they are to learn to do some things—or learn to do something in a different way.” Like general education, special education should challenge students with disabilities “to become all they can be.”

Piaget's Cognitive Developmental Theory

Information Processing

Intelligence

Extremes of Intelligence

Do children enter a new stage of cognitive development in middle and late childhood? How do children process information during this age period? What is the nature of children's intelligence? Let's explore some answers to these questions.

### PIAGET'S COGNITIVE DEVELOPMENTAL THEORY

According to Jean Piaget (1952), the preschool child's thought is preoperational. Preschool children can form stable concepts, and they have begun to reason, but their thinking is flawed by egocentrism and magical belief systems. As we discussed earlier, however, Piaget may have underestimated the cognitive skills of preschool children. Some researchers argue that under the right conditions, young children may display abilities that are characteristic of Piaget's next stage of cognitive development, the stage of concrete operational thought (Gelman, 1969). Here we will cover the characteristics of concrete operational thought and evaluate Piaget's portrait of this stage.

**The Concrete Operational Stage** Piaget proposed that the *concrete operational stage* lasts from approximately 7 to 11 years of age. In this stage, children can perform concrete operations, and they can reason logically as long as reasoning can be applied to specific or concrete examples. Remember that *operations* are mental actions that are reversible, and *concrete operations* are operations that are applied to real, concrete objects.

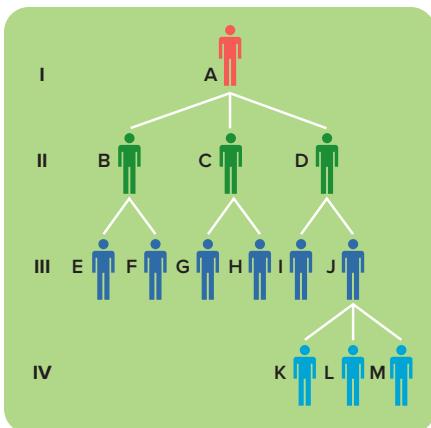

The conservation tasks described earlier indicate whether children are capable of concrete operations. For example, recall that in one task involving conservation of matter, the child is presented with two identical balls of clay. The experimenter rolls one ball into a long, thin shape; the other remains in its original ball shape. The child is then asked if there is more clay in the ball or in the long, thin piece of clay. By the time children reach the age of 7 or 8, most answer that the amount of clay is the same. To answer this problem correctly, children have to imagine the clay rolling back into a ball. This type of imagination involves a reversible mental action applied to a real, concrete object. Concrete operations allow the child to consider several characteristics rather than focusing on a single property of an object. In the clay example, the preoperational child is likely to focus on height or width. The concrete operational child coordinates information about both dimensions.

What other abilities are characteristic of children who have reached the concrete operational stage? One important skill is the ability to classify or divide things into different sets or

#### CLASSIFICATION: AN IMPORTANT ABILITY IN CONCRETE OPERATIONAL THOUGHT.

A family tree of four generations (I to IV): The preoperational child has trouble classifying the members of the four generations, while the concrete operational child can classify the members vertically, horizontally, and obliquely (up and down and across). For example, the concrete operational child understands that a family member can be a son, a brother, and a father, all at the same time.

**seriation** The concrete operation that involves ordering stimuli along a quantitative dimension (such as length).

**transitivity** The ability to logically combine relations to understand certain conclusions.

**neo-Piagetians** Developmentalists who argue that Piaget got some things right but that his theory needs considerable revision. They have elaborated on Piaget's theory, giving more emphasis to information processing, strategies, and precise cognitive steps.

subsets and to consider their interrelationships. Consider the family tree of four generations that is shown in Figure 6 (Furth & Wachs, 1975). This family tree suggests that the grandfather (A) has three children (B, C, and D), each of whom has two children (E through J), and that one of these children (J) has three children (K, L, and M). A child who comprehends the classification system can move up and down a level, across a level, and up and down and across within the system. The concrete operational child understands that person J can at the same time be father, brother, and grandson, for example.

Children who have reached the concrete operational stage are also capable of **seriation**, which is the ability to order stimuli along a quantitative dimension (such as length). To see if students can serialize, a teacher might haphazardly place eight sticks of different lengths on a table. The teacher then asks the students to order the sticks by length. Many young children end up with two or three small groups of "big" sticks or "little" sticks, rather than a correct ordering of all eight sticks. Another mistaken strategy they use is to evenly line up the tops of the sticks but ignore the bottoms. The concrete operational thinker simultaneously understands that each stick must be longer than the one that precedes it and shorter than the one that follows it.

Another aspect of reasoning about the relations between classes is **transitivity**, which is the ability to logically combine relations to understand certain conclusions. In this case, consider three sticks (A, B, and C) of differing lengths. A is the longest, B is intermediate in length, and C is the shortest. Does the child understand that if A is longer than B and B is longer than C, then A is longer than C? In Piaget's theory, concrete operational thinkers do, while preoperational thinkers do not.

**Evaluating Piaget's Concrete Operational Stage** Has Piaget's portrait of the concrete operational child withstood the test of research? According to Piaget, various aspects of a stage should emerge at the same time. In fact, however, some concrete operational abilities do not appear in synchrony. For example, children do not learn to conserve at the same time they learn to cross-classify.

Furthermore, education and culture exert stronger influences on children's development than Piaget reasoned (Bredekamp, 2017; Feeney, Moravcik, & Nolte, 2019; Follari, 2019; Morrison, 2018). Some preoperational children can be trained to reason at a concrete operational stage. And the age at which children acquire conservation skills is related to how much practice their culture provides in these skills.

Thus, although Piaget was a giant in the field of developmental psychology, his conclusions about the concrete operational stage have been challenged. Later, after examining the final stage in his theory of cognitive development, we will further evaluate Piaget's contributions and examine various criticisms of his theory.

**Neo-Piagetians** argue that Piaget got some things right but that his theory needs considerable revision. They give more emphasis to how children use attention, memory, and strategies to process information (Case & Mueller, 2001). They especially believe that a more accurate portrayal of children's thinking requires attention to children's strategies, the speed at which children process information, the particular task involved, and the division of problem solving into smaller, more precise steps (Morra & others, 2008). These are issues addressed by the information-processing approach, and we discuss some of them later in this chapter.

## INFORMATION PROCESSING

If instead of describing children's stages of thinking we were to examine how they process information during middle and late childhood, what would we find? During these years, most children dramatically improve their ability to sustain and control attention (Posner, 2018a, b; Wu & Scerif, 2018). They pay more attention to task-relevant stimuli than to salient stimuli. Other changes in information processing during middle and late childhood involve memory, thinking, metacognition, and executive function (McClelland & others, 2017; Sala & Gobet, 2017; Siegler, 2017).

**Memory** Earlier we concluded that short-term memory increases considerably during early childhood but after the age of 7 does not show as much increase. **Long-term memory**, a relatively permanent and unlimited type of memory, increases with age during middle and late childhood. In part, improvements in memory reflect children's increased knowledge and their increased use of strategies. Keep in mind that it is important not to view memory in terms of how children add something to it but rather to underscore how children actively construct their memory (Bauer & others, 2017).

**Working Memory** Short-term memory is like a passive storehouse with shelves to store information until it is moved to long-term memory. Alan Baddeley (1990, 2001, 2007, 2010, 2012, 2013, 2015, 2017, 2018a, b) defines **working memory** as a kind of mental "workbench" where individuals manipulate and assemble information when they make decisions, solve problems, and comprehend written and spoken language (see Figure 7). Working memory is described as being more active and powerful in modifying information than short-term memory. Working memory involves bringing information to mind and mentally working with or updating it, as when you link one idea to another and relate what you are reading now to something you read earlier.

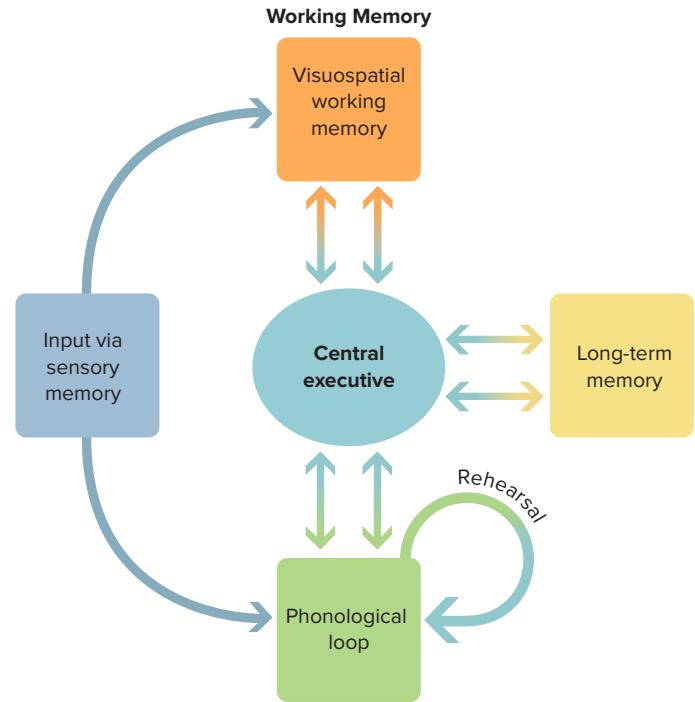

Note in Figure 7 that a key component of working memory is the *central executive*, which supervises and controls the flow of information. The central executive is especially involved in selective attention and inhibition, planning and decision making, and troubleshooting. Recall the description of *executive function* as an umbrella-like concept that encompasses a number of higher-level cognitive processes. One of those cognitive processes is working memory, especially its central executive dimension.

Working memory develops slowly. Even by 8 years of age, children can only hold in memory half the items that adults can remember (Kharitonova, Winter, & Sheridan, 2015).

Working memory is linked to many aspects of children's development (Baddeley, 2018a, b; Nicolaou & others, 2018; Nouwens, Groen, & Verhoeven, 2017; Sala & Gobet, 2017; Sanchez-Perez & others, 2018; Swanson, 2017). For example, children who have better working memory are more advanced in language comprehension, math skills, problem solving, and reasoning than their counterparts with less effective working memory (Fuchs & others, 2016; Ogino & others, 2017; Peng & Fuchs, 2016; Sanchez-Perez & others, 2018; Simms, Frausel, & Richland, 2018; Tsubomi & Watanabe, 2017). In a recent study, children's verbal working memory was linked to these aspects of both first and second language learners: morphology, syntax, and grammar (Verhaegen & Leseman, 2016).

**Knowledge and Expertise** Much of the research on the role of knowledge in memory has compared experts and novices. Experts have acquired extensive knowledge about a particular content area; this knowledge influences what they notice and how they organize, represent, and interpret information (Ericsson, 2017; Ericsson & others, 2016, 2018; Varga & others, 2018). These aspects in turn affect their ability to remember, reason, and solve problems. When individuals have expertise about a particular subject, their memory also tends to be good regarding material related to that subject (Staszewski, 2013).

For example, one study found that 10- and 11-year-olds who were experienced chess players ("experts") were able to remember more information about the location of chess pieces on a chess board than college students who were not chess players ("novices") (Chi, 1978) (see Figure 8). In contrast, when the college students were presented with other stimuli, they were able to remember them better than the children were. Thus, the children's expertise in chess gave them superior memories, but only in chess. A key reason the child chess experts did better at this activity was their ability to organize (chunk) the chess pieces into meaningful subgroups based on their understanding of chess.

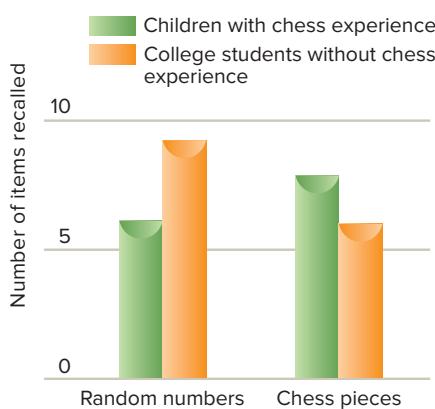

**FIGURE 7**

**WORKING MEMORY.** In Baddeley's working memory model, working memory is like a mental workbench where a great deal of information processing is carried out. Working memory consists of three main components, with the phonological loop and visuospatial working memory helping the central executive do its work. Input from sensory memory goes to the phonological loop, where information about speech is stored and rehearsal takes place, and visuospatial working memory, where visual and spatial information, including imagery, are stored. Working memory is a limited-capacity system, and information is stored there for only a brief time. Working memory interacts with long-term memory, using information from long-term memory in its work and transmitting information to long-term memory for longer storage.

**long-term memory** A relatively permanent type of memory that holds huge amounts of information for a long period of time.

There are developmental changes in expertise (Ericsson, 2014; Ericsson & others, 2018). Older children usually have more expertise about a subject than younger children do, which can contribute to their better memory for the subject.

**Autobiographical Memory** Recall that we discussed *autobiographical memory*, which involves memory of significant events and experiences in one's life. You are engaging in autobiographical memory when you answer questions such as: Who was your first-grade teacher and what was s/he like? What is the most traumatic event that happened to you as a child?

As children go through middle and late childhood, and through adolescence, their autobiographical narratives broaden and become more elaborated (Bauer, 2015, 2016, 2018; Bauer & Fivush, 2014; Bauer, Hattenschwiler, & Larkina, 2016; Bauer & others, 2017). Researchers have found that children develop more detailed, coherent, and evaluative autobiographical memories when their mothers reminisce with them in elaborated and evaluative ways (Fivush, 2010).

Culture influences children's autobiographical memories. American children, especially American girls, produce autobiographical narratives that are longer, more detailed, more specific, and more personal than narratives by children from China and Korea (Bauer, 2013, 2015). In their conversations about past events, American mothers and their children are more elaborate and more focused on themes related to being independent while Korean mothers and their children less often engage in detailed conversations about the past. Possibly the more elaborated content of American children's narratives contributes to the earlier first memories researchers have found in American adults (Han, Leichtman, & Wang, 1998).

**Strategies** If we know anything at all about long-term memory, it is that long-term memory depends on the learning activities individuals engage in when they are learning and remembering information. A key learning activity involves **strategies**, which consist of deliberate mental activities to improve the processing of information (Chu & others, 2018; Graham, 2018a, b; Harris & others, 2018; Nicolielo-Carriho & Hage, 2017). For example, organizing is a strategy that older children, adolescents, and adults use to remember more effectively. Strategies do not occur automatically; they require effort and work.

Following are some effective strategies for adults to use when attempting to improve children's memory skills:

- *Advise children to elaborate on what is to be remembered.* Elaboration is an important strategy that involves engaging in more extensive processing of information. When individuals engage in elaboration, their memory benefits (Schneider, 2011). Thinking of examples and relating information to one's own self and experiences are good ways to elaborate information. Forming personal associations with information makes the information more meaningful and helps children to remember it. For example, if the word *win* is on a list of words a child is asked to remember, the child might think of the last time he won a bicycle race with a friend.
- *Encourage children to engage in mental imagery.* Mental imagery can help even young schoolchildren to remember pictures. However, for remembering verbal information, mental imagery works better for older children than for younger children.
- *Motivate children to remember material by understanding it rather than by memorizing it.* Children will remember information better over the long term if they understand the information rather than just rehearse and memorize it. Rehearsal works well for encoding information into short-term memory, but when children need to retrieve the information from long-term memory, it is much less efficient. For most information, encourage children to understand it, give it meaning, elaborate it, and personalize it. Give children concepts and ideas to remember and then ask them how they can relate the concepts and ideas to their own personal experiences and meanings. Give them practice on elaborating a concept so they will process the information more deeply.
- *Repeat with variation on the instructional information and link early and often.* Variations on a lesson theme increase the number of associations in memory storage and linking expands the network of associations in memory storage; both strategies expand the routes for retrieving information from storage.
- *Embed memory-relevant language when instructing children.* Teachers vary considerably in how much they use memory-relevant language that encourages students to remember

**strategies** Deliberate mental activities that improve the processing of information.

**elaboration** An important strategy for remembering that involves engaging in more extensive processing of information.

information. In research that involved extensive observations of a number of first-grade teachers in the classroom, Peter Ornstein and his colleagues (Ornstein, Coffman, & Grammer, 2007, 2009; Ornstein & others, 2010) found that during the time segments observed, the teachers rarely used strategy suggestions or metacognitive (thinking about thinking) questions. In this research, when lower-achieving students were placed in classrooms in which teachers were categorized as “high-mnemonic teachers” who frequently embedded memory-relevant information in their teaching, the students’ achievement increased (Ornstein, Coffman, & Grammer, 2007).

**Fuzzy Trace Theory** Might something other than knowledge and strategies be responsible for improvement in memory during the elementary school years? Charles Brainerd and Valerie Reyna (1993, 2014; Reyna, 2004; Reyna & others, 2016) argue that fuzzy traces account for much of this improvement. Their **fuzzy trace theory** states that memory is best understood by considering two types of memory representations: (1) verbatim memory trace, and (2) gist. The *verbatim memory trace* consists of the precise details of the information, whereas *gist* refers to the central idea of the information. When gist is used, fuzzy traces are built up. Although individuals of all ages extract gist, young children tend to store and retrieve verbatim traces. At some point during the early elementary school years, children begin to use gist more and, according to the theory, this contributes to the improved memory and reasoning of older children because fuzzy traces are more enduring and less likely to be forgotten than verbatim traces.

**Thinking** Three important aspects of thinking are executive function, critical thinking, and creative thinking.

**Executive Function** In the chapter on “Physical and Cognitive Development in Early Childhood,” you read about executive function and its characteristics in early childhood. Some of the cognitive topics we discuss in this chapter—working memory, critical thinking, creative thinking, and metacognition—can be considered under the umbrella of executive function and linked to the development of the brain’s prefrontal cortex (Bardikoff & Sabbagh, 2017; Groppe & Elsner, 2017; Knapp & Morton, 2017; Muller & others, 2017). Also, earlier in this chapter in the coverage of brain development in middle and late childhood, you read about the increase in cognitive control, which involves flexible and effective control in a number of areas such as focusing attention, reducing interfering thoughts, inhibiting motor actions, and exercising flexibility in deciding between competing choices.

Adele Diamond and Kathleen Lee (2011) highlighted the following dimensions of executive function that they conclude are the most important for 4- to 11-year-old children’s cognitive development and school success:

- *Self-control/inhibition.* Children need to develop self-control that will allow them to concentrate and persist on learning tasks, to inhibit their tendencies to repeat incorrect responses, and to resist the impulse to do something now that they would regret later.
- *Working memory.* Children need an effective working memory to mentally work with the masses of information they will encounter as they go through school and beyond.
- *Flexibility.* Children need to be flexible in their thinking to consider different strategies and perspectives.

Researchers have found that executive function is a better predictor of school readiness than general IQ (Blair & Razza, 2007). A number of diverse activities and factors have been found to increase children’s executive function, such as aerobic exercise (Kvalo & others, 2017); scaffolding of self-regulation (the Tools of the Mind program discussed in the chapter on “Physical and Cognitive Development in Early Childhood” is an example) (Bodrova & Leong, 2015); mindfulness training (Gallant, 2016); and some types of school curricula (the Montessori curriculum, for example) (Diamond & Lee, 2011).

Ann Masten and her colleagues (Herbers & others, 2014; Labella & others, 2018; Masten, 2013, 2014a, b; Masten & Cicchetti, 2016; Masten & Labella, 2016; Monn & others, 2017) have found that executive function and parenting skills are linked to homeless children’s success in school. Masten believes that executive function and good parenting skills are related. In her words, “When we see kids with good executive function, we often see adults around

**fuzzy trace theory** States that memory is best understood by considering two types of memory representations: (1) verbatim memory trace, and (2) gist. In this theory, older children’s better memory is attributed to the fuzzy traces created by extracting the gist of information.

them that are good self-regulators. . . Parents model, they support, and they scaffold these skills" (Masten, 2012, p. 11).

**Critical Thinking** Currently, there is considerable interest among psychologists and educators regarding aspects of critical thinking (Bonney & Sternberg, 2017). **Critical thinking** involves thinking reflectively and productively and evaluating evidence. In this text, the second and third parts of the *Review, Connect, Reflect* sections of each chapter challenge you to think critically about a topic or an issue related to the discussion.

According to Ellen Langer (2005), **mindfulness**—being alert, mentally present, and cognitively flexible while going through life's everyday activities and tasks—is an important aspect of thinking critically. Mindful children and adults maintain an active awareness of the circumstances in their life and are motivated to find the best solutions to tasks. Mindful individuals create new ideas, are open to new information, and explore multiple strategies and perspectives. By contrast, mindless individuals are entrapped in old ideas, engage in automatic behavior, and often use a single strategy or adopt a single perspective.

Jacqueline and Martin Brooks (2001) lament that few schools really teach students to think critically and develop a deep understanding of concepts. Deep understanding occurs when students are stimulated to rethink previously held ideas. In Brooks and Brooks' view, schools spend too much time getting students to give a single correct answer in an imitative way, rather than encouraging them to expand their thinking by coming up with new ideas and rethinking earlier conclusions. They observe that too often teachers ask students to recite, define, describe, state, and list, rather than to analyze, infer, connect, synthesize, criticize, create, evaluate, think, and rethink. Many successful students complete their assignments, do well on tests and get good grades, yet they don't ever learn to think critically and deeply. They think superficially, staying on the surface of problems rather than stretching their minds and becoming deeply engaged in meaningful thinking.

Recently, Robert Roeser and his colleagues (Roeser & Eccles, 2015; Roeser & others, 2014; Roeser & Zelazo, 2012) have emphasized that mindfulness is an important mental process that children can engage in to improve a number of cognitive and socioemotional skills, such as executive function, focused attention, emotion regulation, and empathy. They have proposed that mindfulness training could be implemented in schools through practices such as using age-appropriate activities that increase children's reflection on moment-to-moment experiences and result in improved self-regulation.

In addition to mindfulness training, activities such as yoga, meditation, and tai chi recently have been suggested as candidates for improving children's cognitive and socioemotional development (Bostic & others, 2015; Roeser & Pinela, 2014). Together these activities are being grouped under the topic of *contemplative science*, a cross-disciplinary term that involves the study of how various types of mental and physical training might enhance children's development (Roeser & Eccles, 2015; Roeser & Zelazo, 2012). In a recent study, a social and emotional learning program that focused on mindfulness and caring for others was effective in improving fourth- and fifth-graders' cognitive control, mindfulness, emotional control, optimism, and peer relations, and in reducing depressive symptoms (Schonert-Reichl & others, 2015). In other recent research, mindfulness training has been found to improve children's attention and self-regulation (Poehlmann-Tynan & others, 2016), achievement (Singh & others, 2016), and coping strategies in stressful situations (Dariotis & others, 2016). In a recent study, mindfulness training improved children's attention and self-regulation (Felver & others, 2017). Also, in two recent studies, mindfulness-based interventions reduced public school teachers' stress, produced a better mood at school and at home, and resulted in better sleep (Crain, Schonert-Reichl, & Roeser, 2017; Taylor & others, 2016).

**Creative Thinking** Cognitively competent children not only think critically, but also creatively (Renzulli, 2018; Sternberg, 2018e, f; Sternberg & Kaufman, 2018b; Sternberg & Sternberg, 2017). **Creative thinking** is the ability to think in novel and unusual ways and to come up with unique solutions to problems. Thus, intelligence and creativity are not the same thing. This difference was recognized by J. P. Guilford (1967), who distinguished between **convergent thinking**, which produces one correct answer and characterizes the kind of thinking that is required on conventional tests of intelligence, and **divergent thinking**, which produces many different answers to the same question and characterizes creativity. For example, a typical item on a conventional intelligence test is "How many quarters will you get in return for 60 dimes?" In contrast, the following question has many possible answers: "What image comes to mind when you hear the phrase 'sitting alone in a dark room' or 'some unique uses for a paper clip'?"

**critical thinking** Thinking reflectively and productively, as well as evaluating evidence.

**mindfulness** Being alert, mentally present, and cognitively flexible while going through life's everyday activities and tasks.

**creative thinking** The ability to think in novel and unusual ways and to come up with unique solutions to problems.

**convergent thinking** Thinking that produces one correct answer and is characteristic of the kind of thinking tested by standardized intelligence tests.

**divergent thinking** Thinking that produces many answers to the same question and is characteristic of creativity.

A special concern is that children's creative thinking appears to be declining. A study of approximately 300,000 U.S. children and adults found that creativity scores rose until 1990, but since then have been steadily declining (Kim, 2010). Among the likely causes of the creativity decline are the number of hours U.S. children spend watching TV and playing video games instead of engaging in creative activities, as well as the lack of emphasis on creative thinking skills in schools (Beghetto & Kaufman, 2017; Renzulli, 2017, 2018; Sternberg, 2018e, f). Some countries, though, are placing increased emphasis on creative thinking in schools. For example, historically, creative thinking has been discouraged in Chinese schools. However, Chinese educators are now encouraging teachers to spend more classroom time on creative activities (Plucker, 2010).

It is important to recognize that children will show more creativity in some domains than others (Sternberg, 2018e, f). A child who shows creative thinking skills in mathematics may not exhibit these skills in art, for example. An important goal is to help children become more creative. The *Connecting Development to Life* interlude offers some recommended ways to accomplish this goal.

**Metacognition** Metacognition is cognition about cognition, or knowing about knowing (Flavell, 2004). Metacognition can take many forms, including thinking about and knowing when and where to use particular strategies for learning or solving problems (Fitzgerald, Arvaneh, & Dockree, 2017; Norman, 2017). Conceptualization of metacognition consists of several dimensions of executive function, such as planning (deciding how much time to spend focusing on a task, for example) and self-regulation (modifying strategies as work on a task progresses, for example) (Allen & others, 2017; Fergus & Bardeen, 2018).

Many studies classified as "metacognitive" have focused on *metamemory*, or knowledge about memory. This includes general knowledge about memory, such as knowing that recognition tests are easier than recall tests. It also encompasses knowledge about one's own memory, such as a student's ability to monitor whether she has studied enough for an upcoming test or a child's confidence in eyewitness judgments (Buratti, Allwood, & Johansson, 2014).

Young children do have some general knowledge about memory (Lukowski & Bauer, 2014). By 5 or 6 years of age, children usually know that familiar items are easier to learn than unfamiliar ones, that short lists are easier to memorize than long ones, that recognition is easier than recall, and that forgetting is more likely to occur over time (Lyon & Flavell, 1993). However, in other ways young children's metamemory is limited. They don't understand that related items are easier to remember than unrelated ones and that remembering the gist of a story is easier than remembering information verbatim (Kreutzer, Leonard, & Flavell, 1975). By the fifth grade, students understand that gist recall is easier than verbatim recall.

Young children also have only limited knowledge about their own memory. They have an inflated opinion of their memory abilities. For example, in one study a majority of young children predicted that they would be able to recall all 10 items on a list of 10 items. When tested for this, none of the young children managed this feat (Flavell, Friedrichs, & Hoyt, 1970). As they move through the elementary school years, children give more realistic evaluations of their memory skills (Schneider, 2011).

In addition to metamemory, metacognition includes knowledge about strategies (Graham, 2018a, b; Harris & others, 2018; McCormick, Dimmitt, & Sullivan, 2013). Strategies have been the focus of a number of microgenetic investigations (Braithwaite, Tian, & Siegler, 2018; Siegler & Braithwaite, 2017). Recall from the "Introduction" chapter that the *microgenetic method* involves obtaining detailed information about processing mechanisms as they are occurring from moment to moment (Siegler, 2017). Using the microgenetic approach, researchers have shown that the process of developing effective strategies occurs gradually, not abruptly. This research has found considerable variability in children's use of strategies, even revealing that they may use an incorrect strategy in solving a math problem for which they had used a correct strategy several trials earlier (Siegler & Braithwaite, 2017).

In the view of Michael Pressley (2003), the key to education is helping students learn a rich repertoire of strategies that produce solutions to problems. Good thinkers routinely use strategies and effective planning to solve problems. Good thinkers also know when and where

## Strategies for Increasing Children's Creative Thinking

Following are some strategies for increasing children's creative thinking.

### Encourage Brainstorming

**Brainstorming** is a technique in which people are encouraged to come up with creative ideas in a group, play off each other's ideas, and say practically whatever comes to mind that seems relevant to a particular issue. Facilitators usually tell participants to hold off from criticizing others' ideas at least until the end of the brainstorming session.

### Provide Environments That Stimulate Creativity

Some environments nourish creativity, while others inhibit it. Parents and teachers who encourage creativity often rely on children's natural curiosity. They provide exercises and activities that stimulate children to find insightful solutions to problems, rather than ask a lot of questions that require rote answers (Beghetto, 2018; Renzulli, 2018; Sternberg & Kaufman, 2018a). Teachers also encourage creativity by taking students on field trips to locations where creativity is valued. Science, discovery, and children's museums offer rich opportunities to stimulate creativity.

### Don't Overcontrol

Teresa Amabile (1993, 2018) says that telling children exactly how to do things leaves them feeling that originality is a mistake and exploration is a waste of time. Instead of dictating which activities they should engage in, teachers and parents who let children follow their interests and who support their inclinations are less likely to stifle their natural curiosity (Hennessey, 2011, 2017, 2018).

### Encourage Internal Motivation

Parents and teachers should avoid excessive use of prizes, such as gold stars, money, or toys, which can stifle creativity by undermining the intrinsic pleasure students derive from creative activities (Hennessey, 2011, 2017, 2018). Creative children's motivation is the satisfaction generated by the work itself.

### Build Children's Confidence

To expand children's creativity, teachers and parents should encourage children to believe in their own ability to create something innovative and worthwhile. Building children's confidence in their creative skills aligns with Bandura's (2012) concept of self-efficacy, the belief that one can master a situation and produce positive outcomes.

### Guide Children to Be Persistent and Delay Gratification

Parents and teachers need to be patient and understand that most highly successful creative products take years to develop (Sternberg, 2018g, h). Most creative individuals work on ideas and projects for months and years without being rewarded for their efforts (Sternberg, 2018g, h).

### Encourage Children to Take Intellectual Risks

Parents and teachers should encourage children to take intellectual risks. Creative individuals take intellectual risks and seek to discover or invent something never before discovered or invented. Creative people are not afraid of failing or getting something wrong (Sternberg, 2018e, f).

### Introduce Children to Creative People

Teachers can invite creative people to their classrooms and ask them to describe what helps them become creative or to demonstrate their creative skills. A writer, poet, musician, scientist, and many others can bring their props and productions to the classroom, turning it into a forum for stimulating students' creativity.

to use strategies. Understanding when and where to use strategies often results from monitoring the learning situation (Serra & Metcalfe, 2010).

Pressley and his colleagues (Pressley & others, 2003, 2004, 2007) spent considerable time in recent years observing strategy instruction by teachers and strategy use by students in elementary and secondary school classrooms. They conclude that strategy instruction is far less complete and intense than what students need to receive in order to learn how to use strategies

effectively. They argue that education ought to be restructured so that students are provided with more opportunities to become competent strategic learners.

## INTELLIGENCE

How can intelligence be defined? **Intelligence** is the ability to solve problems and to adapt and learn from experiences. Interest in intelligence has often focused on individual differences and assessment. **Individual differences** are the stable, consistent ways in which people differ from each other (Sackett & others, 2017). We can talk about individual differences in personality or any other domain, but it is in the domain of intelligence that the most attention has been directed at individual differences (Estrada & others, 2017; Giofre & others, 2017). For example, an intelligence test purports to inform us about whether a student can reason better than others who have taken the test (Jaarsveld & Lachmann, 2017). Let's go back in history and see what the first intelligence test was like.

**The Binet Tests** In 1904, the French Ministry of Education asked psychologist Alfred Binet to devise a method of identifying children who were unable to learn in school. School officials wanted to reduce crowding by placing students who did not benefit from regular classroom teaching in special schools. Binet and his student Theophile Simon developed an intelligence test to meet this request. The test is called the 1905 Scale. It consisted of 30 questions on topics ranging from the ability to touch one's ear to the ability to draw designs from memory and define abstract concepts.

Binet developed the concept of **mental age (MA)**, an individual's level of mental development relative to others. Not much later, in 1912, William Stern created the concept of **intelligence quotient (IQ)**, a person's mental age divided by chronological age (CA), multiplied by 100; that is,  $IQ = MA/CA \times 100$ . If mental age is the same as chronological age, then the person's IQ is 100. If mental age is above chronological age, then IQ is more than 100. If mental age is below chronological age, then IQ is less than 100.

The Binet test has been revised many times to incorporate advances in the understanding of intelligence and intelligence tests. These revisions are called the *Stanford-Binet tests* (Stanford University is where the revisions have been done). In 2004, the test—now called the Stanford-Binet 5—was revised to analyze an individual's response in five content areas: fluid reasoning, knowledge, quantitative reasoning, visual-spatial reasoning, and working memory. A general composite score also is still obtained.

By administering the test to large numbers of people of different ages (from preschool through late adulthood) from different backgrounds, researchers have found that scores on the Stanford-Binet approximate a normal distribution (see Figure 9). A **normal distribution** is symmetrical, with a majority of the scores falling in the middle of the possible range of scores and much fewer scores appearing toward the extremes of the range.

**The Wechsler Scales** Another set of widely used tests to assess students' intelligence is called the Wechsler scales, developed by psychologist David Wechsler. They include the

#### THE NORMAL CURVE AND STANFORD-BINET IQ SCORES.

The distribution of IQ scores approximates a normal curve. Most of the population falls in the middle range of scores. Notice that extremely high and extremely low scores are very rare. Slightly more than two-thirds of the scores fall between 85 and 115. Only about 1 in 50 individuals has an IQ higher than 130, and only about 1 in 50 individuals has an IQ lower than 70.

## Verbal Subscales

### Similarities

A child must think logically and abstractly to answer a number of questions about how things might be similar.

Example: "In what way are a lion and a tiger alike?"

### Comprehension

This subscale is designed to measure an individual's judgment and common sense.

Example: "What is the advantage of keeping money in a bank?"

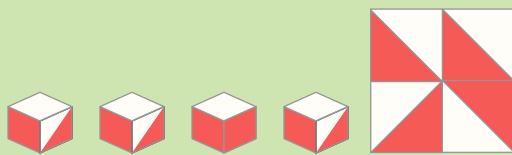

## Nonverbal Subscales

### Block Design

A child must assemble a set of multicolored blocks to match designs that the examiner shows.

Visual-motor coordination, perceptual organization, and the ability to visualize spatially are assessed.

Example: "Use the four blocks on the left to make the pattern on the right."

Wechsler Preschool and Primary Scale of Intelligence—Fourth Edition (WPPSI-IV) to test children from 2.5 years to 7.25 years of age; the Wechsler Intelligence Scale for Children—Fifth Edition (WISC-V) for children and adolescents 6 to 16 years of age; and the Wechsler Adult Intelligence Scale—Fourth Edition (WAIS-IV).

The WISC-V now not only provides an overall IQ score but also yields five composite scores (Verbal Comprehension, Working Memory, Processing Speed, Fluid Reasoning, and Visual Spatial) (Canivez, Watkins, & Dombrowski, 2017). These scores allow the examiner to quickly see whether the individual is strong or weak in different areas of intelligence. The Wechsler scales also include 16 verbal and nonverbal subscales. Three of the Wechsler subscales are shown in Figure 10.

**Types of Intelligence** Is it more appropriate to think of a child's intelligence as a general ability or as a number of specific abilities? Robert Sternberg and Howard Gardner have proposed influential theories oriented to this second viewpoint.

**Sternberg's Triarchic Theory** Robert J. Sternberg (1986, 2004, 2010, 2011, 2012, 2013, 2014a, b, 2015, 2016a, b, 2017a, b; 2018a, b, c, d) developed the **triarchic theory of intelligence**, which states that intelligence comes in three forms: (1) *analytical intelligence*, which refers to the ability to analyze, judge, evaluate, compare, and contrast; (2) *creative intelligence*, which consists of the ability to create, design, invent, originate, and imagine; and (3) *practical intelligence*, which involves the ability to use, apply, implement, and put ideas into practice.

Sternberg (2017a, b, 2018a, b, c, d) says that children with different triarchic patterns "look different" in school. Students with high analytic ability tend to be favored in conventional schooling. They often do well under direct instruction, in which the teacher lectures and gives students objective tests. They often are considered to be "smart" students who get good grades, show up in high-level tracks, do well on traditional tests of intelligence and the SAT, and later get admitted to competitive colleges.

In contrast, children who are high in creative intelligence often are not on the top rung of their class. Many teachers have specific expectations about how assignments should be done, and creatively intelligent students may not conform to those expectations. Instead of giving conformist answers, they give unique answers, for which they might get reprimanded or marked down. No teacher wants to discourage creativity, but Sternberg stresses that too often a teacher's desire to increase students' knowledge suppresses creative thinking.

Like children high in creative intelligence, children with predominantly practical intelligence often do not relate well to the demands of school. However, many of these children do well outside of the classroom's walls. They may have excellent social skills and good common sense. As adults, some become successful managers, entrepreneurs, or politicians in spite of having undistinguished school records.

**Gardner's Eight Frames of Mind** Howard Gardner (1983, 1993, 2002, 2016) suggests there are eight types of intelligence, or "frames of mind." These are described here, with examples of the types of vocations in which they are regarded as strengths (Campbell, Campbell, & Dickinson, 2004):

**Verbal:** The ability to think in words and use language to express meaning. Occupations: authors, journalists, speakers.

**Mathematical:** The ability to carry out mathematical operations. Occupations: scientists, engineers, accountants.

**Spatial:** The ability to think three-dimensionally. Occupations: architects, artists, sailors.

**Bodily-kinesthetic:** The ability to manipulate objects and be physically adept. Occupations: surgeons, craftspeople, dancers, athletes.

**Musical:** A sensitivity to pitch, melody, rhythm, and tone. Occupations: composers and musicians.

*Interpersonal:* The ability to understand and interact effectively with others.

Occupations: successful teachers, mental health professionals.

*Intrapersonal:* The ability to understand oneself. Occupations: theologians, psychologists.

*Naturalist:* The ability to observe patterns in nature and understand natural and human-made systems. Occupations: farmers, botanists, ecologists, landscapers.

According to Gardner, everyone has all of these intelligences to varying degrees. As a result, we prefer to learn and process information in different ways. People learn best when they can do so in a way that uses their stronger intelligences.

**Evaluating the Multiple-Intelligence Approaches** Sternberg's and Gardner's approaches have much to offer. They have stimulated teachers to think more broadly about what makes up children's competencies (Gardner, 2016; Gardner, Kornhaber, & Chen, 2018; Sternberg, 2017a, b, 2018a, b, c). And they have motivated educators to develop programs that instruct students in multiple domains. These approaches have also contributed to interest in assessing intelligence and classroom learning in innovative ways, such as by evaluating student portfolios (Moran & Gardner, 2006, 2007).

However, doubts about multiple-intelligence approaches persist and many psychologists endorse the general intelligence approach (Burkhart, Schubiger, & van Schaik, 2017; Hagmann-von Arx, Lemola, & Grob, 2018). A number of psychologists think that the multiple-intelligence views have taken the concept of specific intelligences too far (Reeve & Charles, 2008). Some argue that a research base to support the three intelligences of Sternberg or the eight intelligences of Gardner has not yet emerged. One expert on intelligence, Nathan Brody (2007), observes that people who excel at one type of intellectual task are likely to excel in others. Thus, individuals who do well at memorizing lists of digits are also likely to be good at solving verbal problems and spatial layout problems. Other critics suggest that if musical skill reflects a distinct type of intelligence, why not label the skills of outstanding chess players, prizefighters, painters, and poets as types of intelligence?

Advocates of the concept of general intelligence point to its accuracy in predicting school and job success. For example, scores on tests of general intelligence are substantially correlated with school grades and achievement test performance, both at the time of the test and years later (Cucina & others, 2016; Strenze, 2007). For example, a recent meta-analysis of 240 independent samples and more than 100,000 individuals found a correlation of +.54 between intelligence and school grades (Roth & others, 2015). Also, a recent study found a significant link between children's general intelligence and their self-control (Meldrum & others, 2017).

The argument between those who support the concept of general intelligence and those who advocate the multiple-intelligence view is ongoing (Gardner, Kornhaber, & Chen, 2018; Hilger & others, 2017). Sternberg (2017a, b, 2018b, c) acknowledges the existence of a general intelligence for the kinds of analytical tasks that traditional IQ tests assess but thinks that the range of tasks those tests measure is far too narrow.

**Interpreting Differences in IQ Scores** The IQ scores that result from tests such as the Stanford-Binet and Wechsler scales provide information about children's mental abilities. However, interpreting what performance on an intelligence test means is a subject of debate among researchers (Deary, 2012; Sternberg, 2017a, b, 2018a, b, c).

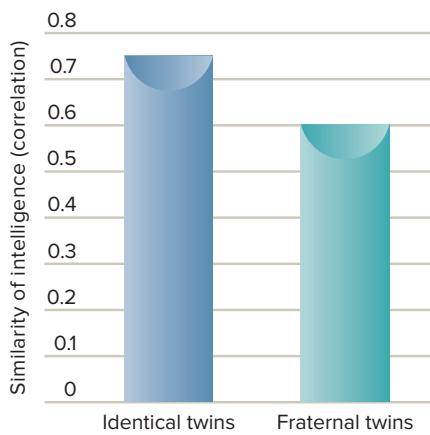

**The Influence of Genetics** How strong is the effect of genetics on intelligence? This question is difficult to answer because making clear-cut distinctions between the influences of heredity and environment is virtually impossible. Also, most research on heredity and environment does not include environments that differ radically. Thus, it is not surprising that many genetic studies show environment to be a fairly weak influence on intelligence.

Have scientists been able to pinpoint specific genes that are linked to intelligence? A research review concluded that there may be more than 1,000 genes that affect intelligence, each possibly having a small influence on an individual's intelligence (Davies & others, 2011). Thus, some scientists argue that there is a strong genetic component to intelligence (Hill & others, 2018; Rimfeld & others, 2017; Zabaneh & others, 2017). One strategy for examining the role of heredity in intelligence is to compare the IQs of identical and fraternal twins. Recall that identical twins have exactly the same genetic makeup but fraternal twins do not. If intelligence is genetically determined, say some investigators, the IQs of identical twins should be

**triarchic theory of intelligence** Sternberg's theory that intelligence consists of analytical intelligence, creative intelligence, and practical intelligence.

### CORRELATION BETWEEN INTELLIGENCE TEST SCORES AND TWIN STATUS

**TEST SCORES AND TWIN STATUS.** The graph represents a summary of research findings that have compared the intelligence test scores of identical and fraternal twins. more similar than the IQs of fraternal twins. A research review of many studies found that the difference between the average correlation of IQs of identical and fraternal twins was .15, a relatively small difference (Grigorenko, 2000) (see Figure 11).

Today, most researchers agree that genetics and environment interact to influence intelligence. For most people, this means that modifications in environment can change their IQ scores considerably. Although genetic endowment may always influence a person's intellectual ability, the environmental influences and opportunities available to children and adults do make a difference (Sternberg, 2017a, b; 2018a, b, c).

**Environmental Influences** In the chapter on "Cognitive Development in Infancy" we described a study that demonstrated the influence of parental communication patterns on children's cognitive abilities. Researchers went into homes and observed how extensively parents from welfare and middle-income professional families communicated with their young children (Hart & Risley, 1995). They found that the middle-income professional parents were much more likely to communicate with their young children than the welfare parents were. How much the parents communicated with their children in the first three years of their lives was correlated with the children's Stanford-Binet IQ scores at age 3. The more parents communicated with their children, the higher the children's IQs were.

The environment's role in intelligence also is reflected in the 12- to 18-point increase in IQ that occurs when children are adopted from lower-SES to middle-SES families (Nisbett & others, 2012). Environmental influences on intelligence also involve schooling (Gustafsson, 2007). The biggest effects have been found when large groups of children have been deprived of formal education for an extended period, resulting in lower intelligence (Ceci & Gilstrap, 2000). Another possible effect of education can be seen in rapidly increasing IQ test scores around the world (Flynn, 1999, 2007, 2011, 2013). IQ scores have been increasing so quickly that a high percentage of people regarded as having average intelligence at the turn of the century would be considered below average in intelligence today (see Figure 12). If a representative sample of people today took the Stanford-Binet test version used in 1932, about 25 percent would be defined as having very superior intelligence, a label usually accorded to fewer than 3 percent of the population. Because the increase has taken place in a relatively short time, it can't be due to heredity, but rather may be due to increasing levels of education attained by a much greater percentage of the world's population, or to other environmental factors such as the explosion of information to which people are exposed (Laciga & Cigler, 2017; Shenk, 2017; Weber, Dekhtyar, & Herlitz, 2017). The worldwide increase in intelligence test scores that has occurred over a short time frame has been called the *Flynn effect* after the researcher who discovered it, James Flynn.

Researchers are increasingly concerned about finding ways to improve the early environment of children who are at risk for impoverished intelligence and poor developmental outcomes (Hardy, Smeeding, & Ziliak, 2018; Yoshikawa & others, 2017). For various reasons, many low-income parents have difficulty providing an intellectually stimulating environment for their children. Programs that educate parents to be more sensitive caregivers and better teachers, as well as support services such as quality child care and early childhood education programs, can make a difference in a child's intellectual development (Follari, 2019; Morrison, 2018; Reynolds, Ou, & Temple, 2018). Thus, the efforts to counteract a deprived early environment's effect on

### INCREASING IQ SCORES FROM 1932 TO 1997

**1997.** As measured by the Stanford-Binet intelligence test, American children seem to be getting smarter. Scores of a group tested in 1932 fell along a bell-shaped curve with half below 100 and half above. Studies show that if children took that same test today, half would score above 120 on the 1932 scale. Very few of them would score in the "intellectually deficient" end on the left side, and about one-fourth would rank in the "very superior" range on the right side. intelligence emphasize prevention rather than remediation. In a recent two-year intervention study with families living in poverty, maternal scaffolding and positive home stimulation improved young children's intellectual functioning (Obradovic & others, 2016).

In sum, there is a consensus among psychologists that both heredity and environment influence intelligence (Grigorenko & others, 2016; Sauce & Matzel, 2018; Sternberg, 2017a, 2018a). This consensus reflects the nature-nurture issue, which focuses on the extent to which development is influenced by nature (heredity) and nurture (environment). Although psychologists agree that intelligence is the product of both nature and nurture, there is still disagreement about how strongly each influences intelligence.

**Culture and Culture-Fair Tests** Differing conceptions of intelligence occur not only among psychologists but also among cultures (Sternberg, 2018f). What is viewed as intelligent in one culture may not be thought of as intelligent in another. For example, people in Western cultures tend to view intelligence in terms of reasoning and thinking skills, whereas people in Eastern cultures see intelligence as a way for members of a community to engage successfully in social roles (Nisbett, 2003).

**Culture-fair tests** are tests of intelligence that are intended to be free of cultural bias. Two types of culture-fair tests have been devised. The first type includes items that are familiar to children from all socioeconomic and ethnic backgrounds, or items that at least are familiar to the children taking the test. For example, a child might be asked how a bird and a dog are different, on the assumption that all children have been exposed to birds and dogs. The second type of culture-fair test has no verbal questions. Even with tests that are designed to be culture-fair, people with more education tend to score higher than do those with less education.

Why is it so hard to create culture-fair tests? Most tests tend to reflect what the dominant culture thinks is important. If tests have time limits, that will bias the test against groups not concerned with time. If languages differ, the same words might have different meanings for different language groups. Even pictures can produce bias because some cultures have less experience with drawings and photographs. Because of such difficulties in creating culture-fair tests, Robert Sternberg concludes that there are no culture-fair tests, only *culture-reduced tests*.

**Ethnic Variations** On average, African American schoolchildren in the United States score 10 to 15 points lower on standardized intelligence tests than White American schoolchildren do (Brody, 2000). Children from Latino families also score lower than White children do. These are average scores, however, and there is significant overlap in the distribution of scores. About 15 to 25 percent of African American schoolchildren score higher than half of White schoolchildren do, and many White schoolchildren score lower than most African American schoolchildren.

As African Americans have gained social, economic, and educational opportunities, the gap between African Americans and non-Latino Whites on standardized intelligence tests is shrinking. A research review concluded that the IQ gap between African Americans and non-Latino Whites has been reduced considerably in recent years (Nisbett & others, 2012). This gap especially narrows in college, where African American and non-Latino White students often experience more similar environments than during the elementary and high school years (Myerson & others, 1998). Further, a recent study using the Stanford Binet Intelligence Scales found no differences in overall intellectual ability between non-Latino White and African American preschool children when the children were matched on age, gender, and parental education level (Dale & others, 2014). Nonetheless, a recent analysis concluded that the underrepresentation of African Americans in STEM (science, technology, engineering, and math) subjects and careers is linked teachers' expectations that African American students have less innate talent in these fields than non-Latino Whites (Leslie & others, 2015).

One potential influence on intelligence test performance is **stereotype threat**, the anxiety that one's behavior might confirm a negative stereotype about one's group (Grand, 2017; von Hippel, Kalokerinos, & Zacher, 2017; Williams & others, 2018). For example, when African Americans take an intelligence test, they may experience anxiety about confirming the old stereotype that Blacks are "intellectually inferior." Research studies have confirmed the existence of stereotype threat (Lyons & others, 2018; Wegmann, 2017). Also, African American students do more poorly on standardized tests if they perceive that they are being evaluated. If they think the test doesn't count, they perform as well as White students (Aronson, 2002). However, some critics argue that the extent to which stereotype threat explains the testing gap has been exaggerated (Sackett, Borneman, & Connelly, 2009).

**culture-fair tests** Tests of intelligence that are designed to be free of cultural bias.

**stereotype threat** The anxiety that one's behavior might confirm a negative stereotype about one's group.

**Using Intelligence Tests** Here are some cautions about IQ that can help you avoid the pitfalls of using information about a child's intelligence in negative ways:

- *Avoid stereotyping and expectations.* A special concern is that the scores on an IQ test easily can lead to stereotypes and expectations about students. Sweeping generalizations are too often made on the basis of an IQ score. An IQ test should always be considered a measure of current performance. It is not a measure of fixed potential. Maturation changes and enriched environmental experiences can increase a student's IQ score.
- *Know that IQ is not a sole indicator of competence.* Another concern about IQ tests involves their use as the main or sole assessment of competence. A high IQ is not the ultimate human value. As we have seen in this chapter, it is important to consider not only students' intellectual competence in such areas as verbal skills but also their creative and practical skills.
- *Use caution in interpreting an overall IQ score.* In evaluating a child's intelligence, it is wiser to think of intelligence as consisting of a number of domains. Keep in mind the different types of intelligence described by Sternberg and Gardner. Remember that by considering the different domains of intelligence you can find that every child has at least one area of strength.

**intellectual disability** A condition of limited mental ability in which the individual (1) has a low IQ, usually below 70 on a traditional intelligence test, (2) has difficulty adapting to the demands of everyday life, and (3) first exhibits these characteristics by age 18.

**organic intellectual disability** A genetic disorder or condition involving brain damage that is linked to a low level of intellectual functioning.

**cultural-familial intellectual disability** Condition in which there is no evidence of organic brain damage but the individual's IQ generally is between 50 and 70.

## EXTREMES OF INTELLIGENCE

Intelligence tests have been used to discover indications of intellectual disability or intellectual giftedness, the extremes of intelligence. At times, intelligence tests have been misused for this purpose. Keeping in mind the theme that an intelligence test should not be used as the sole indicator of intellectual disability or giftedness, we will explore the nature of these intellectual extremes.

**Intellectual Disability** The most distinctive feature of intellectual disability (formerly called mental retardation) is inadequate intellectual functioning. Long before formal tests were developed to assess intelligence, individuals with an intellectual disability were identified by a lack of age-appropriate skills in learning and caring for themselves. Once intelligence tests were developed, they were used to identify the degree of intellectual disability. However, even individuals with an intellectual disability who have the same low IQ may have very different levels of functioning. One might be married, employed, and involved in the community and the other might require constant supervision in an institution. Such differences in social competence led psychologists to include deficits in adaptive behavior in their definition of intellectual disability.

**Intellectual disability** is a condition of limited mental ability in which the individual (1) has a low IQ, usually below 70 on a traditional intelligence test; (2) has difficulty adapting to the demands of everyday life; and (3) first exhibits these characteristics by age 18 (Heward, Alber-Morgan, & Konrad, 2017). The age limit is included in the definition of intellectual disability because, for example, we don't usually think of a college student who suffers massive brain damage in a car accident, resulting in an IQ of 60, as having an "intellectual disability." The low IQ and low adaptiveness should be evident in childhood, not after normal functioning is interrupted by damage of some form (Burack & others, 2016). About 5 million Americans fit this definition of intellectual disability.

Some cases of intellectual disability have an organic cause. **Organic intellectual disability** describes a genetic disorder or a lower level of intellectual functioning caused by brain damage. Down syndrome is one form of organic intellectual disability, and it occurs when an extra chromosome is present. Other causes of organic intellectual disability include fragile X syndrome, an abnormality in the X chromosome that was discussed in "Biological Beginnings"; prenatal malformation; metabolic disorders; and diseases that affect the brain. Most people who suffer from organic intellectual disability have IQs between 0 and 50.

When no evidence of organic brain damage can be found, cases are labeled **cultural-familial intellectual disability**. Individuals with this type of disability have IQs between 55 and 70. Psychologists suspect that this type of disability often results from growing up in a below-average intellectual environment. Children with this type of disability can be identified in schools, where they often fail, need tangible rewards (candy rather than praise), and are highly sensitive to what others expect of them. However, as adults, they are usually not noticeable, perhaps because adult settings don't tax their cognitive skills as sorely. It may also be that they increase their intelligence as they move toward adulthood.

**Giftedness** There have always been people whose abilities and accomplishments outshine those of others—the whiz kid in class, the star athlete, the natural musician. People who are **gifted** have above-average intelligence (an IQ of 130 or higher) and/or superior talent for something. When it comes to programs for gifted students, most school systems select children who have intellectual superiority and academic aptitude, whereas children who are talented in the visual and performing arts (art, drama, dance), who demonstrate skill in athletics, or who have other special aptitudes tend to be overlooked (Olszewski-Kubilius & Thomson, 2013). There also are increasing calls to further widen the criteria for giftedness to include such factors as creativity and commitment (Sternberg, 2017c; Sternberg, 2018g; Sternberg & Kaufman, 2018a).

Estimates vary but indicate that approximately 6 to 10 percent of U.S. students are classified as gifted (National Association for Gifted Children, 2017). This percentage is likely conservative because it focuses more on children who are gifted intellectually and academically, often failing to include those who are gifted in creative thinking or the visual and performing arts (Ford, 2012, 2015a, b, 2016).

**Characteristics** What are the characteristics of children who are gifted? Despite speculation that giftedness is linked with having a mental disorder, no relation between giftedness and mental disorder has been found. Similarly, the idea that gifted children are maladjusted is a myth, as Lewis Terman (1925) found when he conducted an extensive study of 1,500 children whose Stanford-Binet IQs averaged 150. The children in Terman's study were socially well adjusted, and many went on to become successful doctors, lawyers, professors, and scientists. Studies support the conclusion that gifted people tend to be more mature than others, have fewer emotional problems than average, and grow up in a positive family climate (Davidson, 2000). For example, a recent study revealed that parents and teachers identified elementary school children who are not gifted as having more emotional and behavioral risks than children who are gifted (Eklund & others, 2015). In this study, when children who are gifted did have problems, they were more likely to be internalized problems, such as anxiety and depression, than externalized problems such as acting out and high levels of aggression.

Ellen Winner (1996) described three criteria that characterize gifted children, whether in art, music, or academic domains:

1. *Precocity.* Gifted children are precocious. They begin to master an area earlier than their peers. Learning in their domain is more effortless for them than for ordinary children. In most instances, these gifted children are precocious because they have an inborn high ability in a particular domain or domains.
2. *Marching to their own drummer.* Gifted children learn in a qualitatively different way from ordinary children. One way that they march to a different drummer is that they need minimal help, or scaffolding, from adults to learn. In many instances, they resist any kind of explicit instruction. They often make discoveries on their own and solve problems in unique ways.
3. *A passion to master.* Gifted children are driven to understand the domain in which they have high ability. They display an intense, obsessive interest and an ability to focus. They motivate themselves, says Winner, and do not need to be “pushed” by their parents.

Also, researchers have found that children who are gifted learn at a faster pace, process information more rapidly, are better at reasoning, use superior strategies, and monitor their understanding better than their nongifted counterparts (Sternberg & Kaufman, 2018a).

**Nature-Nurture** Is giftedness a product of heredity or environment? Likely both (Duggan & Friedman, 2014; Sternberg & Kaufman, 2018a). Individuals who are gifted recall that they had signs of high ability in a particular area at a very young age, prior to or at the beginning of formal training. This suggests the importance of innate ability in giftedness. However, researchers have also found that individuals with world-class status in the arts, mathematics, science, and sports all report strong family support and years of training and practice (Bloom, 1985). Deliberate practice is an important characteristic of individuals who become experts in a particular domain. For example, in one study the best musicians engaged in twice as much deliberate practice over their lives as did the least successful ones (Ericsson, Krampe, & Tesch-Romer, 1993).

**Domain-Specific Giftedness and Development** Individuals who are highly gifted are typically not gifted in many domains, and research on giftedness is increasingly focused on domain-specific developmental trajectories (Sternberg & Kaufman, 2018a; Winner, 2014).

At age 2, art prodigy Alexandra Nechita (shown here as a teenager) colored in coloring books for hours and also took up pen and ink. She had no interest in dolls or friends. By age 5 she was using watercolors. Once she started school, she would start painting as soon as she got home. At the age of 8, in 1994, she saw the first public exhibit of her work. In succeeding years, working quickly and impulsively on canvases as large as 5 feet by 9 feet, she has completed hundreds of paintings, some of which sell for close to \$100,000 apiece. As an adult she continues to paint—relentlessly and passionately. It is, she says, what she loves to do. *What are some characteristics of children who are gifted?*

#### Nature Versus Nurture

The epigenetic view emphasizes that development is an ongoing, bi-directional interchange between heredity and environment. Connect to “Biological Beginnings.”

**gifted** Having above-average intelligence (an IQ of 130 or higher) and/or superior talent for something.

©Doug Wilson/Corbis/Getty Images

During the childhood years, the domain in which individuals are gifted usually emerges. Thus, at some point in the childhood years the child who is to become a gifted artist or the child who is to become a gifted mathematician begins to show expertise in that domain. Regarding domain-specific giftedness, software genius Bill Gates (1998), the founder of Microsoft and one of the world's richest persons, commented that when you are good at something you have to resist the urge to think that you will be good at everything. Gates says that because he has been so successful at software development, people expect him to be brilliant in other domains where he is far from being a genius.

Identifying an individual's domain-specific talent and providing individually appropriate and optional educational opportunities need to be accomplished at the very latest by adolescence (Keating, 2009). During adolescence, individuals who are talented become less reliant on parental support and increasingly pursue their own interests.

**Education of Children Who Are Gifted** An increasing number of experts argue that the education of children who are gifted in the United States requires a significant overhaul (Renzulli, 2017; Sternberg & Kaufman, 2018a). Ellen Winner (1996, 2009, 2014) argues that too often children who are gifted are socially isolated and underchallenged in the classroom. It is not unusual for them to be ostracized and labeled "nerds" or "geeks." Many eminent adults report that school was a negative experience for them, that they were bored and sometimes knew more than their teachers (Bloom, 1985). Winner argues that American education will benefit when standards are raised for all children. When some children are still underchallenged, she recommends that they be allowed to attend advanced classes in their domain of exceptional ability. Some especially precocious middle school students may benefit from taking college classes in their area of expertise. For example, Bill Gates took college math classes at 13; Yo-Yo Ma, a famous cellist, graduated from high school at 15 and attended Juilliard School of Music in New York City.

A final concern is that African American, Latino, and Native American children are underrepresented in gifted programs (Ford, 2012, 2014, 2015a, b, 2016; Mills, 2015). Much of the underrepresentation involves the lower test scores for these children compared with non-Latino White and Asian American children, which may reflect test bias and fewer opportunities to develop language skills such as vocabulary and comprehension (Ford, 2012, 2014, 2015a, b, 2016).

Vocabulary, Grammar, and Metalinguistic Awareness

Reading

Writing

Second-Language Learning and Bilingual Education

Children gain new skills as they enter school that make it possible for them to learn to read and write (Fox & Alexander, 2017; Graham & Harris, 2017). These skills include increased use of language to talk about things that are not physically present, learning what a word is, and learning how to recognize and talk about sounds. Children also learn the *alphabetic principle*—that the letters of the alphabet represent sounds of the language.

### VOCABULARY, GRAMMAR, AND METALINGUISTIC AWARENESS

During middle and late childhood, changes occur in the way children's mental vocabulary is organized. When asked to say the first word that comes to mind when they hear a word, preschool children typically provide a word that often follows the word in a sentence. For example, when asked to respond to *dog*, the young child may say “barks,” or to the word *eat* respond with “lunch.” At about 7 years of age, children begin to respond with a word that is the same part of speech as the stimulus word. For example, a child may now respond to the word *dog* with “cat” or “horse.” To *eat*, they now might say “drink.” This is evidence that children now have begun to categorize their vocabulary by parts of speech.

The process of categorizing becomes easier as children increase their vocabulary (Clark, 2012, 2017). Children's vocabulary increases from an average of about 14,000 words at age 6 to an average of about 40,000 words by age 11.

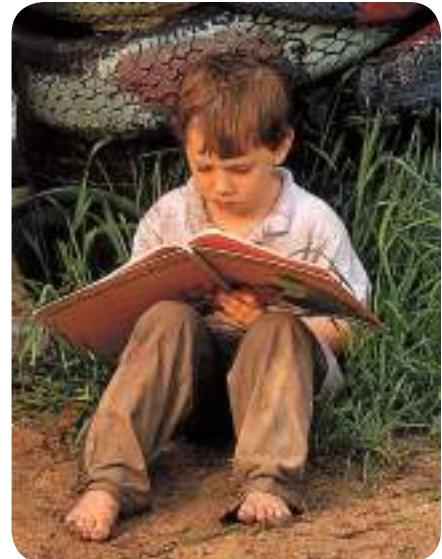

Children make similar advances in grammar (Clark, 2017). During the elementary school years, children's improvement in logical reasoning and analytical skills helps them understand such constructions as the appropriate use of comparatives (*shorter, deeper*) and subjunctives (“If you were president . . .”). During the elementary school years, children become increasingly able to understand and use complex grammar, such as the following sentence: *The boy who kissed his mother wore a hat*. They also learn to use language in a more connected way, producing connected discourse. They become able to relate sentences to one another to produce descriptions, definitions, and narratives that make sense. Children must be able to do these things orally before they can be expected to deal with them in written assignments.

These advances in vocabulary and grammar during the elementary school years are accompanied by the development of **metalinguistic awareness**, which is knowledge about language, such as understanding what a preposition is or being able to discuss the sounds of a language (Schiff, Nuri Ben-Shushan, & Ben-Artzi, 2017; Tong, Deacon, & Cain, 2014; Yeon, Bae, & Joshi, 2017). Metalinguistic awareness allows children “to think about their language, understand what words are, and even define them” (Berko Gleason, 2009, p. 4). It improves considerably during the elementary school years (Pan & Uccelli, 2009). Defining words becomes a regular part of classroom discourse, and children increase their knowledge of syntax as they study and talk about the components of sentences such as subjects and verbs (Crain, 2012). And reading also feeds into metalinguistic awareness as children try to comprehend written text.

Children also make progress in understanding how to use language in culturally appropriate ways—a process called *pragmatics* (Beguin, 2016; Bryant, 2012). By the time they enter adolescence, most children know the rules for using language in everyday contexts—that is, what is appropriate and inappropriate to say.

### READING

Before learning to read, children learn to use language to talk about things that are not present; they learn what a word is; and they learn how to recognize sounds and talk about them. Children who begin elementary school with a robust vocabulary have an advantage when it

**metalinguistic awareness** Knowledge about language, such as understanding what a preposition is or being able to discuss the sounds of a language.

comes to learning to read. Vocabulary development plays an important role in reading comprehension (Vacca & others, 2018).

How should children be taught to read? For many years debate focuses on the whole-language approach versus the phonics approach (Fox & Alexander, 2017; Reutzel & Cooter, 2019).

The **whole-language approach** stresses that reading instruction should parallel children's natural language learning. In some whole-language classes, beginning readers are taught to recognize whole words or even entire sentences, and to use the context of what they are reading to guess at the meaning of words. Reading materials that support the whole-language approach are whole and meaningful—that is, children are given material in its complete form, such as stories and poems, so that they learn to understand language's communicative function. Reading is connected with listening and writing skills. Although there are variations in whole-language programs, most share the premise that reading should be integrated with other skills and subjects, such as science and social studies, and that it should focus on real-world material. Thus, a class might read newspapers, magazines, or books, and then write about and discuss them.

In contrast, the **phonics approach** emphasizes that reading instruction should teach basic rules for translating written symbols into sounds. Early phonics-centered reading instruction should involve simplified materials.

Only after children have learned correspondence rules that relate spoken phonemes to the alphabet letters that are used to represent them should they be given complex reading materials, such as books and poems (Cunningham, 2017; Fox & Alexander, 2017; Leu & Kinzer, 2017).

Which approach is better? Research suggests that children can benefit from both approaches, but instruction in phonics needs to be emphasized (Leu & Kinzer, 2017; Reutzel & Cooter, 2019; Tompkins, 2018). An increasing number of experts in the field of reading now conclude that direct instruction in phonics is a key aspect of learning to read (Cunningham, 2017; Fox & Alexander, 2017).

Beyond the phonics/whole language issue in learning to read, becoming a good reader includes learning to read fluently (Breen & others, 2016). Many beginning or poor readers do not recognize words automatically. Their processing capacity is consumed by the demands of word recognition, so they have less capacity to devote to comprehension of groupings of words as phrases or sentences. As their processing of words and passages becomes more automatic, it is said that their reading becomes more *fluent* (Stevens, Walker, & Vaughn, 2017). Also, children's vocabulary development plays an important role in their reading comprehension (Vacca & others, 2018). And metacognitive strategies, such as learning to monitor one's reading progress, getting the gist of what is being read, and summarizing also are important in becoming a good reader (Schiff, Nuri Ben-Shushan, & Ben-Artzi, 2017).

## WRITING

As they begin to write, children often invent spellings. Parents and teachers should encourage children's early writing but not be overly concerned about the formation of letters or spelling. Corrections of spelling and printing should be selective and made in positive ways that do not discourage the child's writing and spontaneity.

Like becoming a good reader, becoming a good writer takes many years and lots of practice (Graham & Harris, 2017; Tompkins, 2019). Children should be given many writing opportunities. As their language and cognitive skills improve with good instruction, so will their writing skills. For example, developing a more sophisticated understanding of syntax and grammar serves as an underpinning for better writing. So do cognitive skills such as organization and logical reasoning. Through the course of the school years, students develop increasingly sophisticated methods of organizing their ideas.

The metacognitive strategies involved in being a competent writer are linked with those required to be a competent reader because the writing process involves competent reading and rereading during composition and revision (Graham & Harris, 2018; Harris & others, 2018).

**whole-language approach** An approach to reading instruction based on the idea that instruction should parallel children's natural language learning. Reading materials should be whole and meaningful.

**phonics approach** The idea that reading instruction should teach the basic rules for translating written symbols into sounds.

Further, researchers have found that strategy instruction involving planning, drafting, revising, and editing improves older elementary school children's metacognitive awareness and writing competence (Graham, Rouse, & Harris, 2018; Harris & Graham, 2018).

Monitoring one's writing progress is especially important in becoming a good writer (Graham & Harris, 2018; Graham & others, 2018; Harris & Graham, 2018). This includes being receptive to feedback and applying what one learns in writing one paper to making the next paper better.

Major concerns about students' writing competence are increasingly being voiced (Graham, 2017, 2018a, b; Tompkins, 2019). One study revealed that 70 to 75 percent of U.S. students in grades 4 through 12 are low-achieving writers (Persky, Dane, & Jin, 2003). College instructors report that 50 percent of high school graduates are not prepared for college-level writing (Achieve, Inc., 2005).

## SECOND-LANGUAGE LEARNING AND BILINGUAL EDUCATION

Are there sensitive periods in learning a second language? That is, if individuals want to learn a second language, how important is the age at which they begin to learn it? What is the best way to teach children who come from homes in which English is not the primary language?

**Second-Language Learning** For many years, it was claimed that if individuals did not learn a second language prior to puberty they would never reach native-language learners' proficiency in the second language (Johnson & Newport, 1991). However, recent research indicates a more complex conclusion: Sensitive periods likely vary across different language systems (Thomas & Johnson, 2008). Thus, for late language learners, such as adolescents and adults, new vocabulary is easier to learn than new sounds or new grammar (Neville, 2006). For example, children's ability to pronounce words with a native-like accent in a second language typically decreases with age, with an especially sharp drop occurring after the age of about 10 to 12. Also, adults tend to learn a second language faster than children, but their final level of second-language attainment is not as high as children's. And the way children and adults learn a second language differs somewhat. Compared with adults, children are less sensitive to feedback, less likely to use explicit strategies, and more likely to learn a second language from large amounts of input (Thomas & Johnson, 2008).

Students in the United States are far behind their counterparts in many developed countries in learning a second language. For example, in Russia, schools have 10 grades, called forms, which roughly correspond to the 12 grades in American schools. Russian children begin school at age 7 and begin learning English in the third form. Because of this emphasis on teaching English, most Russian citizens under the age of 40 today are able to speak at least some English. The United States is the only technologically advanced Western nation that does not have a national foreign language requirement at the high school level, even for students in rigorous academic programs.

Some aspects of children's ability to learn a second language transfer to success in other areas (Bialystok, 2017). Children who are fluent in two languages perform better than their single-language counterparts on tests of control of attention, concept formation, analytical reasoning, inhibition, cognitive flexibility, cognitive complexity, and cognitive monitoring (Bialystok, 2001, 2007, 2011, 2014, 2015, 2017; Bialystok & Craik, 2010; Sullivan & others, 2014). Recent research also documented that bilingual children are better at theory of mind tasks (Rubio-Fernandez, 2017). They also are more conscious of the structure of spoken and written language and better at noticing errors of grammar and meaning, skills that benefit their reading ability (Bialystok, 1997; Kuo & Anderson, 2012). A recent study of 6- to 10-year-olds found that early bilingual exposure was a key factor in bilingual children outperforming monolingual children on phonological awareness and word learning (Jasinska & Petit, 2018).

Thus, overall, bilingualism is linked to positive outcomes for children's language and cognitive development. (Antovich & Graf Estes, 2018; Singh & others, 2017; Wermelinger, Gampe, & Daum, 2017; Yow & others, 2018). An especially important developmental question that many parents of infants and young children have asked is whether they should teach them two languages simultaneously, or whether this might confuse them. The answer is that teaching

infants and young children two languages simultaneously (as when a mother's native language is English and her husband's is Spanish) has numerous benefits and few drawbacks (Bialystok, 2014, 2015, 2017).

Research indicates that bilingual children do have a smaller vocabulary in each language than monolingual children (Bialystok, 2011). Most children who learn two languages are not exposed to the same quantity and quality of each language. However, bilingual children do not show delays in the rate at which they acquire language overall (Hoff, 2016). In a recent study, by 4 years of age children who continued to learn Spanish and English languages had a total vocabulary growth that was greater than that of monolingual children (Hoff & others, 2014).

However, a different type of bilingualism occurs when immigrant children have used only their native language at home and then must learn the main language of a new country at school. For example, in the United States, many immigrant children go from being monolingual in their home language to bilingual in that language and in English, only to end up being monolingual speakers of English. This is called *subtractive bilingualism*, and it can have negative effects on children, who often become ashamed of their home language.

**Bilingual Education** A current controversy related to bilingualism involves the millions of U.S. children who come from homes in which English is not the primary language and then must learn English in school (Diaz-Rico, 2018; Echevarria, Vogt, & Short, 2017; Esposito & others, 2018; Peregoy & Boyle, 2017). What is the best way to teach these English language learners (ELLs), many of whom in the United States are from immigrant families living in poverty?

ELLs have been taught in one of two main ways: (1) instruction in English only, or (2) a *dual-language* (formerly called *bilingual*) approach that combines instruction in their home language and English (Diaz-Rico, 2018; Echevarria, Vogt, & Short, 2017). In a dual-language approach, instruction is given in both the ELL child's home language and English for varying amounts of time at certain grade levels. One of the arguments for the dual-language approach is the research discussed earlier demonstrating that bilingual children have more advanced information-processing skills than monolingual children (Genesee & Lindholm-Leary, 2012).

If a dual-language instructional strategy is used, too often it has been thought that immigrant children need only one or two years of this type of instruction. However, in general it takes immigrant children approximately three to five years to develop speaking proficiency and seven years to develop reading proficiency in English (Hakuta, Butler, & Witt, 2000). Also, immigrant children vary in their ability to learn English (Diaz-Rico, 2018; Echevarria, Vogt, & Short, 2017). Children who come from lower socioeconomic backgrounds have more difficulty than those from higher socioeconomic backgrounds (Hakuta, 2001; Hoff & Place, 2013). Thus, especially for immigrant children from lower socioeconomic backgrounds, more years of dual-language instruction may be needed than they currently are receiving.

What have researchers found regarding outcomes of ELL programs? Drawing conclusions about the effectiveness of ELL programs is difficult because of variations across programs in the number of years they are in effect, type of instruction, quality of schooling other than ELL instruction, teachers, children, and other factors. Further, no effective experiments have been conducted that compare bilingual education with English-only education in the United States (Snow & Kang, 2006). Some experts have concluded that the quality of instruction is more important in determining outcomes than the language in which it is delivered (Lesaux & Siegel, 2003).

Nonetheless, other experts, such as Kenji Hakuta (2001, 2005), support the combined home language and English approach because (1) children have difficulty learning a subject when it is taught in a language they do not understand; and (2) when both languages are integrated in the classroom, children learn the second language more readily and participate more actively. In support of Hakuta's view, most large-scale studies have found that the academic achievement of ELLs is higher in dual-language programs than English-only programs (Genesee & Lindholm-Leary, 2012). The slow physical growth of middle and late childhood gives way to the dramatic changes of puberty in early adolescence. Significant changes also occur in the adolescent’s brain in which earlier maturation of the amygdala (emotion processing) and later maturation of the prefrontal cortex (decision making, self-regulation) are likely linked to increases in risk-taking and sensation seeking. Sexual development is a normal aspect of adolescence, but having sexual intercourse early in adolescence is associated with a number of problems. Adolescence is a critical juncture in health because many poor health habits begin in adolescence. Despite recent declines, the United States has one of the highest rates of illicit drug use of any developed nation. Adolescent thought is more abstract, idealistic, and logical than children’s. The transition from elementary school to middle school or junior high is difficult for many individuals because it coincides with so many physical, cognitive, and socioemotional changes in development.

## Physical and Cognitive Development in Middle and Late Childhood

### 1 Physical Changes and Health

Body Growth and Change

The Brain

Motor Development

Exercise

Health, Illness, and Disease

LG1

Discuss physical changes and health in middle and late childhood.

- The period of middle and late childhood involves slow, consistent growth. During this period, children grow an average of 2 to 3 inches a year. Muscle mass and strength gradually increase. Among the most pronounced changes in body growth and proportion are decreases in head circumference and waist circumference in relation to body height.
- Changes in the brain in middle and late childhood include advances in functioning in the prefrontal cortex, which are reflected in improved attention, reasoning, and cognitive control. During middle and late childhood, less diffusion and more focal activation occurs in the prefrontal cortex, a change that is associated with an increase in cognitive control.
- During middle and late childhood, motor development becomes much smoother and more coordinated. Children gain greater control over their bodies and can sit and pay attention for longer periods of time. However, their lives should include abundant physical activity.
- Increased myelination of the central nervous system is reflected in improved motor skills. Improved fine motor skills appear in the form of handwriting development. Boys are usually better at gross motor skills, girls at fine motor skills.
- Most American children do not get nearly enough exercise. Parents play an especially important role in guiding children to increase their exercise. Heavy television viewing and computer use are linked to lower activity levels in children.
- For the most part, middle and late childhood is a time of excellent health. The most common cause of severe injury and death in childhood is motor vehicle accidents. Being overweight or obese is an increasingly prevalent child health problem, raising the risk for many medical and psychological problems. Cardiovascular disease is uncommon in children, but the precursors to adult cardiovascular disease are often already apparent during childhood. Cancer is the second leading cause of death in children (after accidents). Leukemia is the most common childhood cancer.

### 2 Children with Disabilities

The Scope of Disabilities

LG2

Identify children with different types of disabilities and discuss issues in educating them.

- Approximately 14 percent of U.S. children from 3 to 21 years of age receive special education or related services. A child with a learning disability has difficulty in learning that involves understanding or using spoken or written language, and the difficulty can appear in listening, thinking, reading, writing, and spelling. A learning disability also may involve difficulty in doing mathematics. To be classified as a learning disability, the learning problem is not primarily the result of visual, hearing, or motor disabilities; intellectual disabilities; emotional disorders; or due to environmental, cultural, or economic disadvantage.
- Dyslexia is a category of learning disabilities that involves a severe impairment in the ability to read and spell. Dysgraphia is a learning disability that involves difficulty in handwriting. Dyscalculia is a learning disability that involves difficulties in math computation.
- Attention deficit hyperactivity disorder (ADHD) is a disability in which individuals consistently show problems in one or more of these areas: (1) inattention, (2) hyperactivity, and (3) impulsivity. ADHD has been increasingly diagnosed. Emotional and behavioral disorders consist of serious, persistent problems that involve relationships, aggression, depression, fears associated with personal or school matters, as well as other inappropriate socioemotional characteristics.

## Educational Issues

- Autism spectrum disorders (ASD), also called pervasive developmental disorders, range from autistic disorder, a severe developmental disorder, to Asperger syndrome, a relatively mild autism spectrum disorder. The current consensus is that autism is a brain dysfunction involving abnormalities in brain structure and neurotransmitters. Children with autism spectrum disorders are characterized by problems in social interaction, verbal and nonverbal communication, and repetitive behaviors.
- In 1975, Public Law 94-142, the Education for All Handicapped Children Act, required that all children with disabilities be given a free, appropriate public education. This law was renamed the Individuals with Disabilities Education Act (IDEA) in 1990 and updated in 2004. IDEA includes requirements that children with disabilities receive an individualized education plan (IEP), which is a written plan that spells out a program tailored to the child and requires that they be educated in the least restrictive environment (LRE), which is a setting that is as similar as possible to the one in which children without disabilities are educated. The term *inclusion* means educating children with disabilities full-time in the regular classroom.

## 3 Cognitive Changes

LG3

Explain cognitive changes in middle and late childhood.

Piaget's Cognitive Developmental Theory

Information Processing

Intelligence

- Piaget said that the stage of concrete operational thought characterizes children from about 7 to 11 years of age. During this stage, children are capable of concrete operations, conservation, classification, seriation, and transitivity. Critics argue that some abilities emerge earlier than Piaget thought, that elements of a stage do not appear at the same time, and that education and culture have more influence on development than Piaget predicted. Neo-Piagetians place more emphasis on how children process information, their use of strategies, speed of information processing, and division of cognitive problems into more precise steps.
- Long-term memory increases in middle and late childhood. Working memory is an important memory process. Knowledge and expertise influence memory. Changes in autobiographical memory occur in middle and late childhood. Strategies can be used by children to improve their memory, and it is important for adults who instruct children to encourage children's strategy use. Fuzzy trace theory has been proposed to explain developmental changes in memory.
- Among the key dimensions of executive function that are important in cognitive development and school success are self-control/inhibition, working memory, and flexibility.
- Critical thinking involves thinking reflectively and productively, as well as evaluating available evidence. Mindfulness is an important aspect of critical thinking. A special concern is the lack of emphasis on critical thinking in many schools.
- Creative thinking is the ability to think in novel and unusual ways and to come up with unique solutions to problems. Guilford distinguished between convergent and divergent thinking. A number of strategies can be used to encourage children's creative thinking, including brainstorming.
- Metacognition is knowing about knowing. Many metacognitive studies have focused on metamemory. Pressley views the key to education as helping students learn a rich repertoire of strategies for problem solving.
- Intelligence consists of problem-solving skills and the ability to adapt to and learn from life's everyday experiences. Interest in intelligence often focuses on individual differences and assessment. Widely used intelligence tests today include the Stanford-Binet tests and Wechsler scales. Results on these tests may be reported in terms of an overall IQ or in terms of performance on specific areas of the tests.
- Sternberg proposed that intelligence comes in three main forms: analytical, creative, and practical. Gardner proposes that there are eight types of intelligence: verbal, mathematical, spatial, bodily-kinesthetic, interpersonal, intrapersonal, musical, and naturalist. The multiple-intelligence approaches have expanded our conception of intelligence, but critics argue that the research base for these approaches is not well established.
- IQ scores are influenced by both genetics and characteristics of the environment. Parents, home environments, schools, and intervention programs can influence these scores.

### Extremes of Intelligence

Intelligence test scores have risen considerably around the world in recent decades. This phenomenon is called the Flynn effect, and it supports the role of environment in intelligence. Group differences in IQ scores may reflect many influences, including cultural bias. Tests may be biased against certain groups that are not familiar with a standard form of English, with the content tested, or with the testing situation. Tests are likely to reflect the values and experience of the dominant culture.

- Intellectual disability involves a low level of intellectual functioning as well as difficulty adapting to the demands of everyday life, with these characteristics occurring prior to age 18. One classification of intellectual disability distinguishes between organic and cultural-familial types.
- Individuals who are gifted have above-average intelligence (an IQ of 130 or higher) and/or superior talent for something. Three characteristics of gifted children are precocity, marching to their own drummer, and a passion to master their domain. Giftedness is likely a consequence of both heredity and environment. Developmental changes characterize giftedness, and increasingly the domain-specific aspect of giftedness is emphasized. Concerns exist about the education of children who are gifted.

## 4 Language Development

LG4

Discuss language development in middle and late childhood.

Vocabulary, Grammar, and Metalinguistic Awareness

Reading

Writing

Second-Language Learning and Bilingual Education

- Children gradually become more analytical and logical in their approach to words and grammar. In terms of grammar, children now better understand comparatives and subjectives. They become increasingly able to use complex grammar and produce narratives that make sense. Improvements in metalinguistic awareness—knowledge about language—are evident during the elementary school years as children increasingly define words, expand their knowledge of syntax, and understand better how to use language in culturally appropriate ways.
- A current debate in reading focuses on the phonics approach versus the whole-language approach. The phonics approach advocates phonetics instruction and giving children simplified materials. The whole-language approach stresses that reading instruction should parallel children's natural language learning and that children should be given whole-language materials such as books and poems. Three key processes in learning to read a printed word are being aware of sound units in words, decoding words, and accessing word meaning.
- Advances in children's language and cognitive development provide the underpinnings for improved writing. Major concerns are increasingly being voiced about children's writing competence. Teachers play a key role in improving children's writing skills.
- Recent research indicates the complexity of determining whether there are sensitive periods in learning a second language. The dual-language approach (formerly called "bilingual") aims to teach academic subjects to immigrant children in their native languages while gradually adding English instruction. Researchers have found that the dual-language approach does not interfere with performance in either language.

Contemporary Approaches to Student Learning  
Socioeconomic Status, Ethnicity, and Culture

In *The Shame of the Nation*, Jonathan Kozol (2005) described his visits to 60 U.S. schools in urban low-income areas in 11 states. He saw many schools in which minorities totaled 80 to 90 percent of the student population. Kozol observed numerous inequities—unkempt classrooms, hallways, and restrooms; inadequate textbooks and supplies; and lack of resources. He also saw teachers mainly instructing students to memorize material by rote, especially as preparation for mandated tests, rather than stimulating them to engage in higher-level thinking. Kozol also frequently observed teachers using threatening disciplinary tactics to control the classroom.

However, some teachers Kozol observed were effective in educating children in these undesirable conditions. At P.S. 30 in the South Bronx, Mr. Bedrock teaches fifth grade. One student in his class, Serafina, recently lost her mother to AIDS. When author Jonathan Kozol visited the class, he was told that two other children had taken the role of “allies in the child’s struggle for emotional survival” (Kozol, 2005, p. 291). Textbooks are in short supply for the class, and the social studies text is so out of date it claims that Ronald Reagan is the country’s president. But Mr. Bedrock told Kozol that it’s a “wonderful” class this year. About their teacher, 56-year-old Mr. Bedrock, one student said, “He’s getting old, . . . but we love him anyway” (p. 292). Kozol observed the students in Mr. Bedrock’s class to be orderly, interested, and engaged.

## topical connections *looking back*

In early childhood, according to Erikson, young children are in the stage of initiative versus guilt. Parents continue to play an important role in their development, and an authoritative parenting style is most likely to have positive outcomes for children. In early childhood, peer relations begin to take on a more significant role as children’s social worlds widen. Play has a special place in young children’s lives and is an important context for both cognitive and socioemotional development.

# preview

The years of middle and late childhood bring many changes to children's social and emotional lives. Transformations in their relationships with parents and peers occur, and schooling takes on a more academic flavor. The development of their self-conceptions, moral reasoning, and moral behavior is also significant.

The Self

Emotional Development

Moral Development

Gender

In this section, we will explore how the self continues to develop during middle and late childhood and the emotional changes that take place during these years. We will also discuss children's moral development and many aspects of the role that gender plays in their development in middle and late childhood.

##### Identity

In adolescence, individuals become more introspective and reflective in their self-understanding as they search for an identity. Connect to "Socioemotional Development in Adolescence."

What is the nature of the child's self-understanding, understanding of others, and self-esteem during the elementary school years? What roles do self-efficacy and self-regulation play in children's achievement?

**The Development of Self-Understanding** Self-understanding becomes more complex in middle and late childhood (Carpendale & Lewis, 2015). From 8 to 11 years of age, children increasingly describe themselves in terms of psychological characteristics and traits, in contrast with the more concrete self-descriptions of younger children. For example, older children are more likely to describe themselves using adjectives such as "*popular, nice, helpful, mean, smart, and dumb*" (Harter, 2006, p. 526).

In addition, during the elementary school years, children become more likely to recognize social aspects of the self (Harter, 2012, 2013, 2016). They include references to social groups in their self-descriptions, such as referring to themselves as a Girl Scout, a Catholic, or someone who has two close friends (Livesly & Bromley, 1973).

Children's self-understanding in the elementary school years also includes increasing reference to social comparison (Harter, 2012, 2013). At this point in development, children are more likely to distinguish themselves from others in comparative rather than in absolute terms. That is, elementary-school-age children are no longer as likely to think about what they do or do not do, but are more likely to think about what they can do in comparison with others.

Consider a series of studies in which Diane Ruble (1983) investigated children's use of social comparison in their self-evaluations. Children were given a difficult task and then offered feedback on their performance, as well as information about the performances of other children their age. The children were then asked for self-evaluations. Children younger than 7 made virtually no reference to the information about other children's performances. However, many children older than 7 included socially comparative information in their self-descriptions.

In sum, in middle and late childhood, self-description increasingly involves psychological and social characteristics, including social comparison.

**Understanding Others** Earlier we described the advances and limitations of young children's social understanding. In middle and late childhood, **perspective taking**, the social cognitive process involved in assuming the perspective of others and understanding their thoughts and feelings, improves. Executive function is at work in perspective taking (Galinsky, 2010). Among the executive functions called on when children engage in perspective taking are cognitive inhibition (controlling one's own thoughts to consider the perspective of others) and cognitive flexibility (seeing situations in different ways). Recent research indicates that children and adolescents who do not have good perspective taking skills are more likely to have difficulty

in peer relations and engage in more aggressive and oppositional behavior (Morosan & others, 2017; Nilsen & Basco, 2017; O'Kearney & others, 2017).

In Robert Selman's (1980) view, at about 6 to 8 years of age, children begin to understand that others may have a different perspective because some people have more access to information. Then, he says, in the next several years, children begin to realize that each individual is aware of the other's perspective and that putting oneself in the other's place is a way of judging the other person's intentions, purposes, and actions.

Perspective taking is thought to be especially important in determining whether children develop prosocial or antisocial attitudes and behavior. In terms of prosocial behavior, taking another's perspective improves children's likelihood of understanding and sympathizing with others when they are distressed or in need.

In middle and late childhood, children also become more skeptical of others' claims (Heyman, Fu, & Lee, 2013). In a study of 6- to 9-year-old children, older children were less trusting and better at explaining the reasons to doubt sources that might distort claims than were younger children (Mills & Elashi, 2014). Also, more intelligent children and children with better social cognitive skills were more likely to detect and explain distorted claims.

**Self-Esteem and Self-Concept** High self-esteem and a positive self-concept are important characteristics of children's well-being (Baumeister, 2013; Miller & Cho, 2018; Oberle, 2018). Investigators sometimes use the terms *self-esteem* and *self-concept* interchangeably or do not precisely define them, but there is a meaningful difference between them (Harter, 2012, 2016). **Self-esteem** refers to global evaluations of the self; it is also called *self-worth* or *self-image*. For example, a child may perceive that she is not merely a person but a *good* person. **Self-concept** refers to domain-specific evaluations of the self. Children can make self-evaluations in many domains of their lives—academic, athletic, appearance, and so on. In sum, *self-esteem* refers to global self-evaluations, *self-concept* to domain-specific evaluations.

The foundations of self-esteem and self-concept emerge from the quality of parent-child interaction in infancy and early childhood (Miller & Cho, 2018). Thus, if children have low self-esteem in middle and late childhood, they may have experienced neglect or abuse in relationships with their parents earlier in development. Children with high self-esteem are more likely to be securely attached to parents and have parents who engage in sensitive caregiving (Lockhart & others, 2017; Thompson, 2016).

Self-esteem reflects perceptions that do not always match reality (Baumeister, 2013; Cramer, 2017). A child's self-esteem might reflect a belief about whether he or she is intelligent and attractive, for example, but that belief is not necessarily accurate. Thus, high self-esteem may refer to accurate, justified perceptions of one's worth as a person and one's successes and accomplishments, but it can also refer to an arrogant, grandiose, unwarranted sense of superiority over others (Gertenberg & others, 2014). In the same manner, low self-esteem may reflect either an accurate perception of one's shortcomings or a distorted, even pathological insecurity and inferiority.

What are the consequences of low self-esteem? Low self-esteem has been implicated in overweight and obesity, anxiety, depression, suicide, and delinquency (Paxton & Damiano, 2017; Rieger & others, 2016; Stadelmann & others, 2017). One study revealed that youths with low self-esteem had lower life satisfaction at 30 years of age (Birkeland & others, 2012). Another study found that low and decreasing self-esteem in adolescence was linked to adult depression two decades later (Steiger & others, 2014).

The foundations of self-esteem and self-concept emerge from the quality of parent-child interaction in infancy and childhood. Children with high self-esteem are more likely to be securely attached to their parents and to have parents who engage in sensitive caregiving (Thompson, 2015). And in a longitudinal study, the quality of children's home environment (which involved assessment of parenting quality, cognitive stimulation, and the physical home environment) was linked to their self-esteem in early adulthood (Orth, 2017).

Although variations in self-esteem have been linked with many aspects of children's development, much of the research is *correlational* rather than *experimental*. Recall that correlation does not equal causation. Thus, if a correlational study finds an association between children's low self-esteem and low academic achievement, low academic achievement could cause the low self-esteem as much as low self-esteem causes low academic achievement. A longitudinal study

# connecting development to life

## Increasing Children's Self-Esteem

Ways to improve children's self-esteem include identifying the causes of low self-esteem, providing emotional support and social approval, helping children achieve, and helping children cope (Bednar, Wells, & Peterson, 1995; Harter, 2006, 2012).

- *Identify the causes of low self-esteem.* Intervention should target the causes of low self-esteem. Children have the highest self-esteem when they perform competently in domains that are important to them. Therefore, children should be encouraged to identify and value areas of competence. These areas might include academic skills, athletic skills, physical attractiveness, and social acceptance.
- *Provide emotional support and social approval.* Some children with low self-esteem come from conflicted families or conditions in which they experienced abuse or neglect—situations in which support was not available. In some cases, alternative sources of support can be arranged either informally through the encouragement of a teacher,

a coach, or another significant adult, or more formally through programs such as Big Brothers and Big Sisters.

- *Help children achieve.* Achievement also can improve children's self-esteem. For example, the straightforward teaching of real skills to children often results in increased achievement and, thus, in enhanced self-esteem. Children develop higher self-esteem because they know how to carry out the important tasks that will achieve their goals, and they have performed them or similar behaviors in the past.
- *Help children cope.* Self-esteem often increases when children face a problem and try to cope with it, rather than avoid it. If coping rather than avoidance prevails, children face problems realistically, honestly, and nondefensively. This produces favorable self-evaluative thoughts, which lead to the self-generated approval that raises self-esteem.

Which parenting approach might help accomplish the last goal mentioned here? How? How can parents help children develop higher self-esteem?

explored whether self-esteem is a cause or consequence of social support in youth (Marshall & others, 2014). In this study, self-esteem predicted subsequent changes in social support, but social support did not predict subsequent changes in self-esteem.

In fact, there are only moderate correlations between school performance and self-esteem, and these correlations do not suggest that high self-esteem produces better school performance (Baumeister, 2013). Efforts to increase students' self-esteem have not always led to improved school performance (Davies & Brember, 1999).

Children with high self-esteem have greater initiative, but this can produce positive or negative outcomes (Baumeister & others, 2003). Children with high self-esteem are prone to both prosocial and antisocial actions (Krueger, Vohs, & Baumeister, 2008).

In addition, a current concern is that too many of today's children grow up receiving praise for mediocre or even poor performance and as a consequence have inflated self-esteem (Graham, 2005; Stipek, 2005). They may have difficulty handling competition and criticism. This theme is vividly captured by the title of a book, *Dumbing Down Our Kids: Why American Children Feel Good About Themselves But Can't Read, Write, or Add* (Sykes, 1995). A similar theme—the promise of high self-esteem for students in education, especially those who are impoverished or marginalized—characterized a more recent book, *Challenging the Cult of Self-Esteem in Education* (Bergeron, 2018). In a series of studies, researchers found that inflated praise, although well intended, may cause children with low self-esteem to avoid important learning experiences, such as tackling challenging tasks (Brummelman & others, 2014). And one study found that narcissistic parents especially overvalue their children's talents (Brummelman & others, 2015).

What are some good strategies for effectively increasing children's self-esteem? See the *Connecting Development to Life* interlude for some answers to this question.

**Self-Efficacy** The belief that one can master a situation and produce favorable outcomes is called **self-efficacy**. Albert Bandura (2001, 2008, 2010a, 2012) states that self-efficacy is a critical factor in whether or not students achieve. Self-efficacy is the belief that “I can”; helplessness is the belief that “I cannot.” Students with high self-efficacy endorse such statements as “I know that I will be able to learn the material in this class” and “I expect to be able to do well at this activity.”

Dale Schunk (2016) has applied the concept of self-efficacy to many aspects of students’ achievement. In his view, self-efficacy influences a student’s choice of activities. Students with low self-efficacy for learning may avoid many learning tasks, especially those that are challenging. By contrast, their counterparts with high self-efficacy eagerly work at learning tasks (Schunk, 2016). Students with high self-efficacy are more likely to expend effort and persist longer at a learning task than students with low self-efficacy.

**Self-Regulation** One of the most important aspects of the self in middle and late childhood is an increased capacity for self-regulation (Blair, 2017; Galinsky & others, 2017; Neuenschwander & Blair, 2017; Schunk & Greene, 2018; Usher & Schunk, 2018; Winne, 2018). This increased capacity is characterized by deliberate efforts to manage one’s behavior, emotions, and thoughts, leading to increased social competence and achievement (Blair, 2017; Eisenberg, 2017; McClelland & others, 2017; Schunk & Greene, 2018). In one study, higher levels of self-control assessed at 4 years of age were linked to improvements in the math and reading achievement of early elementary school children living in predominantly rural and low-income contexts (Blair & others, 2015). Another study found that self-control increased from 4 years to 10 years of age and that high self-control was linked to lower levels of deviant behavior (Vazsonyi & Huang, 2010). In this study, parenting characterized by warmth and positive affect predicted the developmental increase in self-control. Also, a study of almost 17,000 3- to 7-year-old children revealed that self-regulation was a protective factor for children growing up in low-socioeconomic-status (SES) conditions (Flouri, Midouhas, & Joshi, 2014). In this study, 7-year-old children with low self-regulation living in low-SES conditions had more emotional problems than their 3-year-old counterparts with higher self-regulation. Thus, low self-regulation was linked to a widening gap in low-SES children’s emotional problems over time. Another study revealed that children from low-income families who had a higher level of self-regulation earned better grades in school than their counterparts who had a lower level of self-regulation (Buckner, Mezzacappa, & Beardslee, 2009).

The increased capacity for self-regulation is linked to developmental advances in the brain’s prefrontal cortex (Bell, Ross, & Patton, 2018; Wendelken & others, 2016). Recall our earlier discussion of the increased focal activation in the prefrontal cortex that is linked to improved cognitive control, which includes self-regulation (Diamond, 2013).

Some researchers emphasize the early development of self-regulation in childhood and adolescence as a key contributor to adult health and even longevity (Eisenberg, Spinrad, & Valiente, 2016; Llewellyn & others, 2017). For example, Nancy Eisenberg and her colleagues (2014) concluded that research indicates self-regulation fosters conscientiousness later in life, both directly and through its link to academic motivation/success and internalized compliance with norms. Further, a longitudinal study found that a higher level of self-control in childhood was linked to a slower pace of aging (assessed with 18 biomarkers—cardiovascular and immune system, for example) at 26, 32, and 38 years of age (Belsky & others, 2017). An app for iPads has been developed to help children improve their self-regulation (for more information, go to [www.selfregulationstation.com/sr-ipad-app/](http://www.selfregulationstation.com/sr-ipad-app/)).

**Industry Versus Inferiority** Recall Erik Erikson’s (1968) eight stages of human development. His fourth stage, industry versus inferiority, appears during middle and late childhood. The term *industry* expresses a dominant theme of this period: Children become interested in how things are made and how they work. When children are encouraged in their efforts to make, build, and work—whether building a model airplane, constructing a tree house, fixing a bicycle, solving an addition problem, or cooking—their sense of industry increases. However, parents who see their children’s efforts at making things as “mischief” or “making a mess” encourage children’s development of a sense of inferiority.

Children’s social worlds beyond their families also contribute to a sense of industry. School becomes especially important in this regard. Consider children who are slightly

below average in intelligence. They are too bright to be in special classes but not bright enough to be in gifted classes. They fail frequently in their academic efforts, developing a sense of inferiority. By contrast, consider children whose sense of industry is derogated at home. A series of sensitive and committed teachers may revitalize their sense of industry (Elkind, 1970).

## EMOTIONAL DEVELOPMENT

Preschoolers become more adept at talking about their own and others' emotions. They also show a growing awareness of the need to control and manage their emotions to meet social standards. In middle and late childhood, children further develop their understanding and self-regulation of emotion (Calkins & Perry, 2016; Cole & Hollenstein, 2018; Cole, Lougheed, & Ram, 2018; Morris & others, 2018). In a recent study, a low level of emotion regulation in childhood was especially important in predicting a higher level of externalizing problems in adolescence (Perry & others, 2017).

**Developmental Changes** Developmental changes in emotions during the middle and late childhood years include the following (Denham, Bassett, & Wyatt, 2015; Calkins & Perry, 2016; Kuebli, 1994; Perry & Calkins, 2018; Thompson, 2015):

- *Improved emotional understanding.* For example, children in elementary school develop an increased ability to understand such complex emotions as pride and shame. These emotions become less tied to the reactions of other people; they become more self-generated and integrated with a sense of personal responsibility. Also, during middle and late childhood as part of their understanding of emotions, children can engage in "mental time travel," in which they anticipate and recall the cognitive and emotional aspects of events (Hjortsvang & Lagattuta, 2017; Kramer & Lagattuta, 2018; Lagattuta, 2014a, b; Lagattuta & others, 2015).
- *Increased understanding that more than one emotion can be experienced in a particular situation.* A third-grader, for example, may realize that achieving something might involve both anxiety and joy.
- *Increased tendency to be aware of the events leading to emotional reactions.* A fourth-grader may become aware that her sadness today is influenced by her friend moving to another town last week.
- *Ability to suppress or conceal negative emotional reactions.* A fifth-grader has learned to tone down his anger better than he used to when one of his classmates irritates him.
- *The use of self-initiated strategies for redirecting feelings.* In the elementary school years, children become more reflective about their emotional lives and increasingly use strategies to control their emotions. They become more effective at cognitively managing their emotions, such as soothing themselves after an upset.
- *A capacity for genuine empathy.* For example, a fourth-grader feels sympathy for a distressed person and experiences vicariously the sadness the distressed person is feeling.

**Social-Emotional Education Programs** An increasing number of social-emotional educational programs have been developed to improve many aspects of children's and adolescents' lives. Two such programs are the Second Step program created by the Committee for Children (2018) and the Collaborative for Academic, Social, and Emotional Learning (CASEL, 2018). Many social-emotional education programs only target young children, but Second Step can be implemented in pre-K through eighth grade and CASEL can be used with pre-K through twelfth-grade students.

- *Second Step* focuses on these aspects of social-emotional learning from pre-K through the eighth grade: (1) pre-K: self-regulation and executive function skills that improve their attention and help them control their behavior; (2) K-grade 5: making friends, self-regulation of emotion, and solving problems; and (3) grades 6–8: communication skills, coping with stress, and decision making to avoid engaging in problem behaviors.

- CASEL targets five core social and emotional learning domains: (1) self-awareness (recognizing one's emotions and how they affect behavior, for example); (2) self-management (self-control, coping with stress, and impulse control, for example); (3) social awareness (perspective taking and empathy, for example); (4) relationship skills (developing positive relationships and communicating effectively with individuals from diverse backgrounds, for example); and (5) responsible decision making (engaging in ethical behavior, and understanding the consequences of one's actions, for example).

**Coping with Stress** An important aspect of children's emotional lives is learning how to cope with stress (Almy & Cicchetti, 2018; Masten, 2017; Masten & Kalstabakken, 2018; Narayan & others, 2017). As children get older, they are able to more accurately appraise a stressful situation and determine how much control they have over it. Older children generate more coping alternatives for stressful conditions and use more cognitive coping strategies (Saarni & others, 2006). They are better than younger children at intentionally shifting their thoughts to something that is less stressful and at reframing, or changing their perception of a stressful situation. For example, younger children may be very disappointed that their teacher did not say hello to them when they arrived at school. Older children may reframe this type of situation and think, "She may have been busy with other things and just forgot to say hello."

By 10 years of age, most children are able to use cognitive strategies to cope with stress (Saarni, 1999). However, in families that have not been supportive and are characterized by turmoil or trauma, children may be so overwhelmed by stress that they do not use such strategies.

Disasters can especially harm children's development and produce adjustment problems (Masten, 2017; Masten & Kalstabakken, 2018; Narayan & others, 2017). Among the outcomes for children who experience disasters are acute stress reactions, depression, panic disorder, and post-traumatic stress disorder (Danielson & others, 2017; Lieber, 2017). The likelihood that a child will face these problems following a disaster depends on factors such as the nature and severity of the disaster and the type of support available to the child.

In research on disasters/trauma, the term *dose-response effects* is often used. A widely supported finding in this research area is that the more severe the disaster/trauma (dose), the worse the adaptation and adjustment (response) following the disaster/trauma (Masten, 2017; Masten & Kalstabakken, 2018; Narayan & others, 2017).

The terrorist attacks on the World Trade Center in New York City and the Pentagon in Washington, D.C., on September 11, 2001, and hurricanes Katrina and Rita in September 2005 raised special concerns about how to help children cope with such stressful events.

Children who have developed a number of coping techniques have the best chance of adapting and functioning competently in the face of disasters and traumas (Ungar, 2015). Researchers have offered the following recommendations for parents, teachers, and other adults caring for children after a disaster (Gurwitch & others, 2001, pp. 4–11):

- Reassure children (numerous times, if necessary) of their safety and security.
- Allow children to retell events and be patient in listening to them.
- Encourage children to talk about any disturbing or confusing feelings, reassuring them that such feelings are normal after a stressful event.
- Protect children from re-exposure to frightening situations and reminders of the trauma—for example, by limiting discussion of the event in front of the children.
- Help children make sense of what happened, keeping in mind that children may misunderstand what took place. For example, young children "may blame themselves, believe things happened that did not happen, believe that terrorists are in the school, etc. Gently help children develop a realistic understanding of the event" (p. 10).

Child and adolescent psychiatrists are among the mental health professionals who help youth cope with stress, including traumatic experiences. To read about a child psychiatrist who treats children and adolescents, see *Connecting with Careers*.

Traumatic events may cause individuals to think about the moral aspects of life. Hopelessness and despair may short-circuit moral development when a child is confronted by the violence of war zones and impoverished inner cities (Nader, 2001). Let's further explore children's moral development.

## Melissa Jackson, Child Psychiatrist

Dr. Melissa Jackson is a child and adolescent psychiatrist in Miami, Florida. She obtained a medical degree from the University of Florida and then completed an internship and residency in psychiatry at Advocate Lutheran General Hospital in Chicago, followed by a fellowship in child and adolescent psychiatry at the University of Southern California. Among the problems and disorders that Dr. Jackson treats are post-traumatic stress disorder, ADHD, anxiety, autism, depression, and a number of behavioral issues. In addition to her psychiatric treatment of children, she founded Health for Honduras, which includes trips to Honduras to provide services to children in orphanages.

To become a child and adolescent psychiatrist like Melissa Jackson, you would need to obtain an undergraduate degree, then earn a medical degree, then spend three to four years as a resident physician in general psychiatry, and then complete a two-year fellowship in the subspecialty of child and adolescent psychiatry. An important aspect of being a psychiatrist is that psychiatrists can prescribe medication, which psychologists cannot do.

## MORAL DEVELOPMENT

Recall our description of Piaget's view of moral development. Piaget proposed that younger children are characterized by heteronomous morality—but that by 10 years of age they have moved into a higher stage called autonomous morality. According to Piaget, older children consider the intentions of the individual, believe that rules are subject to change, and are aware that punishment does not always follow wrongdoing.

A second major perspective on moral development was proposed by Lawrence Kohlberg (1958, 1986). Piaget's cognitive stages of development serve as the underpinnings for Kohlberg's theory, but Kohlberg suggested that there are three levels of moral development. These levels, he argued, are universal. Development from one level to another, said Kohlberg, is fostered by opportunities to take the perspective of others and to experience conflict between one's current level of moral thinking and the reasoning of someone at a higher level.

Kohlberg arrived at his view after 20 years of using a unique interview with children. In the interview, children are presented with a series of stories in which characters face moral dilemmas. The following is the most popular Kohlberg dilemma:

In Europe a woman was near death from a special kind of cancer. There was one drug that the doctors thought might save her. It was a form of radium that a druggist in the same town had recently discovered. The drug was expensive to make, but the druggist was charging ten times what the drug cost him to make. He paid \$200 for the radium and charged \$2,000 for a small dose of the drug. The sick woman's husband, Heinz, went to everyone he knew to borrow the money, but he could only get together \$1,000, which is half of what it cost. He told the druggist that his wife was dying and asked him to sell it cheaper or let him pay later. But the druggist said, "No, I discovered the drug, and I am going to make money from it." So Heinz got desperate and broke into the man's store to steal the drug for his wife. (Kohlberg, 1969, p. 379)

This story is one of 11 that Kohlberg devised to investigate the nature of moral thought. After reading the story, the interviewee answers a series of questions about the moral dilemma. Should Heinz have stolen the drug? Was stealing it right or wrong? Why? Is it a husband's duty to steal the drug for his wife if he can get it no other way? Would a good husband steal? Did the druggist have the right to charge that much when there was no law setting a limit on the price? Why or why not?

**The Kohlberg Levels** Based on the answers interviewees gave for this and other moral dilemmas, Kohlberg described three levels of moral thinking. A key concept in understanding progression through the levels is that the person's morality gradually becomes more

internal or mature. That is, their reasons for moral decisions or values begin to go beyond the external or superficial reasons they gave when they were younger. Let's further examine Kohlberg's levels.

**Kohlberg's Level 1: Preconventional Reasoning** **Preconventional reasoning** is the lowest level of moral reasoning in Kohlberg's theory. At this level, children interpret good and bad in terms of external rewards and punishments. For example, children and adolescents obey adults because adults tell them to obey. Or they might be nice to others so that others will be nice to them. This earliest level has sometimes been described as "What's in it for me?"

**Kohlberg's Level 2: Conventional Reasoning** **Conventional reasoning** is the second, or intermediate, level in Kohlberg's theory of moral development. Individuals abide by certain standards (internal), but they are the standards of others, such as parents or the laws of society.

**Kohlberg's Level 3: Postconventional Reasoning** **Postconventional reasoning** is the third and highest level in Kohlberg's theory. At this level, morality is more internal. Also, in postconventional reasoning, individuals engage in deliberate checks on their reasoning to ensure that it meets high ethical standards.

Kohlberg maintained that these levels occur in a sequence and are age-related: Before age 9, most children use level 1, preconventional reasoning based on external rewards and punishments, when they consider moral choices. By early adolescence, their moral reasoning is increasingly based on the application of standards set by others, reflecting conventional reasoning. By early adulthood, a small number of individuals reason in postconventional ways.

**Influences on the Kohlberg Levels** What factors influence movement through Kohlberg's levels? Although moral reasoning at each level presupposes a certain level of cognitive development, Kohlberg argued that advances in children's cognitive development did not ensure development of moral reasoning. Instead, moral reasoning also reflects children's experiences in dealing with moral questions and moral conflict.

Kohlberg emphasized that peer interaction and perspective taking are critical aspects of the social stimulation that challenges children to change their moral reasoning. Whereas adults characteristically impose rules and regulations on children, the give-and-take among peers gives children an opportunity to take the perspective of another person and to generate rules democratically.

**Kohlberg's Critics** Kohlberg's theory has provoked debate, research, and criticism (Graham & others, 2018; Gray & Graham, 2018; Hoover & others, 2018; Killen & Dahl, 2018; Narvaez, 2016, 2017a, b, 2018; Raitton, 2017; Turiel & Gingo, 2017). Key criticisms involve the link between moral thought and moral behavior, whether moral reasoning is conscious/deliberative or unconscious/automatic, the role of emotion, the contexts of culture and the family in moral development, and the significance of caring for others.

**Moral Thought and Moral Behavior** Kohlberg's theory has been criticized for placing too much emphasis on moral thought and not enough emphasis on moral behavior (Walker, 2004). Moral reasons can sometimes be a shelter for immoral behavior. Corrupt CEOs and politicians endorse the loftiest of moral virtues in public before their own behavior is exposed. Whatever the latest public scandal, you will probably find that the culprits displayed virtuous thoughts but engaged in immoral behavior. No one wants a nation of cheaters and thieves who can reason at the postconventional level. The cheaters and thieves may know what is right yet still do what is wrong. Heinous actions can be cloaked in a mantle of moral virtue.

**Conscious/Deliberate Versus Unconscious/Automatic** Social psychologist Jonathan Haidt (2006, 2013, 2017) argues that a major flaw in Kohlberg's theory is his view that moral thinking is deliberative and that individuals go around all the time contemplating and reasoning about morality. Haidt believes that moral thinking is more often an intuitive gut reaction, with deliberative moral reasoning serving as an after-the-fact justification. Thus, in his view, much of morality begins with rapid evaluative judgments of others rather than with strategic reasoning about moral circumstances.

**The Role of Emotion** Kohlberg argued that emotion has negative effects on moral reasoning. However, increasing evidence indicates that emotions play an important role in moral

**preconventional reasoning** The lowest level in Kohlberg's theory of moral development. The individual's moral reasoning is controlled primarily by external rewards and punishment.

**conventional reasoning** The second, or intermediate, level in Kohlberg's theory of moral development. At this level, individuals abide by certain standards, but these are standards set by others such as parents or society.

**postconventional reasoning** The highest level in Kohlberg's theory of moral development. At this level, the individual recognizes alternative moral courses, explores the options, and then decides on a personal moral code.

This 14-year-old boy in Nepal is thought to be the sixth-holiest Buddhist in the world. In one study of 20 adolescent male Buddhist monks in Nepal, the issue of justice, a basic theme in Kohlberg's theory, was not a central focus in the monks' moral views (Huebner & Garrod, 1993). Also, the monks' concerns about prevention of suffering and the importance of compassion are not captured in Kohlberg's theory.

thinking (Seibt & others, 2017; Singer & others, 2017). Researchers have found that individuals who have damage to a particular region in the brain's prefrontal cortex lose the ability to integrate emotions into their moral judgments (Damasio, 1994). Losing their intuitive feelings about what is right or wrong, they can't adequately decide which actions to take and have trouble making choices involving moral issues. Research with healthy individuals also has shown that the moral decisions individuals make are linked to the intensity and activation of emotion in the prefrontal cortex and the amygdala (Shenhav & Greene, 2014).

**Culture and Moral Reasoning** Kohlberg emphasized that his levels of moral reasoning are universal, but some critics claim his theory is culturally biased (Christen, Narváez, & Gutzwiller, 2018; Graham & others, 2017; Gray & Graham, 2018). Both Kohlberg and his critics may be partially correct. In one study, individuals in diverse cultures developed through the first two levels in sequence as Kohlberg predicted. Level three thinking, however, has not been found in all cultures (Gibbs & others, 2007; Snarey, 1987).

Darcia Narváez and Tracy Gleason (2013) have described cohort effects regarding moral reasoning. In recent decades, postconventional moral reasoning has been declining in college students, not down to the next level (conventional), but to the lowest level (personal interests) (Thoma & Bebeau, 2008). Narváez and Gleason (2013) also argue that declines in prosocial behavior have occurred in recent years and that humans, especially those living in Western cultures, are "on a fast train to demise." They emphasize that the solution to improving people's moral lives lies in better child-rearing strategies and social supports for families and children. In more recent commentary, Narváez and her colleagues (Christen, Narváez, & Gutzwiller, 2018) stress that we need better progress in dealing with an increasing array of temptations and possible wrongdoings in a human social world in which complexity is increasing over time.

In sum, although Kohlberg's approach does capture much of the moral reasoning voiced in various cultures around the world, his approach misses or misconstrues some important moral concepts in specific cultures (Gibbs, 2014; Gray & Graham, 2018).

**Families and Moral Development** Kohlberg argued that family processes are essentially unimportant in children's moral development. As noted earlier, he argued that parent-child relationships usually provide children with little opportunity for give-and-take or perspective taking. Rather, Kohlberg said that such opportunities are more likely to be provided by children's peer relationships. However, most experts on children's moral development conclude that parents' moral values and actions influence children's development of moral reasoning (Carlo & others, 2017; Christen, Narváez, & Gutzwiller, 2017). Nonetheless, most developmentalists agree with Kohlberg and Piaget that peers play an important role in the development of moral reasoning.

**Gender and the Care Perspective** The most publicized criticism of Kohlberg's theory has come from Carol Gilligan (1982, 1992, 1996), who argues that Kohlberg's theory reflects a gender bias. According to Gilligan, Kohlberg's theory is based on a male norm that puts abstract principles above relationships and concern for others and sees the individual as standing alone and independently making moral decisions. It puts justice at the heart of morality. In contrast with Kohlberg's **justice perspective**, Gilligan argues for a **care perspective**, which is a moral perspective that views people in terms of their connectedness with others and emphasizes interpersonal communication, relationships with others, and concern for others. According to Gilligan, Kohlberg greatly underplayed the care perspective, perhaps because he was a male, because most of his research was with males rather than females, and because he used male responses as a model for his theory.

However, questions have been raised about Gilligan's gender conclusions (Walker & Frimer, 2009). For example, a meta-analysis (a statistical analysis that combines the results of many different studies) casts doubt on Gilligan's claim of substantial gender differences in moral judgment (Jaffee & Hyde, 2000). And a research review concluded that girls' moral orientations are "somewhat more likely to focus on care for others than on abstract principles of justice, but they can use both moral orientations when needed (as can boys . . .)" (Blakemore, Berenbaum, & Liben, 2009, p. 132).

In sum, Kohlberg's theory was a very important pioneering effort in describing and understanding the development of moral reasoning. As indicated in the criticisms of the theory, although it is still relevant in understanding the development of moral reasoning, the theory is no longer as influential as it once was. Let's now explore some alternative views of moral development.

**Domain Theory: Moral, Social Conventional, and Personal Reasoning** The **domain theory of moral development** states that there are different domains of social knowledge and reasoning, including moral, social conventional, and personal domains. In domain theory, children's and adolescents' moral, social conventional, and personal knowledge and reasoning emerge from their attempts to understand and deal with different forms of social experience (Jambon & Smetana, 2018; Killen & Dahl, 2018; Mulvey & others, 2016; Turiel & Gingo, 2017).

Some theorists and researchers argue that Kohlberg did not adequately distinguish between moral reasoning and social conventional reasoning (Killen & Smetana, 2015; Turiel & Gingo, 2017). **Social conventional reasoning** focuses on conventional rules that have been established by social consensus in order to control behavior and maintain the social system. The rules themselves are arbitrary, such as raising your hand in class before speaking, using one staircase at school to go up and the other to go down, not cutting in front of someone standing in line to buy movie tickets, and stopping at a stop sign when driving. There are sanctions if we violate these conventions, although they can be changed by consensus.

In contrast, moral reasoning focuses on ethical issues and rules of morality. Unlike conventional rules, moral rules are not arbitrary. They are obligatory, widely accepted, and somewhat impersonal (Turiel & Gingo, 2017). Rules pertaining to lying, cheating, stealing, and physically harming another person are moral rules because violation of these rules affronts ethical standards that exist apart from social consensus and convention. Moral judgments involve concepts of justice, whereas social conventional judgments are concepts of social organization. Violating moral rules is usually more serious than violating conventional rules.

The social conventional approach is a serious challenge to Kohlberg's approach because Kohlberg argued that social conventions are a stop-over on the road to higher moral sophistication. For social conventional reasoning advocates, social conventional reasoning is not lower than postconventional reasoning but rather something that needs to be disentangled from the moral thread (Killen & Dahl, 2018).

Recently, a distinction also has been made between moral and conventional issues, which are viewed as legitimately subject to adult social regulation, and personal issues, which are more likely subject to the child's or adolescent's independent decision making and personal discretion (Jambon & Smetana, 2018). Personal issues include control over one's body, privacy, and choice of friends and activities. Thus, some actions belong to a *personal* domain and are not governed by moral reasoning or social norms.

**Prosocial Behavior** Whereas Kohlberg's and Gilligan's theories have focused primarily on the development of moral reasoning, the study of prosocial moral behavior has placed more emphasis on the behavioral aspects of moral development (Carlo & others, 2018; Dirks, Dunfield, & Recchia, 2018; Laible & others, 2017). Children engage in immoral, antisocial acts such as lying and cheating and also display prosocial moral behavior such as showing empathy or acting altruistically (Eisenberg & Spinrad, 2016). Even during the preschool years, children may care for others or comfort others in distress (Spinrad & Gal, 2018).

William Damon (1988) described how sharing develops. During their first years, when children share, it is usually not for reasons of empathy but for the fun of the social play ritual or out of imitation. Then, at about 4 years of age, a combination of empathic awareness and adult encouragement produces a sense of obligation on the part of the child to share with others. Most 4-year-olds are not selfless saints, however. Children believe they have an obligation to share but do not necessarily think they should be as generous to others as they are to themselves.

Children's sharing comes to reflect a more complex sense of what is just and right during middle and late childhood. By the start of the elementary school years, children begin to express objective ideas about fairness. It is common to hear 6-year-old children use the word *fair* as synonymous with *equal* or *same*. By the mid- to late elementary school years, children believe that equity can sometimes mean that people with special merit or special needs deserve special treatment.

**Moral Personality** Beyond the development of moral reasoning and specific moral feelings and prosocial behaviors, do children also develop a pattern of moral characteristics that is distinctively their own? In other words, do children develop a *moral personality*, and if so, what are its components? Researchers have focused attention on three possible components: (1) moral identity, (2) moral character, and (3) moral exemplars:

- **Moral identity.** Individuals have a moral identity when moral notions and moral commitments are central to their lives (Jia & Krettenauer, 2017; Walker, 2016). They construct the

**domain theory of moral development** Theory that identifies different domains of social knowledge and reasoning, including moral, social conventional, and personal domains. These domains arise from children's and adolescents' attempts to understand and deal with different forms of social experience.

**social conventional reasoning** Thoughts about social consensus and convention, in contrast with moral reasoning, which stresses ethical issues.

self with reference to moral categories. Violating their moral commitment would place the integrity of their self at risk (Lapsley & Stey, 2014). A study of 15- to 18-year-olds found that a higher level of moral identity could possibly reduce the negative effects of moral disengagement and low self-regulation (Hardy, Bean, & Olsen, 2015). In another recent study of individuals from adolescence through middle adulthood, external moral identity motivation decreased while internal moral identity motivation increased, suggesting that as people get older moral motivation become more self-integrated (Krettenauer & Victor, 2017).

- *Moral character.* A person with moral character has the willpower, desire, and integrity to stand up to pressure, overcome distractions and disappointments, and behave morally. A person of good moral character displays moral virtues such as “honesty, truthfulness, and trustworthiness, as well as those of care, compassion, thoughtfulness, and considerateness. Other salient traits revolve around virtues of dependability, loyalty, and conscientiousness” (Walker, 2002, p. 74).
- *Moral exemplars.* Moral exemplars are people who have lived exemplary moral lives. Their moral personality, identity, character, and set of virtues reflect moral excellence and commitment (Walker, 2016). The point of studying and conducting research on moral exemplars is to be able to characterize the ideal endpoint of moral development and understand how people got there.

In sum, moral development is a multifaceted, complex concept. Included in this complexity are an individual’s thoughts, feelings, behaviors, and personality.

## GENDER

Gilligan’s claim that Kohlberg’s theory of moral development reflects gender bias reminds us of the pervasive influence of gender on development. Long before elementary school, boys and girls show preferences for different toys and activities (Leaper & Bigler, 2018). Preschool children display a gender identity and gender-typed behavior that reflects biological, cognitive, and social influences. Here we will examine gender stereotypes as well as gender similarities and differences.

Frogs and snails  
And puppy-dogs’ tails.  
What are little girls made of?  
Sugar and spice  
And all that is nice.

—J. O. HALLIWELL  
*English Author, 19th Century*

**Gender Stereotypes** According to the old ditty, boys are made of “frogs and snails” and girls are made of “sugar and spice and all that is nice.” In the past, a well-adjusted boy was supposed to be independent, aggressive, and powerful. A well-adjusted girl was supposed to be dependent, nurturing, and uninterested in power. These notions reflect **gender stereotypes**, which are broad categories that reflect general impressions and beliefs about females and males.

Recent research has found that gender stereotypes are, to a great extent, still present in today’s world, in the lives of both children and adults (Biernat, 2017; Ellemers, 2018; Hyde, 2017; Leaper, 2015; Liben, 2017). Gender stereotyping continues to change during middle and late childhood and adolescence (Blakemore, Berenbaum, & Liben, 2009; Brannon, 2017). By the time children enter elementary school, they have considerable knowledge about which activities are linked with being male or female. Until about 7 to 8 years of age, gender stereotyping is extensive because young children don’t recognize individual variations in masculinity and femininity. By 5 years of age, both boys and girls stereotype boys as powerful and in more negative terms, such as mean, and girls in more positive terms, such as nice (Martin & Ruble, 2010). Across the elementary school years, children become more flexible in their gender attitudes (Trautner & others, 2005).

A study of 3- to 10-year-old U.S. children revealed that girls and older children used a higher percentage of gender stereotypes (Miller & others, 2009). In this study, appearance stereotypes were more prevalent on the part of girls while activity (sports, for example) and trait (aggressive, for example) stereotyping was more commonly engaged in by boys. Another study of 6- to 10-year-olds found that both boys and girls indicated math is for boys (Cvencek, Meltzoff, & Greenwald, 2011). Researchers also have found that boys’ gender stereotypes are more rigid than girls’ (Blakemore, Berenbaum, & Liben, 2009).

**Gender Similarities and Differences** What is the reality behind gender stereotypes? Let’s examine some of the similarities and differences between the sexes, keeping in mind that (1) the differences are averages—not all females versus all males; (2) even when differences are reported, there is considerable overlap between the sexes; and (3) the

**gender stereotypes** Broad categories that reflect our impressions and beliefs about females and males.

differences may be due primarily to biological factors, sociocultural factors, or both. First, we will examine physical similarities and differences, and then we will turn to cognitive and socioemotional similarities and differences.

**Physical Development** Women have about twice the body fat of men, most of it concentrated around their breasts and hips. In males, fat is more likely to go to the abdomen. On average, males grow to be 10 percent taller than females. Other physical differences are less obvious. From conception on, females have a longer life expectancy than males, and females are less likely than males to develop physical or mental disorders. Males have twice the risk of coronary disease compared with females.

Does gender matter when it comes to brain structure and function? Human brains are much alike, whether the brain belongs to a male or a female (Halpern & others, 2007). However, researchers have found some differences in the brains of males and females (Hofer & others, 2007). Female brains are approximately 10 percent smaller than male brains (Giedd, 2012; Giedd & others, 2012). However, female brains have more folds; the larger folds (called convolutions) allow more surface brain tissue within the skulls of females than males (Luders & others, 2004). An area of the parietal lobe that functions in visuospatial skills is larger in males than females (Frederikse & others, 2000). And the areas of the brain involved in emotional expression show more metabolic activity in females than males (Gur & others, 1995).

Although some differences in brain structure and function have been found, many of these differences are small or research results are inconsistent regarding the differences. Also, when sex differences in the brain have been revealed, in many cases they have not been directly linked to psychological differences (Blakemore, Berenbaum, & Liben, 2009). Although research on sex differences in the brain is still in its infancy, it is likely that there are far more similarities than differences in the brains of females and males. A further point is worth noting: Anatomical sex differences in the brain may be due to the biological origins of these differences, behavioral experiences (which underscores the brain's continuing plasticity), or a combination of these factors.

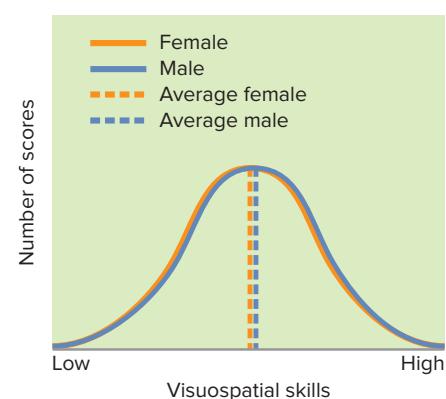

**Cognitive Development** No gender differences in general intelligence have been revealed, but some gender differences have been found in some cognitive areas (Ganley, Vasilyeva, & Dulaney, 2014; Halpern, 2012). Research has shown that in general girls and women have slightly better verbal skills than boys and men, although in some verbal skill areas the differences are substantial (Blakemore, Berenbaum, & Liben, 2009).

Are there gender differences in math skills? A very large-scale study of more than 7 million U.S. students in grades 2 through 11 revealed no differences in math test scores for boys and girls (Hyde & others, 2008). Further, in the National Assessment of Educational Progress (2013) there were virtually no gender differences in math scores at the fourth- and eighth-grade levels. And a meta-analysis found no gender differences in math skills for adolescents (Lindberg & others, 2010). A research review concluded that girls have more negative math attitudes and that parents' and teachers' expectancies for children's math competence are often gender-biased in favor of boys (Gunderson & others, 2012).

One area of math that has been examined for possible gender differences is visuospatial skills, which include being able to rotate objects mentally and to determine what they would look like when rotated (Halpern, 2012). These types of skills are important in courses such as plane and solid geometry and geography. A research review revealed that boys have better visuospatial skills than girls (Halpern & others, 2007). For example, despite equal participation in the National Geography Bee, in most years all 10 finalists are boys (Liben, 1995). A research review found that having a stronger masculine gender role was linked to better spatial ability in males and females (Reilly & Neumann, 2013). However, some experts argue that the gender difference in visuospatial skills is small (Hyde, 2014; Hyde, 2017) (see Figure 1).

Are there gender differences in reading and writing skills? There is strong evidence that females outperform males in reading and writing. In the National Assessment of Educational Progress (2013), girls had higher reading achievement than boys (National Assessment of Educational Progress, 2013). Also, an international study in 65 countries found that girls had higher reading achievement than did boys in every country (Reilly, 2012). In this study, the gender difference in reading was stronger in countries with less gender equity and lower economic prosperity. In the United States, girls also consistently have outperformed boys in writing skills in the National Assessment of Educational Progress in fourth-, eighth-, and twelfth-grade assessments.

Are there gender differences in school contexts and achievement? With regard to school achievement, girls earn better grades and complete high school at a higher rate, and they are

**FIGURE 1**  
**VISUOSPATIAL SKILLS OF MALES AND FEMALES.** Notice that although an average male's visuospatial skills are higher than an average female's, the scores for the two sexes almost entirely overlap. Not all males have better visuospatial skills than all females—the overlap indicates that although the average male score is higher, many females outperform most males on such tasks.

less likely to drop out of school than boys are (Halpern, 2012). Males are more likely than females to be assigned to special/remedial education classes. Girls are more likely than boys to be engaged with academic material, be attentive in class, put forth more academic effort, and participate more in class (DeZolt & Hull, 2001).

Keep in mind that measures of achievement in school or scores on standardized tests may reflect many factors besides cognitive ability. For example, performance in school may in part reflect attempts to conform to gender roles or differences in motivation, self-regulation, or other socioemotional characteristics (Eccles, 2014; Watt & Eccles, 2008).

Might single-sex education be better for children than coeducation? The argument for single-sex education is that it eliminates distraction from the other sex and reduces sexual harassment. Single-sex public education has increased dramatically in recent years. In 2002, only 12 public schools in the United States provided single-sex education; during the 2011–2012 school year, 116 public schools were single-sex and an additional 390 provided such experiences (NASSPE, 2012).

The increase in single-sex education has especially been fueled by its inclusion in the No Child Left Behind legislation as a means of improving the educational experiences and academic achievement of low-income students of color. It appears that many of the public schools offering single-sex education have a high percentage of such youth (Klein, 2012). However, two research reviews concluded that there have been no documented benefits of single-sex education for low-income students of color (Goodkind, 2013; Halpern & others, 2011). One review, titled “The Pseudoscience of Single-Sex Schooling,” by Diane Halpern and her colleagues (2011) concluded that single-sex education is highly misguided, misconstrued, and unsupported by any valid scientific evidence. They emphasize that among the many arguments against single-sex education, the strongest is its reduction in the opportunities for boys and girls to work together in a supervised, purposeful environment.

There has been a special call for single-sex public education for one group of adolescents—African American boys—because of their historically poor academic achievement and high dropout rate from school (Mitchell & Stewart, 2013). In 2010, Urban Prep Academy for Young Men became the first all-male, all African American public charter school. One hundred percent of its first graduates enrolled in college, despite the school’s location in a section of Chicago where poverty, gangs, and crime predominate. Because so few public schools focus solely on educating African American boys, it is too early to tell whether this type of single-sex education can be effective across a wide range of participants.

**Socioemotional Development** Three areas of socioemotional development in which gender similarities and differences have been studied extensively are aggression, emotion, and prosocial behavior.

One of the most consistent gender differences found is that boys are more physically aggressive than girls are (Hyde, 2017). The difference occurs in all cultures and appears very early in children’s development (Dayton & Malone, 2017). The physical aggression difference is especially pronounced when children are provoked. Both biological and environmental factors have been proposed to account for gender differences in aggression. Biological factors include heredity and hormones. Environmental factors include cultural expectations, adult and peer models, and social agents that reward aggression in boys and punish aggression in girls.

Although boys are consistently more physically aggressive than girls, might girls show levels of verbal aggression, such as yelling, that equal or exceed the levels shown by boys? When verbal aggression is considered, gender differences often disappear, although sometimes verbal aggression is more pronounced in girls (Eagly & Steffen, 1986).

Recently, increased attention has been directed to *relational aggression*, which involves harming someone by manipulating a relationship. Relational aggression includes such behaviors as spreading malicious rumors about someone in order to make others dislike that person (Casper & Card, 2017; Cooley & Fife, 2016). Relational aggression increases in middle and late childhood (Dishion & Piehler, 2009). Mixed findings have

characterized research on whether girls show more relational aggression than boys, but one consistent finding is that relational aggression comprises a greater percentage of girls' overall aggression than is the case for boys (Putallaz & others, 2007). And a research review revealed that girls engage in more relational aggression than boys in adolescence but not in childhood (Smith, Rose, & Schwartz-Mette, 2010). Further, in a longitudinal study, preschool relational aggression predicted adolescent relational aggression for girls, but not for boys (Nelson & others, 2014).

Gender differences occur in some aspects of emotion (Brody, Hall, & Stokes, 2018; Leaper, 2013, 2015). Females express emotion more than do males, are better at decoding emotion, smile more, cry more, and are happier (Gross, Fredrickson, & Levenson, 1994; LaFrance, Hecht, & Paluck, 2003). Males report experiencing and expressing more anger than females do (Kring, 2000). A meta-analysis found that females are better than males at recognizing nonverbal displays of emotion (Thompson & Voyer, 2014). Another meta-analysis found that girls showed more positive emotions (sympathy, for example) and more internalized emotions (sadness and anxiety, for example); however, in this meta-analysis, overall gender differences in children's emotional expression were small (Chaplin & Aldao, 2013). The gender difference in positive emotions became more pronounced with age as girls more strongly expressed positive emotions than boys in middle and late childhood and in adolescence.

An important skill is to be able to regulate and control one's emotions and behavior (Perry & others, 2017; Usher & Schunk, 2018). Boys usually show less self-regulation than girls do (Berke, Reidy, & Zeichner, 2018). This low self-control can translate into behavior problems.

Are there gender differences in prosocial behavior? Females view themselves as more prosocial and empathic (Eisenberg & Spinrad, 2016). Across childhood and adolescence, females engage in more prosocial behavior than males do (Hastings, Miller, & Troxel, 2015). The biggest gender difference occurs for kind and considerate behavior, with a smaller difference in sharing.

**Gender in Context** Gender stereotypes describe people in terms of personality traits such as "aggressive" or "caring." However, the traits people display may vary with the situation (Leaper, 2015; Liben, 2017). Thus, the nature and extent of gender differences may depend on the context.

Consider helping behavior. The stereotype is that females are better than males at helping. But it depends on the situation. Females are more likely than males to volunteer their time to help children with personal problems and to engage in caregiving behavior. However, in situations in which males feel a sense of competence and in circumstances that involve danger, males are more likely than females to help (Eagly & Crowley, 1986). For example, a male is more likely than a female to stop and help a person stranded by the roadside with a flat tire. Indeed, one study documented that males are more likely to help when the context is masculine in nature (MacGeorge, 2003).

The importance of considering gender in context is nowhere more apparent than when examining what is culturally prescribed behavior for females and males in different countries around the world (Hyde & Else-Quest, 2013; UNICEF, 2016). Although there has been greater acceptance of androgyny and similarities in male and female behavior in the United States in recent years, in many countries gender roles have remained gender-specific. For example, in many Middle Eastern countries, the division of labor between males and females is dramatic. Males are socialized and schooled to work in the public sphere, females in the private world of home and child rearing. Also, in Iran the dominant view is that the man's duty is to provide for his family and the woman's is to care for her family and household. China also has been a male-dominant culture. Although women have made some strides in China, especially in urban areas, the male role is still dominant. Most males in China do not accept androgynous behavior or gender equity.

In a recent study of eighth-grade students in 36 countries, in every country girls had more egalitarian attitudes about gender roles than did boys (Dotti Sani & Quaranta, 2015). In this study, girls had more egalitarian gender attitudes in countries with higher levels of societal gender equality. In another recent study of 15- to 19-year-olds in the country of Qatar, males had more negative views of gender equality than did females (Al-Ghanim & Badahdah, 2017).

In China, females and males are usually socialized to behave, feel, and think differently. The old patriarchal traditions of male supremacy have not been completely uprooted. Chinese women still make considerably less money than Chinese men do, and in rural China (such as here in the Lixian Village of Sichuan) male supremacy still governs many women's lives.

### DEVELOPMENTAL CHANGES IN PARENT-CHILD RELATIONSHIPS

As children move into the middle and late childhood years, parents spend considerably less time with them (Grusec, 2017; Pomerantz & Grodnick, 2017). In one study, parents spent less than half as much time with their children aged 5 to 12 in caregiving, instruction, reading, talking, and playing as they did when the children were younger (Hill & Stafford, 1980). However, parents continue to be extremely important in their children's lives. One analysis concluded: "Parents serve as gatekeepers and provide scaffolding as children assume more responsibility for themselves and . . . regulate their own lives" (Huston & Ripke, 2006, p. 422).

Parents especially play an important role in supporting and stimulating children's academic achievement in middle and late childhood (Lansford & others, 2018; Longo & others, 2017). The value parents place on education can determine whether children do well in school. Parents not only influence children's in-school achievement, but they also make decisions about children's out-of-school activities. Whether children participate in sports, music, and other activities is heavily influenced by the extent to which parents sign up children for such activities and encourage their participation (Simpkins, Fredricks, & Eccles, 2015).

Elementary school children tend to receive less physical discipline than preschoolers. Instead of spanking or coercive holding, their parents are more likely to use deprivation of privileges, appeals to the child's self-esteem, comments designed to increase the child's sense of guilt, and statements that the child is responsible for his or her actions. During middle and late childhood, some control is transferred from parent to child. A gradual process, it produces coregulation rather than control by either the child or the parent alone. Parents continue to exercise general supervision and control, while children are allowed to engage in

moment-to-moment self-regulation. The major shift to autonomy does not occur until about the age of 12 or later. A key developmental task as children move toward autonomy is learning to relate to adults outside the family on a regular basis—adults such as teachers who interact with children much differently from their parents.

## PARENTS AS MANAGERS

Parents can play important roles as managers of children's opportunities, as monitors of their behavior, and as social initiators and arrangers (Clarke-Stewart & Parke, 2014; Longo & others, 2017). Mothers are more likely than fathers to engage in a managerial role in parenting.

Family management practices are positively related to students' grades and self-responsibility, and negatively to school-related problems (Eccles, 2007; Taylor & Lopez, 2005). Among the most important are maintaining a structured and organized family environment, such as establishing routines for homework, chores, bedtime, and so on, and effectively monitoring the child's behavior. A research review of the role of family functioning in determining African American students' academic achievement found that when parents monitored their son's academic achievement by ensuring that homework was completed, by restricting time spent on nonproductive distractions (such as video games and TV), and by participating in a consistent, positive dialogue with teachers and school officials, their son's academic achievement benefited (Mandara, 2006).

## ATTACHMENT IN FAMILIES

You have read about the importance of secure attachment in infancy and the role of sensitive parenting in attachment (Roisman & Cicchetti, 2018; Thompson, 2016). In middle and late childhood, attachment becomes more sophisticated and as children's social worlds expand to include peers, teachers, and others, they typically spend less time with parents. Kathryn Kerns and her colleagues (Brumariu & Kerns, 2013; Brumariu, Kerns, & Seibert, 2012; Kerns & Brumariu, 2016; Kerns & Seibert, 2012, 2016; Movahed Abtahi & Kerns, 2017; Siener & Kerns, 2012) have studied links between attachment to parents and various child outcomes in the middle and late childhood years and found that secure attachment is associated with a lower level of internalized symptoms, anxiety, and depression in children (Brumariu & Kerns, 2010; Kerns & Brumariu, 2016). One study revealed that children who were less securely attached to their mothers reported having more anxiety (Brumariu, Kerns, & Seibert, 2012). Also in this study, secure attachment was linked to a higher level of children's emotion regulation and less difficulty in identifying emotions.

## STEPFAMILIES

Not only has divorce become commonplace in the United States, so has remarriage. It takes time to marry, have children, get divorced, and then remarry. Consequently, stepfamilies include far more elementary and secondary school children than infants or preschool children. The number of remarriages involving children has grown steadily in recent years. Also, divorces occur at a 10 percent higher rate in remarriages than in first marriages (Cherlin & Furstenberg, 1994). About half of all children whose parents divorce will have a stepparent within four years of the separation.

Remarried parents face unique tasks (Ganong, Coleman, & Russell, 2015; Papernow, 2018). The couple must define and strengthen their marriage while renegotiating the biological parent-child relationships and establishing stepparent-stepchild and stepsibling relationships. The complex histories and multiple relationships make adjustment difficult (Dodson & Davies, 2014). Only one-third of stepfamily couples stay remarried.

Most stepfamilies are preceded by divorce rather than death of a spouse (Pasley & Moorefield, 2004). Three common types of stepfamily structure are (1) stepfather, (2) stepmother, and (3) blended or complex. In stepfather families, the mother typically had custody of the children and remarried, introducing a stepfather into her children's lives. In stepmother families, the father usually had custody and remarried,

introducing a stepmother into his children's lives. In a blended or complex stepfamily, both parents bring children from previous marriages. In E. Mavis Hetherington's (2006) longitudinal analyses, children and adolescents who had been in a simple stepfamily (stepfather or stepmother) for a number of years were adjusting better than in the early years of the remarried family and were functioning well in comparison with children and adolescents in conflictual nondivorced families and children and adolescents in complex (blended) stepfamilies. More than 75 percent of the adolescents in long-established simple stepfamilies described their relationships with their stepparents as "close" or "very close." Hetherington (2006) concluded that in long-established simple stepfamilies adolescents seem to eventually benefit from the presence of a stepparent and the resources provided by the stepparent.

Children often have better relationships with their custodial parents (mothers in stepfather families, fathers in stepmother families) than with stepparents (Antfolk & others, 2017; Santrock, Sitterle, & Warshak, 1988). However, a recent study found that when children have a better parent-child affective relationship with their stepparent, the children have fewer internalizing and externalizing problems (Jensen & others, 2018). Also, children in simple stepfamilies (stepmother, stepfather) often show better adjustment than their counterparts in complex (blended) families (Hetherington & Kelly, 2002). As in divorced families, children in stepfamilies show more adjustment problems than children in nondivorced families (Hetherington & Kelly, 2002)—academic problems and lower self-esteem, for example (Anderson & others, 1999). However, the majority of children in stepfamilies do not have such problems. In one analysis, 25 percent of children from stepfamilies showed adjustment problems compared with 10 percent in intact, never-divorced families (Hetherington & Kelly, 2002). Adolescence is an especially difficult time for the formation of a stepfamily (Gosselin, 2010). This difficulty may occur because becoming part of a stepfamily exacerbates normal adolescent concerns about identity, sexuality, and autonomy.

## 3 Peers

### LG3

Identify changes in peer relationships in middle and late childhood.

Developmental Changes

Peer Status

Social Cognition

Bullying

Friends

Having positive relationships with peers is especially important in middle and late childhood (Nesi & others, 2017; Rubin & Barstead, 2018; Vitaro, Boivin, & Poulin, 2018; Witgow, Rickert, & Cullen, 2017). Engaging in positive interactions with peers, resolving conflicts in nonaggressive ways, and maintaining quality friendships not only produce positive outcomes at this time in children's lives, but also are linked to more positive relationships in adolescence and adulthood (Bukowski & Raufelder, 2018; Kindermann & Gest, 2018; Laursen, 2018;

Laursen & Adams, 2018; Vitaro, Boivan, & Poulin, 2018). In one longitudinal study, being popular with peers and engaging in low levels of aggression at 8 years of age were related to higher levels of occupational status at 48 years of age (Huesmann & others, 2006). Another study found that peer competence (a composite measure that included social contact with peers, popularity with peers, friendship, and social skills) in middle and late childhood was linked to having better relationships with coworkers in early adulthood (Collins & van Dulmen, 2006). And another study indicated that low peer status in childhood (low acceptance/likability) was linked to increased probability of being unemployed and having mental health problems in adulthood (Almquist & Brannstrom, 2014).

## DEVELOPMENTAL CHANGES

As children enter the elementary school years, reciprocity becomes especially important in peer interchanges. Researchers estimate that the percentage of time spent in social interaction with peers increases from approximately 10 percent at 2 years of age to more than 30 percent in middle and late childhood (Rubin, Bukowski, & Parker, 2006). In an early classic study, a typical day in elementary school included approximately 300 episodes with peers (Barker & Wright, 1951). As children move through middle and late childhood, the size of their peer group increases, and peer interaction is less closely supervised by adults. Until about 12 years of age, children's preference for same-sex peer groups increases.

## PEER STATUS

Which children are likely to be popular with their peers and which ones tend to be disliked? Developmentalists address this and similar questions by examining *sociometric status*, a term that describes the extent to which children are liked or disliked by their peer group (Achterberg & others, 2017; Cillessen & Bukowski, 2018). Sociometric status is typically assessed by asking children to rate how much they like or dislike each of their classmates. Or it may be assessed by asking children to name the children they like the most and those they like the least.

Developmentalists have distinguished five peer statuses (Wentzel & Asher, 1995):

- **Popular children** are frequently nominated as a best friend and are rarely disliked by their peers.
- **Average children** receive an average number of both positive and negative nominations from their peers.
- **Neglected children** are infrequently nominated as a best friend but are not disliked by their peers.
- **Rejected children** are infrequently nominated as someone's best friend and are actively disliked by their peers.
- **Controversial children** are frequently nominated both as someone's best friend and as being disliked.

Popular children have many social skills that contribute to their being well liked (McDonald & Asher, 2018). They give out reinforcements, listen carefully, maintain open lines of communication with peers, are happy, control their negative emotions, show enthusiasm and concern for others, and are self-confident without being conceited (Hartup, 1983; Rubin, Bukowski, & Bowker, 2015). Rejected children often have serious adjustment problems (Bukowski & others, 2015; Prinstein & others, 2018). Peer rejection is consistently linked to the development and maintenance of conduct problems (Chen, Drabick, & Burgers, 2015; Prinstein & others, 2018). In a recent study of young adolescents, peer rejection predicted increases in aggressive and rule-breaking behavior (Janssens & others, 2017).

John Coie (2004, pp. 252–253) provided three reasons why aggressive, peer-rejected boys have problems in social relationships:

- “First, the rejected, aggressive boys are more impulsive and have problems sustaining attention. As a result, they are more likely to be disruptive of ongoing activities in the classroom and in focused group play.

What are some statuses that children have with their peers?

**popular children** Children who are frequently nominated as a best friend and are rarely disliked by their peers.

**average children** Children who receive an average number of both positive and negative nominations from peers.

**neglected children** Children who are infrequently nominated as a best friend but are not disliked by their peers.

**rejected children** Children who are infrequently nominated as a best friend and are actively disliked by their peers.

**controversial children** Children who are frequently nominated both as a best friend and as being disliked by their peers.

- Second, rejected, aggressive boys are more emotionally reactive. They are aroused to anger more easily and probably have more difficulty calming down once aroused. Because of this they are more prone to become angry at peers and attack them verbally and physically. . . .
- Third, rejected children have fewer social skills in making friends and maintaining positive relationships with peers.”

Not all rejected children are aggressive (Rubin, Bukowski, & Barker, 2015). Although aggression and its related characteristics of impulsiveness and disruptiveness underlie rejection about half the time, approximately 10 to 20 percent of rejected children are shy.

Rejected children can be taught to more accurately assess whether the intentions of their peers are negative (Bierman & Powers, 2009). They can engage in role playing or discuss hypothetical situations involving negative encounters with peers, such as when a peer cuts into a line ahead of them. In some programs, children watch videotapes of appropriate peer interaction and are asked to draw lessons from what they have seen (Ladd, Buhs, & Troop, 2004).

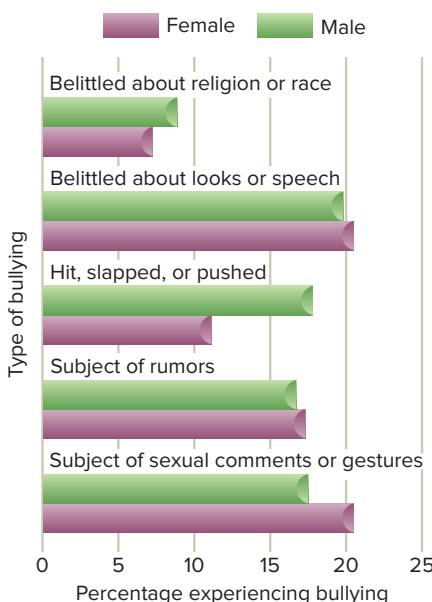

## SOCIAL COGNITION

A boy accidentally trips and knocks another boy’s soft drink out of his hand. That boy misinterprets the encounter as hostile, which leads him to retaliate aggressively against the boy who tripped. Through repeated encounters of this kind, the aggressive boy’s classmates come to perceive him as habitually acting in inappropriate ways. This encounter demonstrates the importance of *social cognition*—thoughts about social matters, such as the aggressive boy’s interpretation of an encounter as hostile and his classmates’ perception of his behavior as inappropriate (Carpendale & Lewis, 2015). Children’s social cognition about their peers becomes increasingly important for understanding peer relationships in middle and late childhood. Of special interest are the ways in which children process information about peer relations and their social knowledge (Dodge, 2011a, b). Kenneth Dodge (1983, 2011a, b) argues that children go through six steps in processing information about their social world. They (1) selectively attend to social cues, (2) attribute intent by interpreting social cues, (3) establish social goals, (4) access behavioral scripts from memory and generate problem-solving strategies, (5) evaluate the likely effectiveness of strategies and make decisions, and (6) enact behavior. Subsequently, children may evaluate the effectiveness of their response. Boys are less likely to spontaneously engage in this kind of self-evaluation of the outcomes of their behavior, and thus more likely than girls to engage in impulsive and aggressive behavior. Aggressive boys are more likely to perceive another child’s actions as hostile when the child’s intention is ambiguous. And when aggressive boys search for cues to determine a peer’s intention, they respond more rapidly, less efficiently, and less reflectively than do nonaggressive children. These are among the social cognitive factors believed to be involved in children’s conflicts.

Social knowledge also is involved in children’s ability to get along with peers (Carpendale & Lewis, 2015). They need to know what goals to pursue in poorly defined or ambiguous situations, how to initiate and maintain a social bond, and what scripts to follow to get other children to be their friends. For example, as part of the script for getting friends, it helps to know that saying nice things, regardless of what the peer does or says, will make the peer like the child more.

## BULLYING

Significant numbers of students are victimized by bullies (Hall, 2017; Muijs, 2017; Salmivalli & Peets, 2018; Wang & others, 2017; Zarate-Garza & others, 2017). In a survey of 15,000 sixth- through tenth-grade students, nearly one-third said that they had experienced occasional or frequent involvement as a victim or perpetrator in bullying (Nansel & others, 2001). Bullying was defined as verbal or physical behavior intended to disturb someone less powerful. Being belittled about looks or speech was the most frequent type of bullying (see Figure 2). Boys are more likely to be bullies than girls, but gender differences regarding victims of bullies are less clear (Peets, Hodges, & Salmivalli, 2011). In the study boys and younger middle school students were most likely to be bullied (Nansel & others, 2001). Bullied children reported more loneliness and difficulty in making friends, while those who did the bullying were more likely to have low grades and to smoke cigarettes and drink alcohol.

**FIGURE 2**

### BULLYING BEHAVIORS AMONG U.S. YOUTH.

This graph shows the types of bullying most often experienced by U.S. youth. The percentages reflect the extent to which bullied students said that they had experienced a particular type of bullying. In terms of gender, note that when they were bullied, boys were more likely to be hit, slapped, or pushed than girls were.

Anxious, socially withdrawn, and aggressive children are often the victims of bullying (Coplan & others, 2018; Rubin & Barstead, 2018). Anxious and socially withdrawn children may be victimized because they are nonthreatening and unlikely to retaliate if bullied, whereas aggressive children may be the targets of bullying because their behavior is irritating to bullies. Overweight and obese children are often bullied (Bacchini & others, 2017; Gibson & others, 2017).

Social contexts such as poverty, family, school, and peer groups also influence bullying (Prinstein & Giletta, 2016; Salmivalli & Peets, 2018; Troop-Gordon, 2017). A meta-analysis indicated that positive parenting behavior (including having good communication, a warm relationship, being involved, and engaging in supervision of their children) and negative parenting behavior (including child maltreatment—physical abuse and neglect), was related to a greater likelihood of becoming either a bully/victim or a victim at school (Lereya, Samara, & Wolke, 2013).

The social context of the peer group also plays an important role in bullying (Salmivalli & Peets, 2018; Troop-Gordon, 2017). Seventy to 80 percent of victims and their bullies are in the same classroom (Salmivalli & Peets, 2009). Classmates are often aware of bullying incidents (Barhight & others, 2017). Bullies often torment victims to gain higher status in the peer group and need others to witness their power displays. Many bullies are not rejected by the peer group. A longitudinal study explored the costs and benefits of bullying in the context of the peer group (Reijntjes & others, 2013). Although young bullies were on a developmental trajectory that over the long run was problematic, the shorter-term personal benefits of bullying often outweighed the disadvantages. Frequent bullying was linked to high social status as indexed by perceived popularity in the peer group, and bullies also were characterized by self-perceived personal competence.

Peer victimization in the fifth grade has been associated with worse physical and mental health in the tenth grade (Bogart & others, 2014). Children who are bullied are more likely to experience depression, engage in suicidal ideation, and attempt suicide than their counterparts who have not been the victims of bullying (Undheim & Sund, 2013; Yen & others, 2014). Peer victimization during the elementary school years has been linked to stress and suicidal ideation (Kowalski & others, 2014). One study indicated that peer victimization during the elementary school years was a leading indicator of internalizing problems (depression, for example) in adolescence (Schwartz & others, 2015). Also, a longitudinal study found that children who were bullied at 6 years of age were more likely to have excess weight gain when they were 12 to 13 years of age (Sutin & others, 2016). Further, a longitudinal study of 6,000 children found that children who were the victims of peer bullying from 4 to 10 years of age were more likely to engage in suicidal ideation at 11½ years of age (Winsper & others, 2012). And a research analysis concluded that bullying can have long-term effects, including difficulty in forming lasting relationships and problems in the workplace (Wolke & Lereya, 2015).

Longitudinal studies have indicated that victims bullied in childhood and adolescence have higher rates of agoraphobia (an abnormal fear of being in public, open, and crowded places), depression, anxiety, panic disorder, and suicidality in their early to mid-twenties compared with those who have not been bullied in childhood and adolescence (Arseneault, 2017; Copeland & others, 2013). In addition, another recent study revealed that being a victim of bullying in childhood was linked to increased use of mental health services by the victims five decades later (Evans-Lacko & others, 2017).

An increasing concern is peer bullying and harassment on the Internet (called *cyberbullying*) (Vollink, Dehue, & McGuckin, 2016; Wolke, Lee, & Guy, 2017). A study involving third- to sixth-graders revealed that engaging in cyber aggression was related to loneliness, lower self-esteem, fewer mutual friendships, and lower peer popularity (Schoffstall & Cohen, 2011). A meta-analysis concluded that being the victim of cyberbullying was linked to stress and suicidal ideation (Kowalski & others, 2014), and another study found it was more strongly associated with suicidal ideation than traditional bullying was (van Geel, Vedder, & Tanilon, 2014). One meta-analysis revealed that cyberbullying occurred twice as much as traditional bullying and that those who engaged in cyberbullying were likely to also have engaged in traditional bullying (Modecki & others, 2014). Further, a longitudinal study found that adolescents experiencing social and emotional difficulties were more likely to be both cyberbullied and traditionally bullied than to be traditionally bullied only (Cross, Lester, & Barnes, 2015). Adolescents targeted in both ways stayed away from school more than their counterparts who were traditionally bullied only. And a recent study revealed that adolescents who were bullied

both in a direct way and through cyberbullying had more behavioral problems and lower self-esteem than adolescents who were only bullied in one of these two ways (Wolke, Lee, & Guy, 2017). Information about preventing cyberbullying can be found at [www.stopcyberbullying.org/](http://www.stopcyberbullying.org/). Also, an excellent book on the topic is *Bullying Beyond the Schoolyard: Preventing and Responding to Cyberbullying* (Hinduja & Patchin, 2015).

Increasing interest is being directed to finding ways to prevent and treat bullying and victimization (Gower, Cousin, & Borowsky, 2017; Hall, 2017; Menesini & Salmivalli, 2017; Muijs, 2017; Salmivalli & Peets, 2018). School-based interventions vary greatly, ranging from involving the whole school in an antibullying campaign to providing individualized social skills training (Alsaker & Valanover, 2012). One of the most promising bullying intervention programs has been created by Dan Olweus (2003, 2013). This program focuses on 6- to 15-year-olds with the goal of decreasing opportunities and rewards for bullying. School staff are instructed in ways to improve peer relations and make schools safer. When properly implemented, the program reduces bullying by 30 to 70 percent (Ericson, 2001; Olweus, 2003). Information on how to implement the program can be obtained from the Center for the Prevention of Violence at the University of Colorado ([www.blueprintsprograms.com](http://www.blueprintsprograms.com)). A research review concluded that interventions focused on the whole school, such as Olweus', are more effective than interventions involving classroom curricula or social skills training (Cantone & others, 2015).

## FRIENDS

What are some characteristics of children's friendships?

©Design Pics/Don Hammond

Friendship is an important aspect of children's development (Bagwell & Bukowski, 2018; Rubin & Barstead, 2018; Smetana & Ball, 2018). Like adult friendships, children's friendships are typically characterized by similarity (Prinstein & Giletta, 2016). Throughout childhood, friends are more similar than dissimilar in terms of age, sex, race, and many other factors. Friends often have similar attitudes toward school, similar educational aspirations, and closely aligned achievement orientations.

Willard Hartup (1983, 1996, 2009) has studied peer relations and friendship for more than three decades. He concludes that friends provide cognitive and emotional resources from childhood through old age, such as fostering self-esteem and a sense of well-being. More specifically, children's friendships can serve six functions (Gottman & Parker, 1987):

- *Companionship.* Friendship provides children with a familiar partner and playmate, someone who is willing to spend time with them and join in collaborative activities.
- *Stimulation.* Friendship provides children with interesting information, excitement, and amusement.
- *Physical support.* Friendship provides resources and assistance.
- *Ego support.* Friendship provides the expectation of support, encouragement, and feedback, which helps children maintain an impression of themselves as competent, attractive, and worthwhile individuals.
- *Social comparison.* Friendship provides information about where the child stands vis-à-vis others and whether the child is doing okay.
- *Affection and intimacy.* Friendship provides children with a warm, close, trusting relationship with another individual. **Intimacy in friendships** is characterized by self-disclosure and the sharing of private thoughts. Research suggests that intimate friendships may not appear until early adolescence (Berndt & Perry, 1990).

### developmental connection

#### Peers

Beginning in early adolescence, teenagers typically prefer to have a smaller number of friendships that are more intense and intimate. Connect to "Socioemotional Development in Adolescence."

Although having friends can be a developmental advantage, friendships are not all alike (Bagwell & Bukowski, 2018; de la Haye & others, 2017; Smetana & Ball, 2018; Zhang & others, 2018). People differ in the company they keep—that is, who their friends are. Developmental advantages occur when children have friends who are socially skilled and supportive (Chow, Tan, & Buhrmester, 2015; Laursen, 2018; Kindermann & Gest, 2018; Schneider, 2016). However, it is not developmentally advantageous to have coercive and conflict-ridden friendships (Laursen & Adams, 2018). One study found that students who engaged in classroom aggressive-disruptive behavior were more likely to have aggressive friends (Powers & Bierman, 2013).

Friendship also plays an important role in children's emotional well-being and academic success (Ryan & Shin, 2018). Students with friends who are academically oriented are more likely to achieve success in school themselves (Wentzel & Ramani, 2016).

Contemporary Approaches to Student Learning

Socioeconomic Status, Ethnicity, and Culture

For most children, entering the first grade signals new obligations. They develop new relationships and adopt new standards by which to judge themselves. School provides children with a rich source of new ideas to shape their sense of self. They will spend many years in schools as members of small societies in which there are tasks to be accomplished, people to socialize with and be socialized by, and rules that define and limit behavior, feelings, and attitudes. By the time students graduate from high school, they have spent 12,000 hours in the classroom.

## CONTEMPORARY APPROACHES TO STUDENT LEARNING

Controversy swirls about the best way to teach children and how to hold schools and teachers accountable for whether children are learning (Borich, 2017).

### Constructivist and Direct Instruction Approaches

The **constructivist approach** to instruction is a learner-centered approach that emphasizes the importance of individuals actively constructing their knowledge and understanding with guidance from the teacher. In the constructivist view, teachers should not attempt to simply pour information into children's minds. Rather, children should be encouraged to explore their world, discover knowledge, reflect, and think critically with careful monitoring and meaningful guidance from the teacher (Brophy & Alleman, 2018; Kauchak & Eggen, 2017). Constructivists believe that for too long in American education children have been required to sit still, be passive learners, and roteley memorize irrelevant as well as relevant information (Orlich & Harder, 2018).

Constructivism may include an emphasis on collaboration—children working with each other in their efforts to know and understand (Daniels, 2017; Johnson & others 2018). A teacher with a constructivist instructional philosophy would not have children memorize information roteley but would give them opportunities to meaningfully construct their knowledge and understand the material while guiding their learning (Sadker & Zittleman, 2016).

**constructivist approach** A learner-centered educational approach that emphasizes the importance of individuals actively constructing their knowledge and understanding with guidance from the teacher.

By contrast, the **direct instruction approach** is a structured, teacher-centered approach that is characterized by teacher direction and control, high teacher expectations for students' progress, maximum time spent by students on academic tasks, and efforts by the teacher to keep negative affect to a minimum. An important goal in the direct instruction approach is maximizing student learning time (Webb & Metha, 2017).

Advocates of the constructivist approach argue that the direct instruction approach turns children into passive learners and does not adequately challenge them to think in critical and creative ways. Direct instruction enthusiasts say that the constructivist approaches do not give enough attention to the content of a discipline, such as history or science. They also believe that the constructivist approaches are too relativistic and vague.

Some experts believe that many effective teachers use both a constructivist *and* a direct instruction approach rather than relying exclusively on one or the other (Johnson & others, 2018; Webb & Metha, 2017). Some circumstances may call more for a constructivist approach, others for direct instruction. For example, experts increasingly recommend an explicit, intellectually engaging direct instruction approach when teaching students who have a reading or a writing disability (Cunningham, 2017; Temple & others, 2018).

**Accountability** Since the 1990s, the U.S. public and governments at every level have demanded increased accountability from schools. One result was the spread of state-mandated testing to measure just what students had or had not learned (Martin, Sargrad, & Batel, 2017; Popham, 2017). Many states identified objectives for students in their state and created tests to measure whether students were meeting those objectives. This approach became national policy in 2002 when the No Child Left Behind (NCLB) legislation was signed into law.

**No Child Left Behind (NCLB)** Advocates argue that state-wide standardized testing will have a number of positive effects. These include improved student performance; more time spent teaching the subjects that are tested; high expectations for all students; identification of poorly performing schools, teachers, and administrators; and improved confidence in schools as test scores rise.

Critics argue that the NCLB legislation is doing more harm than good (Ladd, 2017; Sadker & Zittleman, 2016). One criticism stresses that using a single test as the sole indicator of students' progress and competence presents a very narrow view of students' skills (Lewis, 2007). This criticism is similar to the one leveled at IQ tests. To assess student progress and achievement, many psychologists and educators emphasize that a number of measures should be used, including tests, quizzes, projects, portfolios, classroom observations, and so on. Also, the tests used as part of NCLB don't measure creativity, motivation, persistence, flexible thinking, or social skills (Stiggins, 2008). Teachers may end up spending far too much class time "teaching to the test" by drilling students and having them memorize isolated facts rather than focusing on the development of thinking skills needed for success in life (Ladd, 2017). Also, some individuals are concerned that gifted students are neglected in the effort to raise the achievement level of students who are not doing well (Ballou & Springer, 2017).

Each state is allowed to establish its own criteria for what constitutes passing or failing grades on tests designated for NCLB inclusion. An analysis of NCLB data indicated that almost every fourth-grade student in Mississippi knows how to read but only half of Massachusetts' students do (Birman & others, 2007). Because state standards vary greatly, state-by-state comparisons of success on NCLB tests are likely to be unreliable. Many states have taken the safe route and kept the standard for passing low. Thus, while one of NCLB's goals is to raise standards for achievement in U.S. schools, apparently allowing states to set their own standards has lowered achievement standards.

**Common Core** In 2009, the Common Core State Standards Initiative was endorsed by the National Governors Association in an effort to implement more rigorous state guidelines for educating students. The Common Core Standards specify what students should know and the skills they should develop at each grade level in various content areas (Common Core State Standards Initiative, 2016). A large majority of states have agreed to implement the Standards, but they have generated considerable controversy. Some critics argue that they are simply a further effort by the federal government to control education and that they emphasize a "one size fits all" approach that pays little attention to individual variations in students. Supporters say that the Standards provide much-needed detailed guidelines and important milestones for students to achieve.

**direct instruction approach** A structured, teacher-centered educational approach that is characterized by teacher direction and control, mastery of academic skills, high expectations for students' progress, maximum time spent on learning tasks, and efforts to keep negative affect to a minimum.

**Every Student Succeeds Act (ESSA)** The most recent initiative for accountability in education is the *Every Student Succeeds Act (ESSA)*, which was passed into law in December 2015 and was to be fully implemented during the 2017–2018 school year. In early 2018, the Trump administration began going forward with ESSA but was giving states much more flexibility in implementing the law (Klein, 2018a, b). The law replaced *No Child Left Behind*, modifying but not completely eliminating standardized testing. ESSA retains annual testing for reading and writing in grades 3 to 8, then once more in high school. The new law also allows states to scale back the role of tests in holding schools accountable for student achievement. And schools must use at least one nonacademic factor—such as student engagement—in tracking success. Other aspects of the new law include continuing to require states and districts to improve their lowest-performing schools and to ensure that they improve their work with historically underperforming students, such as English-language learners, ethnic minority students, and students with a disability. States and districts are required to implement challenging academic standards, although they can opt out of state standards involving Common Core.

## SOCIOECONOMIC STATUS, ETHNICITY, AND CULTURE

Children from low-income, ethnic minority backgrounds have more difficulties in school than do their middle-socioeconomic-status, White counterparts. Why? Critics argue that schools have not done a good job of educating low-income, ethnic minority students to overcome the barriers to their achievement (Koppleman, 2017; Troppe & others, 2017).

**The Education of Students from Low-Income Backgrounds** Many children living in poverty face problems that present barriers to their learning (Duncan, Magnuson, & Vtroba-Drzal, 2017; Nieto & Bode, 2018; Sawyer & others, 2018; Watson, 2018). They might have parents who don't set high educational standards for them, who are incapable of reading to them, or who can't afford educational materials and experiences, such as books and trips to zoos and museums. They may be malnourished or live in areas with high rates of crime and violence. One study revealed that the longer children experienced poverty, the more detrimental the poverty was to their cognitive development (Najman & others, 2009).

Schools in low-income areas are likely to have more students with low achievement test scores, lower graduation rates, and smaller percentages of students going to college; they are more likely to have young teachers with less experience; and they are more likely to encourage rote learning (Duncan, Magnuson, & Votruba-Drzal, 2017; Gollnick & Chinn, 2017; Sawyer & others, 2018). Many of the schools' buildings and classrooms are old and crumbling. These are the types of undesirable conditions Jonathan Kozol (2005) observed in many inner-city schools. Far too many schools in low-income neighborhoods provide students with environments that are not conducive to effective learning (Bradley, 2015; Leventhal, Dupere, & Shuey, 2015). In a recent research review, it was concluded that increases in family income for children in poverty were associated with increased achievement in middle school as well as greater educational attainment in adolescence and emerging adulthood (Duncan, Magnuson, & Votruba-Drzal, 2017).

Schools and school programs are the focus of some poverty interventions (Dragoset & others, 2017). In a recent intervention with first-generation immigrant children attending high-poverty schools, the City Connects program was successful in improving children's math and reading achievement at the end of elementary school (Dearing & others, 2016). The program is directed by a full-time school counselor or social worker in each school. Annual reviews of children's needs are conducted during the first several months of the school year. Then site coordinators and teachers collaborate to develop a student support plan that might include an after-school program, tutoring, mentoring, or family counselling. For children identified as having intense needs

In *The Shame of a Nation*, Jonathan Kozol (2005) criticized the inadequate quality and lack of resources in many U.S. schools, especially those in the poverty areas of inner cities that have high concentrations of ethnic minority children. ### Ahou Vaziri, Teach for America Instructor

Ahou Vaziri was a top student in author John Santrock's educational psychology course at the University of Texas at Dallas, where she majored in Psychology and Child Development. The following year she served as a teaching intern for the educational psychology course, then submitted an application to join Teach for America and was accepted. Ahou was assigned to work in a low-income area of Tulsa, Oklahoma, where she taught English to seventh- and eighth-graders. In her words, "The years I spent in the classroom for Teach for America were among the most rewarding experiences I have had thus far in my career. I was able to go home every night after work knowing that I truly made a difference in the lives of my students."

Upon completion of her two-year teaching experience with Teach for America, Ahou continued working for the organization by recruiting college students to serve as Teach for America instructors. Subsequently, she moved into a role that involved developing curricula for Teach for America. Recently she earned a graduate degree in counseling from Southern Methodist University, and she has continued working to improve children's lives.

(about 8 to 10 percent of the children), a wider team of professionals becomes involved, possibly including school psychologists, principals, nurses, and/or community agency staff, to create additional supports.

Another important effort to improve the education of children who are growing up in low-income conditions is Teach for America (2018), a nonprofit organization that recruits and selects college graduates from universities to serve as teachers for two years in public schools in low-income communities. Since its inception in 1990, more than 42,000 individuals have taught more than 50,000 students for Teach for America. These teachers can be, but are not required to be, education majors. During the summer before beginning to teach, they attend an intensive training program. To read about one individual who became a Teach for America instructor, see *Connecting with Careers*.

**Ethnicity in Schools** More than one-third of African American and almost one-third of Latino students attend schools in the 47 largest city school districts, compared with only 5 percent of White and 22 percent of Asian American students. Many of these inner-city schools continue to be racially segregated, are grossly underfunded, and do not provide adequate opportunities for children to learn effectively. Thus, the effects of SES and of ethnicity are often intertwined (Chaudry & others, 2017; Umana-Taylor & Douglass, 2017; Sawyer & others, 2018; Watson, 2018).

The school experiences of students from different ethnic groups vary considerably (Koppleman, 2017; Nieto & Bode, 2018). African American and Latino students are much less likely than non-Latino White or Asian American students to be enrolled in college preparatory programs and more likely to be enrolled in remedial and special education programs. Asian American students are far more likely to take advanced math and science courses. African American students are twice as likely as Latinos, Native Americans, or non-Latino Whites to be suspended from school.

However, diversity characterizes every ethnic group (Gollnick & Chinn, 2017; Nieto & Bode, 2018; Spencer & others, 2017). For example, the higher percentage of Asian American students in advanced classes is mainly true for students with Chinese, Taiwanese, Japanese,

Korean, and East Indian cultural backgrounds; students with Hmong and Vietnamese cultural backgrounds have had less academic success. Following are some strategies for improving relationships among ethnically diverse students:

- *Turn the class into a jigsaw classroom.* When Eliot Aronson was a professor at the University of Texas at Austin, the school system contacted him for ideas on how to reduce the increasing racial tension in classrooms. Aronson (1986) developed the concept of a “jigsaw classroom” in which students from different cultural backgrounds are placed in a cooperative group in which they have to construct different parts of a project to reach a common goal. Aronson used the term *jigsaw* because he saw the technique as much like a group of students cooperating to put different pieces together to complete a jigsaw puzzle. How might this work? Team sports, drama productions, and musical performances are examples of contexts in which students participate cooperatively to reach a common goal; however, the jigsaw technique also lends itself to group science projects, history reports, and other learning experiences with a variety of subject matter.
- *Encourage students to have positive personal contact with diverse other students.* Mere contact does not do the job of improving relationships with diverse others. For example, busing ethnic minority students to predominantly White schools, or vice versa, has not reduced prejudice or improved interethnic relations. What matters is what happens after children get to school. Especially beneficial in improving interethnic relations is sharing one’s worries, successes, failures, coping strategies, interests, and other personal information with people of other ethnicities. When this happens, people tend to look at others as individuals rather than as members of a homogeneous group.
- *Reduce bias.* Teachers can reduce bias by displaying images of children from diverse ethnic and cultural groups, selecting play materials and classroom activities that encourage cultural understanding, helping students resist stereotyping, and working with parents to reduce children’s exposure to bias and prejudice at home.
- *View the school and community as a team.* James Comer (1988, 2004, 2006, 2010) advocates a community-based, team approach as the best way to educate children. Three important aspects of the Comer Project for Change are (1) a governance and management team that develops a comprehensive school plan, assessment strategy, and staff development plan; (2) a mental health or school support team; and (3) a parents’ program. Comer believes that the entire school community should have a cooperative rather than an adversarial attitude. The Comer program is currently operating in more than 600 schools in 26 states
- *Be a competent cultural mediator.* Teachers can play a powerful role as cultural mediators by being sensitive to biased content in materials and classroom interactions, learning more about different ethnic groups, being aware of children’s ethnic attitudes, viewing students of color positively, and thinking of positive ways to get parents of color more involved as partners with teachers in educating children.

**Cross-Cultural Comparisons** International assessments indicate that the United States has not fared well in comparisons with many other countries in the areas of math and science (Desilver, 2017). In 2015, comparisons of 15-year-olds on the Program for International Student Assessment (PISA), the United States placed 38th out of 71 countries in math and 24th in science (PISA, 2015). In another assessment of fourth- and eighth-grade students on the Trends in International Mathematics and Science Study (TIMSS), U.S. students fared somewhat better, placing 11th out of 48 countries in fourth-grade math and 8th in fourth-grade science (TIMSS, 2015). Also in the TIMSS, U.S. students placed 8th in math and 8th in science in the 37 countries studied. The top five spots in the international assessments mainly go to East Asian countries, especially Singapore, China, and Japan. The

#### MOTHERS' BELIEFS ABOUT THE FACTORS RESPONSIBLE FOR CHILDREN'S MATH ACHIEVEMENT IN THREE COUNTRIES.

In one study, mothers in Japan and Taiwan were more likely to believe that their children's math achievement was due to effort rather than innate ability, while U.S. mothers were more likely to believe their children's math achievement was due to innate ability (Stevenson, Lee, & Stigler, 1986). If parents believe that their children's math achievement is due to innate ability and their children are not doing well in math, the implication is that they are less likely to think their children will benefit from putting forth more effort.

**mindset** The cognitive view, either fixed or growth, that individuals develop for themselves.

only two countries to crack the top five in recent years for math and science are Finland and Estonia.

Despite the recent gains by U.S. elementary school students, especially disconcerting, though, is that in most comparisons, the rankings for U.S. students in reading, math, and science compared with students in other countries decline as they go from elementary school to high school. Also, U.S. students' achievement scores in math and science are still far below those of students in many East Asian countries.

Harold Stevenson's (1995, 2000; Stevenson, Hofer, & Randel, 1999; Stevenson & others, 1990) research explores possible reasons for the poor performance of American students compared with students in selected Asian countries. Stevenson and his colleagues have completed five cross-cultural comparisons of students in the United States, China, Taiwan, and Japan. In these studies, Asian students consistently outperform American students. And, the longer the students are in school, the wider the gap becomes between Asian and American students—the lowest difference is in the first grade, the highest in the eleventh grade (the highest grade studied). Stevenson and his colleagues spent thousands of hours observing in classrooms, as well

as interviewing and surveying teachers, students, and parents. They found that the Asian teachers spent more of their time teaching math than did the American teachers. More than one-fourth of total classroom time in the first grade was spent on math instruction in Japan, compared with only one-tenth of the time in U.S. first-grade classrooms. Also, the Asian students were in school an average of 240 days a year, compared with 178 days in the United States.

Differences were also found between the Asian and American parents. The American parents had much lower expectations for their children's education and achievement than did the Asian parents. Also, the American parents were more likely to believe that their children's math achievement was due to innate ability, while the Asian parents were more likely to say that their children's math achievement was the consequence of effort and training (see Figure 3). The Asian students were more likely to do math homework than were the American students, and the Asian parents were far more likely to help their children with their math homework than were the American parents (Chen & Stevenson, 1989). *Connecting Through Research* explores why parenting practices may be an important aspect of the lower achievement of U.S. children compared with East Asian children.

Related to the differences between Asian and U.S. parents in explaining the roles of effort and ability, Carol Dweck (2006, 2012, 2015, 2016) described the importance of children's **mindset**, which she defines as the cognitive view individuals develop for themselves. She concludes that each individual has one of two mindsets: (1) a *fixed mindset*, in which they believe that their qualities are carved in stone and cannot change; or (2) a *growth mindset*, in which they believe their qualities can change and improve through their own effort. Dweck (2006, 2012) argued that individuals' mindsets influence whether they will be optimistic or pessimistic, what their goals will be and how hard they will strive to reach those goals, and what they will achieve. Dweck says that mindsets begin to be shaped in childhood as children interact with parents, teachers, and coaches, who themselves have either a fixed mindset or a growth mindset. However, recent research indicates that many parents and teachers with growth mindsets don't always instill them in children and adolescents (Haimovitz & Dweck, 2016, 2017). The following approach has been found to increase adolescents' growth mindset: teach for understanding, provide feedback that improves understanding, give students opportunities to revise their work, communicate how effort and struggling are involved in learning, and function as a partner with children and adolescents in the learning process (Haimovitz & Dweck, 2017; Hooper & others, 2016; Sun, 2015).

In recent research by Dweck and her colleagues, students from lower-income families were less likely to have a growth mindset than their counterparts from wealthier families (Claro, Paunesku, & Dweck, 2016). However, the achievement of students from lower-income families who did have a growth mindset was more likely to be protected from the negative effects of poverty.

Dweck and her colleagues (Blackwell & Dweck, 2008; Blackwell & others, 2007; Dweck, 2012, 2015, 2016; Dweck & Master, 2009) have incorporated information about the brain's plasticity into their efforts to improve students' motivation to achieve and succeed. In one

## Parenting and Children's Achievement: My Child Is My Report Card, Tiger Mothers, and Tiger Babies Strike Back

There is rising concern that U.S. children are not reaching their full academic potential, which ultimately will reduce the capacity of the United States to compete globally (Pomerantz, 2018; Pomerantz & Grolnick, 2017; Qu, Pomerantz, & Deng, 2016). Interested in identifying how parents can maximize their children's motivation and achievement in school while also maintaining positive emotional adjustment, Eva Pomerantz and her colleagues are conducting research with children and their parents in the United States and China, where children often attain higher levels of achievement than their U.S. counterparts (Pomerantz, 2017; Pomerantz, Cheung, & Qin, 2012; Pomerantz & Grolnick, 2017; Pomerantz & Kempner, 2013; Pomerantz, Kim, & Cheung, 2012; Qu, Pomerantz, & Deng, 2016).

East Asian parents spend considerably more time helping their children with homework than do U.S. parents (Chen & Stevenson, 1989). Pomerantz's research indicates that East Asian parental involvement in children's learning is present as early as the preschool years and continues during the elementary school years (Ng, Pomerantz, & Deng, 2014; Ng, Pomerantz, & Lam, 2013; Pomerantz, 2017; Pomerantz & Grolnick, 2017; Rowe, Ramani, & Pomerantz, 2016; Siegler & Mu, 2008). In East Asia, children's learning is considered to be a far greater responsibility of parents than in the United States (Ng, Pomerantz, & Lam, 2013; Pomerantz, Kim, & Cheung, 2012).

Pomerantz and her colleagues also are conducting research on the role of parental control in children's achievement (Cheung & others, 2016). In a research study whose title included the phrase "My Child Is My Report Card," Chinese mothers exerted more control (especially psychological control) over their children than did U.S. mothers (Ng, Pomerantz, & Deng, 2014). Chinese mothers' self-worth was more contingent on their children's achievement than was the case for U.S. mothers.

Pomerantz's research reflects the term "training parents," a variation of authoritarian parenting in which the parenting strategy of many Asian parents is to train their children to achieve high levels of academic success. Amy Chua's 2011 book, *Battle Hymn of the Tiger Mother*, sparked considerable interest in the role of parenting in children's achievement. Chua uses the term Tiger Mother to mean a mother who engages in strict disciplinary practices. In another book, *Tiger Babies Strike Back*, Kim Wong Keltner (2013) argues that the Tiger Mother parenting style can be so demanding and confining that being an Asian American child is like being in an "emotional jail." She says that the Tiger Mother authoritarian style does provide some advantages for children, such as learning to go for what you want and

not to take no for an answer, but that too often the results are not worth the emotional costs.

Researchers studying Chinese American immigrant families with first- and second-grade children have found that the children with authoritarian (highly controlling) parents are more aggressive, are more depressed, have a higher anxiety level, and show poorer social skills than children whose parents have non-authoritarian styles (Zhou & others, 2012). Qing Zhou (2013), lead author on the study just described and the director of the University of California's Culture and Family Laboratory, is conducting workshops to teach Chinese mothers positive parenting strategies such as listening skills, praising their children for good behavior, and spending more time with their children in fun activities. Also, in a recent study in China, young adolescents with authoritative parents showed better adjustment than their counterparts with authoritarian parents (W. Zhang & others, 2017). In sum, while an authoritarian, psychologically controlling style of parenting

may be associated with higher levels of achievement, especially in Asian children, there are concerns that an authoritarian style also may produce more emotional difficulties in children (Pomerantz, 2018; Pomerantz & Grolnick, 2017).

Eva Pomerantz (2018) offers the following recommendations for parents who want to increase the motivation of their children and adolescents to do well in school:

- *Realize that ability is not fixed and can change.* Although it is difficult and takes a lot of patience, understand that children's and adolescents' abilities can improve.
- *Be involved.* One of the most important things parents can do is to become involved in their children's and adolescents' academic life and talk often with them about what they are learning.
- *Support autonomy and self-initiative.* An important aspect of children's and adolescents' motivation to do well in school is whether they believe they are responsible for their learning and are self-motivated.
- *Be positive.* Schoolwork and homework can be frustrating for children and adolescents. Interact with them in positive ways and let them know that life is often tough but that you know they can do well and overcome difficulties.
- *Understand that every child and adolescent is different.* Get to know your child or adolescent—don't let them be a psychological stranger to you. Be sensitive to their unique characteristics and know that sometimes you may need to adapt to such idiosyncrasies.

*What are the best parenting strategies for rearing children to reach high levels of achievement and be emotionally healthy?*

- One of Carol Dweck's exercises in the growth-mindset group was titled "You Can Grow Your Brain." Can you

study, they assigned two groups of students to eight sessions of either (1) study skills instruction or (2) study skills instruction plus information about the importance of developing a growth mindset (called incremental theory in the research) (Blackwell & others, 2007). One of the exercises in the growth mindset group was titled "You Can Grow Your Brain" and emphasized that the brain is like a muscle that can change and grow as it is exercised and develops new connections. Students were informed that the more you challenge your brain to learn, the more your brain cells grow. Both groups had a pattern of declining math scores prior to the intervention. Following the intervention, the math scores of the group who only received the study skills instruction continued to decline, but the group that received the combination of study skills instruction plus the growth mindset emphasis

reversed the downward trend and improved their math achievement. In a recent study conducted by Dweck and her colleagues (Paunesku & others, 2015), underachieving high school students read online modules about how the brain changes when you learn and study hard. Following the online exposure about the brain and learning, the underachieving students improved their grade point averages.

Dweck created a computer-based workshop, "Brainology," to teach students that their intelligence can change (Blackwell & Dweck, 2008; Dweck, 2012, 2015, 2016). Students experience six modules about how the brain works and how they can make their brain improve (see Figure 4). After the program was tested in 20 New York City schools, students strongly endorsed the value of the modules. Said one student, "I will try harder because I know that the more you try the more your brain knows" (Dweck & Master, 2009, p. 137).

In adolescence, children begin spending more time thinking about their identity—who they are, what they are all about, and where they are going in life. Time spent with peers increases in adolescence, and friendships become more intense and intimate. Dating and romantic relationships also become more central to the lives of most adolescents. Parents continue to have an important influence on adolescent development. Having good relationships with parents provides support for adolescents as they seek more autonomy and explore a widening social world. Problems that adolescents can develop include juvenile delinquency and depression.

## Socioemotional Development in Middle and Late Childhood

### 1 Emotional and Personality Development

#### The Self

LG1

Discuss emotional and personality development in middle and late childhood.

- In middle and late childhood, self-understanding increasingly involves social and psychological characteristics, including social comparison. Children increase their perspective taking in middle and late childhood, and their social understanding shows increasing psychological sophistication as well.
- Self-concept refers to domain-specific evaluations of the self. Self-esteem refers to global evaluations of the self and is also referred to as self-worth or self-image. Self-esteem is only moderately related to school performance but is more strongly linked to initiative. Four ways to increase self-esteem are to (1) identify the causes of low self-esteem, (2) provide emotional support and social approval, (3) help children achieve, and (4) help children cope.
- Self-efficacy is the belief that one can master a situation and produce positive outcomes. Bandura believes that self-efficacy is a critical factor in whether students will achieve. Schunk argues that self-efficacy influences a student's choice of tasks, with low-efficacy students avoiding many learning tasks.
- The development of self-regulation is an important aspect of children's development. Erikson's fourth stage of development, industry versus inferiority, characterizes the middle and late childhood years.
- Developmental changes in emotion include increased understanding of complex emotions such as pride and shame, detecting that more than one emotion can be experienced in a particular situation, taking into account the circumstances that led up to an emotional reaction, improvements in the ability to suppress and conceal negative emotions, and the use of self-initiated strategies to redirect feelings. As children get older, they use a greater variety of coping strategies and more cognitive strategies.
- Kohlberg argued that moral development occurs on three levels—preconventional, conventional, and postconventional. Kohlberg maintained that these levels were age-related. Movement through the levels is influenced by cognitive development, imitation and cognitive conflict, peer relations, and perspective taking.
- Criticisms of Kohlberg's theory have been made, especially by Gilligan, who advocates a stronger care perspective. Other criticisms focus on the inadequacy of moral reasoning to predict moral behavior, culture, and family influences.
- The domain theory of moral development states that there are different domains of social knowledge and reasoning, including moral, social conventional, and personal.
- Prosocial behavior involves positive moral behaviors such as sharing. Most sharing in the first three years is not done for empathy, but at about 4 years of age empathy contributes to sharing. By the start of the elementary school years, children express objective ideas about fairness. By the mid- to late elementary school years, children believe equity can mean that others with special needs/merit deserve special treatment. Recently, there has been a surge of interest in moral personality.
- Gender stereotypes are prevalent around the world. A number of physical differences exist between males and females. Some experts argue that cognitive differences between males and females have been exaggerated. In terms of socioemotional differences, males are more physically aggressive than females, whereas females regulate their emotions better and engage in more prosocial behavior than males do. When thinking about gender it is important to consider the social context involved.

## 2 Families

Developmental Changes in Parent-Child Relationships

Parents as Managers

Attachment in Families

Stepfamilies

LG2

Describe developmental changes in parent-child relationships, parents as managers, attachment in families, and stepfamilies.

- Parents spend less time with children during middle and late childhood than in early childhood. Parents especially play an important role in supporting and stimulating children's academic achievement. Discipline changes, and control becomes more coregulatory.
- Parents have important roles as managers of children's opportunities, as monitors of their behavior, and as social initiators and arrangers. Mothers are more likely to function in these parental management roles than fathers are.
- Secure attachment to parents is linked to a lower level of internalized symptoms, anxiety, and depression in children during middle and late childhood. Also in middle and late childhood, attachment becomes more complex as children's social worlds expand.
- As in divorced families, children living in stepparent families face more adjustment problems than their counterparts in nondivorced families. However, a majority of children in stepfamilies do not have adjustment problems. Children in complex (blended) stepfamilies have more problems than children in simple stepfamilies or nondivorced families.

## 3 Peers

Developmental Changes

Peer Status

Social Cognition

Bullying

Friends

LG3

Identify changes in peer relationships in middle and late childhood.

- Among the developmental changes in peer relations in middle and late childhood are increased preference for same-sex groups, increased time spent in peer relations, and less supervision of the peer group by adults.
- Popular children are frequently named as a best friend and are rarely disliked by their peers. Average children receive an average number of both positive and negative nominations from their peers. Neglected children are infrequently named as a best friend but are not disliked by their peers. Rejected children are infrequently named as a best friend and are actively disliked by their peers. Controversial children are frequently named both as a best friend and as being disliked by peers. Rejected children are especially at risk for a number of problems.
- Social information-processing skills and social knowledge are two important dimensions of social cognition in peer relations.
- Significant numbers of children are bullied, and this can result in short-term and long-term negative effects for both the victims and bullies.
- Like adult friends, children who are friends tend to be similar to each other. Children's friendships serve six functions: companionship, stimulation, physical support, ego support, social comparison, and intimacy/affection.

## 4 Schools

Contemporary Approaches to Student Learning

Socioeconomic Status, Ethnicity, and Culture

LG4

Characterize aspects of schooling in children's development in middle and late childhood.

- Two contemporary issues involve whether it is better to educate students by using a constructivist approach (a learner-centered approach) or a direct instruction approach (a teacher-centered approach) and how to hold teachers accountable for whether children are learning.
- In the United States, standardized testing of elementary school students has been mandated by many state governments and by the No Child Left Behind federal legislation. Numerous criticisms of NCLB have been made. Common Core standards, which attempt to provide more specific recommendations for what students need to know at different grade levels, have recently been proposed by the U.S. Department of Education. And the most recent educational legislation, the Every Student Succeeds Act (ESSA), was passed into law in December 2015 to replace NCLB. ESSA reduces the number of state-mandated tests and advocates multiple measures of school success.
- Children in poverty face many barriers to learning at school as well as at home. The effects of SES and ethnicity on schools are intertwined, and many U.S. schools are segregated. Low expectations for ethnic minority children represent one of the barriers to their learning.

- American children are more achievement-oriented than children in many countries but are less achievement-oriented than many children in Asian countries such as China, Taiwan, and Japan.
- Mindset is the cognitive view, either fixed or growth, that individuals develop for themselves. Dweck argues that a key aspect of supporting children's development is to guide them in developing a growth mindset. Pomerantz emphasizes that parental involvement is a key aspect of children's achievement.

## Adolescence

Adolescents try on one face after another, seeking to find a face of their own. Their generation of young people is the fragile cable by which the best and the worst of their parents' generation is transmitted to the present. In the end, there are only two lasting bequests parents can leave youth—one is roots, the other wings. This section contains two chapters: "Physical and Cognitive Development in Adolescence" and "Socioemotional Development in Adolescence."

**F**ifteen-year-old Latisha developed a drinking problem, and she was kicked off the cheerleading squad for missing too many practice sessions—but that didn’t make her stop drinking. She and her friends began skipping school regularly so they could drink.

Fourteen-year-old Arnie is a juvenile delinquent. Last week he stole a TV set, struck his mother and bloodied her face, broke some streetlights in the neighborhood, and threatened a boy with a wrench and hammer.

Twelve-year-old Katie, more than just about anything else, wanted a playground in her town. She knew that the other kids also wanted one, so she put together a group that generated funding ideas for the playground. They presented their ideas to the town council. Her group attracted more youth, and they raised money by selling candy and sandwiches door-to-door. The playground became a reality, a place where, as Katie says, “People have picnics and make friends.” Katie’s advice: “You won’t get anywhere if you don’t try.”

Adolescents like Latisha and Arnie are the ones we hear about the most. But there are many adolescents like Katie who contribute in positive ways to their communities and competently make the transition through adolescence. Indeed, for most young people, adolescence is not a time of rebellion, crisis, pathology, and deviance. A far more accurate vision of adolescence is that it is a time of evaluation, decision making, commitment, and carving out a place in the world. Most of the problems of today’s youth are not with the youth themselves, but with needs that go unmet. To reach their full potential, adolescents need a range of legitimate opportunities as well as long-term support from adults who care deeply about them (Miller & Cho, 2018; Ogden & Haden, 2019).

## topical connections *looking back*

In middle and late childhood, physical growth continues but at a slower pace than in infancy and early childhood. Gross motor skills become much smoother and more coordinated, and fine motor skills also improve. Significant advances in the development of the prefrontal cortex occur. Cognitive and language skills also improve considerably. In terms of cognitive development, most children become concrete operational thinkers, long-term memory increases, and metacognitive skills improve, especially if children learn a rich repertoire of strategies. In terms of language development, children’s understanding of grammar and syntax increases, and learning to read becomes an important achievement.

# preview

Adolescence is a transitional period in the human life span, linking childhood and adulthood. We begin the chapter by examining some general characteristics of adolescence and then explore the major physical changes and health issues of adolescence. Next, we consider the significant cognitive changes that characterize adolescence and conclude the chapter by describing various aspects of schools for adolescents.

## 1 The Nature of Adolescence

**LG1** Discuss the nature of adolescence.

As in development during childhood, genetic/biological and environmental/social factors influence adolescent development. During their childhood years, adolescents experienced thousands of hours of interactions with parents, peers, and teachers, but now they face dramatic biological changes, new experiences, and new developmental tasks. Relationships with parents take a different form, moments with peers become more intimate, and dating occurs for the first time, as do sexual exploration and possibly intercourse. The adolescent's thoughts become more abstract and idealistic. Biological changes trigger a heightened interest in body image. Adolescence has both continuity and discontinuity with childhood.

There is a long history of worrying about how adolescents will "turn out." In 1904, G. Stanley Hall proposed the "storm-and-stress" view that adolescence is a turbulent time charged with conflict and mood swings. However, when Daniel Offer and his colleagues (1988) studied the self-images of adolescents in the United States, Australia, Bangladesh, Hungary, Israel, Italy, Japan, Taiwan, Turkey, and West Germany, at least 73 percent of the adolescents displayed a healthy self-image. Although there were differences among them, the adolescents were happy most of the time, they enjoyed life, they perceived themselves as able to exercise self-control, they valued work and school, they felt confident about their sexual selves, they expressed positive feelings toward their families, and they felt they had the capability to cope with life's stresses—not exactly a storm-and-stress portrayal of adolescence.

Public attitudes about adolescence emerge from a combination of personal experience and media portrayals, neither of which produces an objective picture of how normal adolescents develop (Feldman & Elliott, 1990). Some of the readiness to assume the worst about adolescents likely involves the short memories of adults. Many adults measure their current perceptions of adolescents by their memories of their own adolescence. Adults may portray today's adolescents as more troubled, less respectful, more self-centered, more assertive, and more adventurous than they were.

Growing up has never been easy. However, adolescence is not best viewed as a time of rebellion, crisis, pathology, and deviance. A far more accurate vision of adolescence describes it as a time of evaluation, of decision making, of commitment, and of carving out a place in the world. Most of the problems of today's youth are not with the youth themselves. *What adolescents need is access to a range of legitimate opportunities and to long-term support from adults who care deeply about them. What might be some examples of such support and caring?*

However, in matters of taste and manners, the young people of every generation have seemed unnervingly radical and different from adults—different in how they look, in how they behave, in the music they enjoy, in their hairstyles, and in the clothing they choose. It would be an enormous error, though, to confuse adolescents' enthusiasm for trying on new identities and enjoying moderate amounts of outrageous behavior with hostility toward parental and societal standards. Acting out and boundary testing are time-honored ways in which adolescents move toward accepting, rather than rejecting, parental values.

Negative stereotyping of adolescence has been extensive (Jiang & others, 2018; Petersen & others, 2017). However, much of the negative stereotyping has been fueled by media reports of a visible minority of adolescents. In the last decade there has been a call for adults to have a more positive attitude toward youth and emphasize their positive development. Indeed, researchers have found that a majority of adolescents are making the transition from childhood through adolescence to adulthood in a positive way (Seider, Jayawickreme, & Lerner, 2017). For example, a recent study of non-Latino White and African American 12- to 20-year-olds in the United States found that they were characterized much more by positive than problematic development, even in their most vulnerable times (Gutman & others, 2017). Their engagement in healthy behaviors, supportive relationships with parents and friends, and positive self-perceptions were much stronger than their angry and depressed feelings.

Although most adolescents negotiate the lengthy path to adult maturity successfully, too large a group does not. Ethnic, cultural, gender, socioeconomic, age, and lifestyle differences influence the actual life trajectory of each adolescent (Green & others, 2018; Hadley, 2018; Kimmel & Aronson, 2018; McQueen, 2017; Ruck, Peterson-Badali, & Freeman, 2017). Different portrayals of adolescence emerge, depending on the particular group of adolescents being described. Today's adolescents are exposed to a complex menu of lifestyle options through the media, and many face the temptations of drug use and sexual activity at increasingly young ages (Johnston & others, 2018). Too many adolescents are not provided with adequate opportunities and support to become competent adults (Bill & Melinda Gates Foundation, 2018; Edalati & Nicholls, 2018; Lo & others, 2017; Loria & Caughy, 2018; Miller & Cho, 2018; Umana-Taylor & Douglass, 2017).

Recall that *social policy* is the course of action designed by the national government to influence the welfare of its citizens. Currently, many researchers in adolescent development are designing studies that they hope will lead to wise and effective social policy decision making (Duncan, Magnuson, & Votruba-Drzal, 2017; Galinsky & others, 2017; Hall, 2017).

Research indicates that youth benefit enormously when they have caring adults in their lives in addition to parents or guardians (Frydenberg, 2019; Masten, 2017; Masten & Kalstabakken, 2018; Ogden & Hagen, 2019; Pomerantz & Grolnick, 2017). Caring adults—such as coaches, neighbors, teachers, mentors, and after-school leaders—can serve as role models, confidants, advocates, and resources. Relationships with caring adults are powerful when youth know they are respected, that they matter to the adult, and that the adult wants to be a resource in their lives. However, in a survey, only 20 percent of U.S. 15-year-olds reported having meaningful relationships with adults outside their family who were helping them to succeed in life (Search Institute, 2010).

role parents play in their children's lives leading up to adolescence that might influence adolescents' development?

### Reflect Your Own Personal Journey of Life

- Was your adolescence better described as a stormy and stressful time or as one of trying out new identities as you sought to find an identity of your own? Explain.

## 2 Physical Changes

LG2

Describe the changes involved in puberty, as well as changes in the brain and sexuality during adolescence.

Puberty

The Brain

Adolescent Sexuality

One father remarked that the problem with his teenage son was not that he grew, but that he did not know when to stop growing. As we will see, there is considerable variation in the timing of the adolescent growth spurt. In addition to pubertal changes, other physical changes we will explore involve sexuality and the brain.

### PUBERTY

Puberty is not the same as adolescence. For most of us, puberty ends long before adolescence does, although puberty is the most important marker of the beginning of adolescence.

**Puberty** is a brain-neuroendocrine process occurring primarily in early adolescence that provides stimulation for the rapid physical changes that take place during this period of development (Berenbaum, Beltz, & Corley, 2015; Shalitin & Kiess, 2017; Susman & Dorn, 2013). Puberty is not a single, sudden event. We know whether a young boy or girl is going through puberty, but pinpointing puberty's beginning and end is difficult. Among the most noticeable changes are signs of sexual maturation and increases in height and weight.

**Sexual Maturation, Height, and Weight** Think back to the onset of your puberty. Of the striking changes that were taking place in your body, what was the first to occur? Researchers have found that male pubertal characteristics typically develop in this order: increase in penis and testicle size, appearance of straight pubic hair, minor voice change, first ejaculation (which usually occurs through masturbation or a wet dream), appearance of kinky pubic hair, onset of maximum growth in height and weight, growth of hair in armpits, more detectable voice changes, and, finally, growth of facial hair.

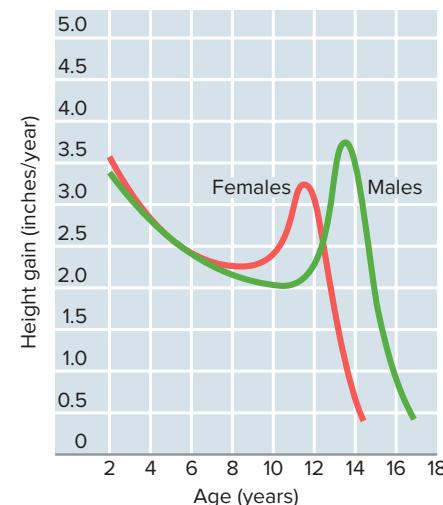

What is the order of appearance of physical changes in females? First, either the breasts enlarge or pubic hair appears. Later, hair appears in the armpits. As these changes occur, the female grows in height and her hips become wider than her shoulders. **Menarche**—a girl's first menstruation—comes rather late in the pubertal cycle. Initially, her menstrual cycles may be highly irregular. For the first several years, she may not ovulate every menstrual cycle; some girls do not ovulate at all until a year or two after menstruation begins. No voice changes comparable to those in pubertal males occur in pubertal females. By the end of puberty, the female's breasts have become more fully rounded.

Marked weight gains coincide with the onset of puberty. During early adolescence, girls tend to outweigh boys, but by about age 14 boys begin to surpass girls. Similarly, at the beginning of the adolescent period, girls tend to be as tall as or taller than boys of their age, but by the end of the middle school years most boys have caught up or, in many cases, surpassed girls in height.

As indicated in Figure 1, the growth spurt occurs approximately two years earlier for girls than for boys. The mean age at the beginning of the growth spurt in girls is 9; for boys, it is 11. The peak rate of pubertal change occurs at 11½ years for girls and 13½ years for boys. During their growth spurt, girls increase in height about 3½ inches per year, boys about 4 inches. Boys and girls who are shorter or taller than their peers before adolescence are likely to remain so during adolescence; however, as much as 30 percent of an individual's height in late adolescence is unexplained by his or her height in the elementary school years.

Is age of pubertal onset linked to how tall boys and girls will be toward the end of adolescence? One study found that for girls, earlier onset of menarche, breast development, and growth spurt were linked to shorter height at 18 years of age; however, for boys, earlier age of growth spurt and slower progression through puberty were associated with being taller at 18 years of age (Yousefi & others, 2013).

**Hormonal Changes** Behind the first whisker in boys and the widening of hips in girls is a flood of **hormones**, powerful chemical substances secreted by the endocrine glands and carried through the body by the bloodstream.

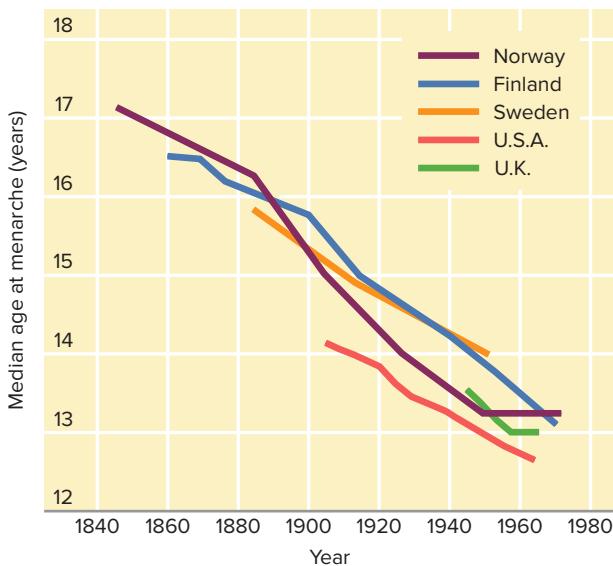

**FIGURE 1**

**PUBERTAL GROWTH SPURT.** On average, the peak of the growth spurt during puberty occurs two years earlier for girls (11½) than for boys (13½). How are hormones related to the growth spurt and to the difference between the average height of adolescent boys and that of girls?

**puberty** A period of rapid physical maturation, occurring primarily in early adolescence, that involves hormonal and bodily changes.

**menarche** A girl's first menstruation.

**hormones** Powerful chemical substances secreted by the endocrine glands and carried through the body by the bloodstream.

**FIGURE 2**

**AGE AT MENARCHE IN NORTHERN EUROPEAN COUNTRIES AND THE UNITED STATES IN THE**

**NINETEENTH AND TWENTIETH CENTURIES.** Notice the steep decline in the age at which girls experienced menarche in four northern European countries and the United States from 1845 to 1969. Recently the age at which girls experience menarche has been leveling off.

The concentrations of certain hormones increase dramatically during adolescence (Berenbaum, Beltz, & Corley, 2015; Herting & Sowell, 2017; Nguyen, 2018; Piekarski & others, 2017). *Testosterone* is a hormone associated in boys with genital development, increased height, and deepening of the voice. *Estradiol* is a type of estrogen that in girls is associated with breast, uterine, and skeletal development. In one study, testosterone levels increased eighteenfold in boys but only twofold in girls during puberty; estradiol increased eightfold in girls but only twofold in boys (Nottelmann & others, 1987). Thus, both testosterone and estradiol are present in the hormonal makeup of both boys and girls, but testosterone dominates in male pubertal development, estradiol in female pubertal development (Benyi & Savendahl, 2017). A study of 9- to 17-year-old boys found that testosterone levels peaked at 17 years of age (Khairullah & others, 2014).

The same influx of hormones that grows hair on a male's chest and increases the fatty tissue in a female's breasts may also contribute to psychological development in adolescence (Berenbaum, Beltz, & Corley, 2015; Wang & others, 2017). In one study of boys and girls ranging in age from 9 to 14, a higher concentration of testosterone was present in boys who rated themselves as more socially competent (Nottelmann & others, 1987). However, a research review concluded that there is insufficient quality research to confirm that changing testosterone levels during puberty are linked to mood and behavior in adolescent males (Duke, Balzer, & Steinbeck, 2014). And hormonal effects by themselves do not account for adolescent development (Susman & Dorn, 2013). For example, in one study, social factors were much better predictors of young adolescent girls' depression and anger than hormonal factors (Brooks-Gunn & Warren, 1989). Behavior and moods also can affect hormones (DeRose & Brooks-Gunn, 2008). Stress, eating patterns, exercise, sexual activity, tension, and depression can activate or suppress various aspects of the hormonal system (Marceau, Dorn, & Susman, 2012). In sum, the hormone-behavior link is complex (Susman & Dorn, 2013).

**Timing and Variations in Puberty** In the United States—where children mature up to a year earlier than children in European countries—the average age of menarche has declined significantly since the mid-nineteenth century (see Figure 2). Also, recent studies in Korea and Japan (Cole & Mori, 2018), China (Song & others, 2017), and Saudi Arabia (Al Alwan & others, 2017) found that pubertal onset has been occurring earlier in recent years. Fortunately, however, we are unlikely to see pubescent toddlers, since what has happened in the past century is likely the result of improved nutrition and health.

Why do the changes of puberty occur when they do, and how can variations in their timing be explained? The basic genetic program for puberty is wired into the species (Day & others, 2017; Kiess & others, 2016). Weight also is linked to pubertal onset. A cross-cultural study in 29 countries found that childhood obesity was linked to early puberty in girls (Currie & others, 2012). And a study of Chinese girls confirmed that childhood obesity contributed to an earlier onset of puberty (Zhai & others, 2015).

Experiences that are linked to earlier pubertal onset include nutrition, an urban environment, low socioeconomic status, adoption, father absence, family conflict, maternal harshness, child maltreatment, and early substance use (Bratke & others, 2017). For example, a recent study found that child sexual abuse was linked to earlier pubertal onset (Noll & others, 2017). In many cases, puberty comes months earlier in these situations, and this earlier onset of puberty is likely explained by high rates of conflict and stress in these social contexts.

For most boys, the pubertal sequence may begin as early as age 10 or as late as 13½, and it may end as early as age 13 or as late as 17. Thus, the normal range is wide enough that, given two boys of the same chronological age, one might complete the pubertal sequence before the other one has begun it. For girls, menarche is considered within the normal range if it appears between the ages of 9 and 15. An increasing number of U.S. girls are beginning puberty at 8 and 9 years of age, with African American girls developing earlier than non-Latino White girls (Herman-Giddens, 2007; Selkie, 2018; Sorensen & others, 2012).

What are some of the differences in the ways girls and boys experience pubertal growth?

**Body Image** One psychological aspect of physical change in puberty is universal: Adolescents are preoccupied with their bodies and develop images of what their bodies are like (Senin-Calderon & others, 2017; Solomon-Krakus & others, 2017). Preoccupation with body image is strong throughout adolescence but is especially acute during early adolescence, a time when adolescents are more dissatisfied with their bodies than in late adolescence.

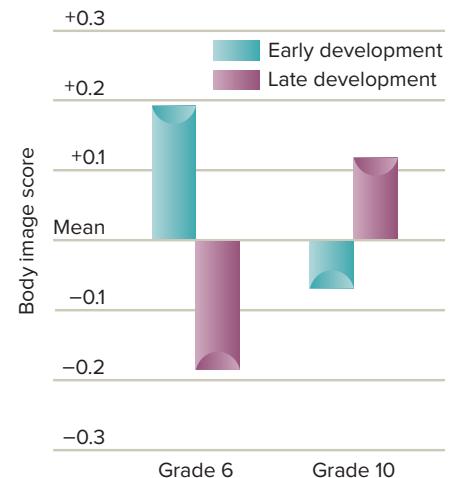

The recent dramatic increase in Internet and social media use has raised concerns about their influence on adolescents' body images. For example, a recent study of U.S. 12- to 14-year-olds found that heavier social media use was associated with body dissatisfaction (Burnette, Kwitowski, & Mazzeo, 2017). Also, in a recent study of U.S. college women, spending more time on Facebook was related to more frequent body and weight concern comparisons with other women, more attention to the physical appearance of others, and more negative feelings about their own bodies (Eckler, Kalyango, & Paasch, 2017). In sum, various aspects of exposure to the Internet and social media are increasing the body dissatisfaction of adolescents and emerging adults, especially females.

Gender differences characterize adolescents' perceptions of their bodies (Hoffman & Warschburger, 2017; Mitchison & others, 2017). In general, girls are less happy with their bodies and have more negative body images than boys throughout puberty (Griffiths & others, 2017). In a recent U.S. study of young adolescents, boys had a more positive body image than girls (Morin & others, 2017). Girls' more negative body images may be due to media portrayals of the attractiveness of being thin and the increase in body fat in girls during puberty (Benowitz-Fredericks & others, 2012). One study found that both boys' and girls' body images became more positive as they moved from the beginning to the end of adolescence (Holsen, Carlson Jones, & Skogbrott Birkeland, 2012).

**Early and Late Maturation** You may have entered puberty earlier or later than average, or perhaps you were right on schedule. Adolescents who mature earlier or later than their peers perceive themselves differently (Lee & others, 2017; Wang & others, 2018). In the Berkeley Longitudinal Study some years ago, early-maturing boys perceived themselves more positively and had more successful peer relations than did their late-maturing counterparts (Jones, 1965). When the late-maturing boys were in their thirties, however, they had developed a stronger sense of identity than the early-maturing boys had (Peskin, 1967). This identity development may have occurred because the late-maturing boys had more time to explore life's options, or because the early-maturing boys continued to focus on their advantageous physical status instead of on career development and achievement. More recent research confirms, though, that at least during adolescence it is advantageous to be an early-maturing rather than a late-maturing boy (Graber, Brooks-Gunn, & Warren, 2006).

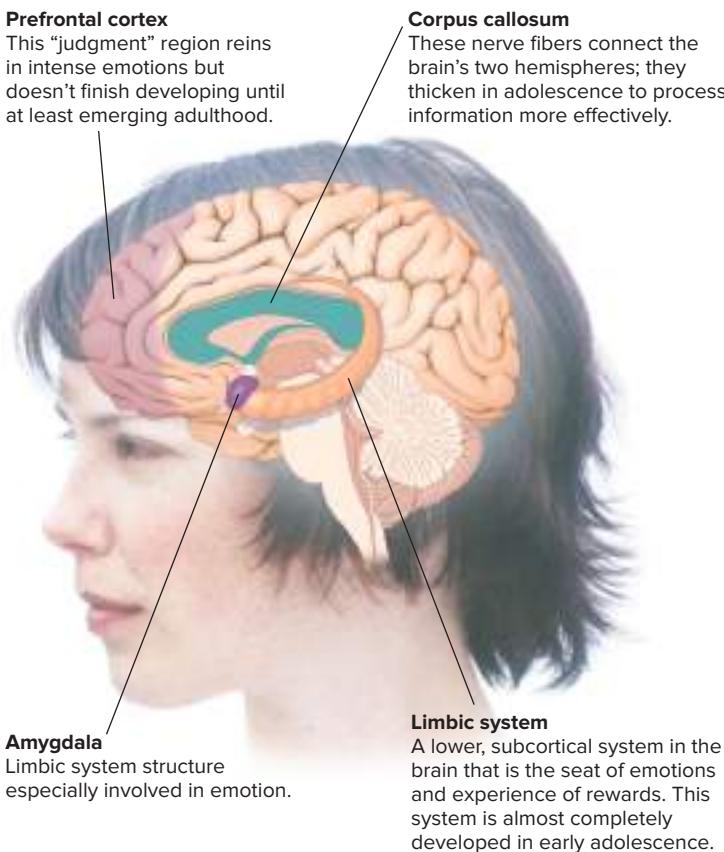

Early and late maturation have been linked with body image. In one study, in the sixth grade, early-maturing girls showed greater satisfaction with their figures than did late-maturing girls, but by the tenth grade late-maturing girls were more satisfied (Simmons & Blyth, 1987) (see Figure 3). A possible reason for this is that in late adolescence early-maturing girls are shorter and stockier, whereas late-maturing girls are taller and thinner. Thus, late-maturing girls in late adolescence have bodies that more closely approximate the current American ideal of feminine beauty—tall and thin. Also, one study found that in the early high school years, late-maturing boys had a more negative body image than early-maturing boys (de Guzman & Nishina, 2014).

An increasing number of researchers have found that early maturation increases girls' vulnerability to a number of problems (Selkie, 2018). Early-maturing girls are more likely to smoke, drink, be depressed, have an eating disorder, engage in delinquency, struggle for earlier independence from their parents, and have older friends; and their bodies are likely to elicit responses from males that lead to earlier dating and earlier sexual experiences (Ibitoye & others, 2017; Pomerantz & others, 2017; Wang & others, 2018). In a recent study, onset of menarche before 11 years of age was linked to a higher incidence of distress disorders, fear disorders, and externalizing disorders in females (Platt & others, 2017). Another study found that early maturation predicted a stable higher level of depression for adolescent girls (Rudolph & others, 2014). Further, researchers recently found that early-maturing girls had higher rates of depression and antisocial behavior as middle-aged adults, mainly because their difficulties began in adolescence and did not lessen over time (Mendle & others, 2018). Further, early-maturing girls tend to have sexual intercourse earlier and to have more unstable sexual relationships, and they are more at risk for physical and verbal abuse in dating (Chen, Rothman, & Jaffee, 2017; Moore, Harden, & Mendle, 2014). And early-maturing girls are less

**FIGURE 3**  
**EARLY- AND LATE-MATURING ADOLESCENT GIRLS' PERCEPTIONS OF BODY IMAGE IN EARLY AND LATE ADOLESCENCE.**

The sixth-grade girls in this study had positive body image scores if they were early maturers but negative body image scores if they were late maturers (Simmons & Blyth, 1987). Positive body image scores indicated satisfaction with their figures. By the tenth grade, however, it was the late maturers who had positive body image scores.

### developmental connection

#### Brain Development

Although the prefrontal cortex shows considerable development in childhood, it is still not fully mature even in adolescence. Connect to “Physical and Cognitive Development in Middle and Late Childhood.”

Using fMRI brain scans, scientists have recently discovered that adolescents’ brains undergo significant structural changes (Aoki, Romeo, & Smith, 2017; Crone, Peters, & Steinbeis, 2018; Goddings & Mills, 2017; Rudolph & others, 2017). The **corpus callosum**, where fibers connect the brain’s left and right hemispheres, thickens in adolescence, and this improves adolescents’ ability to process information (Chavarria & others, 2014). We have described advances in the development of the prefrontal cortex—the highest level of the frontal lobes involved in reasoning, decision making, and self-control. However, the prefrontal cortex doesn’t finish maturing until the emerging adult years, approximately 18 to 25 years of age, or later (Cohen & Casey, 2017; Juraska & Willing, 2017; Sousa & others, 2018).

At a lower, subcortical level, the **limbic system**, which is the seat of emotions and where rewards are experienced, matures much earlier than the prefrontal cortex and is almost completely developed in early adolescence (Mueller & others, 2017). The limbic system structure that is especially involved in emotion is the **amygdala**. Figure 4 shows the locations of the corpus callosum, prefrontal cortex, and the limbic system.

With the onset of puberty, the levels of neurotransmitters change (Cohen & Casey, 2017). For example, an increase in the neurotransmitter dopamine occurs in both the prefrontal cortex and the limbic system during adolescence (Cohen & Casey, 2017). Increases in dopamine have been linked to increased risk taking and the use of addictive drugs (Webber & others, 2017). Researchers also have found that dopamine plays an important role in reward seeking during adolescence (Dubol & others, 2018).

Earlier we described the increased focal activation that is linked to synaptic pruning in a specific region, such as the prefrontal cortex. In middle and late childhood, while there is increased focal activation within a specific brain region such as the prefrontal cortex, there are limited connections across distant brain regions. As adolescents develop, they have more connections across brain areas (Lebel & Deoni, 2018; Quinlin & others, 2017; Sousa & others, 2018; Tashjian, Goldenberg, & Galvan, 2017). The increased connectedness (referred to as brain networks) is especially prevalent across more distant brain regions. Thus, as children

likely to graduate from high school and tend to cohabit and marry earlier (Cavanagh, 2009). Apparently as a result of their social and cognitive immaturity, combined with early physical development, early-maturing girls are easily lured into problem behaviors, not recognizing the possible long-term negative effects on their development.

In sum, early maturation often has more favorable outcomes in adolescence for boys, especially in early adolescence. However, late maturation may be more favorable for boys, especially in terms of identity and career development. Research increasingly has found that early-maturing girls are vulnerable to a number of problems.

## THE BRAIN

Along with the rest of the body, the brain changes during adolescence, but the study of adolescent brain development is still in its infancy. As advances in technology take place, significant strides are also likely to be made in charting developmental changes in the adolescent brain (Cohen & Casey, 2017; Crone, Peters, & Steinbeis, 2018; Sherman, Steinberg, & Chein, 2018; Steinberg & others, 2018; Vijayakumar & others, 2018). What do we know now?

The dogma of the unchanging brain has been discarded, and researchers are mainly focused on context-induced plasticity of the brain over time (Romeo, 2017; Steinberg, 2017; Zelazo, 2013). The development of the brain mainly changes in a bottom-up, top-down sequence with sensory, appetitive (eating, drinking), sexual, sensation-seeking, and risk-taking brain linkages maturing first and higher-level brain linkages such as self-control, planning, and reasoning maturing later (Zelazo, 2013).

develop, greater efficiency and focal activation occurs in close-by areas of the brain, and simultaneously there is an increase in brain networks connecting more distant brain regions. In a recent study, reduced connectivity between the brain's frontal lobes and amygdala during adolescence was linked to increased depression (Scheuer & others, 2017).

Many of the changes in the adolescent brain that have been described here involve the rapidly emerging fields of *developmental cognitive neuroscience* and *developmental social neuroscience*, in which connections between development, the brain, and cognitive or socioemotional processes are studied (Lauharatanahirun & others, 2018; Mueller & others, 2017; Romer, Reyna, & Sattherthwaite, 2017; Sherman, Steinberg, & Chein, 2018; Steinberg & others, 2018). For example, consider leading researcher Charles Nelson's (2003) view that, although adolescents are capable of very strong emotions, their prefrontal cortex hasn't adequately developed to the point at which they can control these passions. It is as if their brain doesn't have the brakes to slow down their emotions. Or consider this interpretation of the development of emotion and cognition in adolescents: "early activation of strong 'turbo-charged' feelings with a relatively unskilled set of 'driving skills' or cognitive abilities to modulate strong emotions and motivations" (Dahl, 2004, p. 18).

Of course, a major question is which comes first, biological changes in the brain or experiences that stimulate these changes (Lerner, Boyd, & Du, 2008; Steinberg, 2017). In a longitudinal study, 11- to 18-year-olds who lived in poverty conditions had diminished brain functioning at 25 years of age (Brody & others, 2017). However, the adolescents from poverty backgrounds whose families participated in a supportive parenting intervention did not show this diminished brain functioning in adulthood. Another study found that the prefrontal cortex thickened and more brain connections formed when adolescents resisted peer pressure (Paus & others, 2007). Scientists have yet to determine whether the brain changes come first or whether they result from experiences with peers, parents, and others (Lauharatanahirun & others, 2018; Webber & others, 2017). Once again, we encounter the nature-nurture issue that is so prominent in an examination of development through the life span. Nonetheless, there is adequate evidence that environmental experiences make important contributions to the brain's development (Cohen & Casey, 2017; Crone, 2017; Sherman, Steinberg, & Chein, 2018).

In closing this section on the development of the brain in adolescence, a further caution is in order. Much of the research on neuroscience and the development of the brain in adolescence is correlational in nature, and thus causal statements need to be scrutinized (Steinberg & others, 2018). This caution, of course, applies to any period in the human life span.

## ADOLESCENT SEXUALITY

Not only is adolescence characterized by substantial changes in physical growth and the development of the brain, but adolescence also is a bridge between the asexual child and the sexual adult (Diamond & Alley, 2018; Savin-Williams, 2017, 2018). Adolescence is a time of sexual exploration and experimentation, of sexual fantasies and realities, of incorporating sexuality into one's identity. Adolescents have an almost insatiable curiosity about sexuality. They are concerned about whether they are sexually attractive, how to do sex, and what the future holds for their sexual lives. Although most adolescents experience times of vulnerability and confusion, the majority will eventually develop a mature sexual identity.

In the United States, the sexual culture is widely available to adolescents. In addition to any advice adolescents get from parents, they learn a great deal about sex from television, videos, magazines, the lyrics of popular music, and the Internet (Bleakley & others, 2017; Kinsler & others, 2018; van Oosten & Vandenbosch, 2017). In some schools, sexting is common, as indicated in a recent study of 656 high school students at one school in which 15.8 percent of males and 13.6 percent of females reported sending and 40.5 percent of males and 30.6 percent of females reported receiving explicit sexual pictures on cell phones (Strassberg, Cann, & Velarde, 2017). And in another recent study of 13- to 21-year-old Latinos, engaging in sexting was linked to engaging in penetrative sex (oral, vaginal, and anal sex) (Romo & others, 2017).

**Developing a Sexual Identity** Mastering emerging sexual feelings and forming a sense of sexual identity are multifaceted and lengthy processes (Diamond & Alley, 2018; Savin-Williams, 2017, 2018). They involve learning to manage sexual feelings (such as sexual arousal and attraction), developing new forms of intimacy, and learning how to regulate sexual behavior to avoid undesirable consequences.

Sexual arousal emerges as a new phenomenon in adolescence and it is important to view sexuality as a normal aspect of adolescent development.

—SHIRLEY FELDMAN

*Contemporary Psychologist, Stanford University*

An adolescent's sexual identity involves activities, interests, styles of behavior, and an indication of sexual orientation (whether an individual has same-sex or other-sex attractions, or both) (Goldberg & Halpern, 2017). For example, some adolescents have a high anxiety level about sex, others a low level. Some adolescents are strongly aroused sexually, others less so. Some adolescents are very active sexually, others not at all (Hyde & DeLamater, 2017). Some adolescents are sexually inactive in response to their strong religious upbringing; others go to church regularly and yet their religious training does not inhibit their sexual activity.

It is commonly thought that most gays and lesbians quietly struggle with same-sex attractions in childhood, do not engage in heterosexual dating, and gradually recognize that they are a gay or lesbian in mid- to late adolescence. Many youth do follow this developmental pathway, but others do not (Diamond & Alley, 2018; Savin-Williams, 2017, 2018). For example, many youth have no recollection of early same-sex attractions and experience a more abrupt sense of their same-sex attraction in late adolescence. The majority of adolescents with same-sex attractions also experience some degree of other-sex attractions (Carroll, 2018). Even though some adolescents who are attracted to individuals of their same sex fall in love with these individuals, others claim that their same-sex attractions are purely physical (Diamond & Alley, 2018; Savin-Williams, 2017, 2018).

Further, the majority of sexual minority (gay, lesbian, and bisexual) adolescents have competent and successful paths of development through adolescence and become healthy and productive adults. However, in a recent large-scale study, sexual minority adolescents did engage in a higher prevalence of health-risk behaviors (greater drug use and sexual risk taking, for example) compared with heterosexual adolescents (Kann & others, 2016b).

**The Timing of Adolescent Sexual Behaviors** What is the current profile of sexual activity of adolescents? In a U.S. national survey conducted in 2015, 58 percent of twelfth-graders reported having experienced sexual intercourse, compared with 24 percent of ninth-graders (Kann & others, 2016a). By age 20, 77 percent of U.S. youth report having engaged in sexual intercourse (Dworkin & Santelli, 2007). Nationally, 46 percent of twelfth-graders, 33.5 percent of eleventh-graders, 25.5 percent of tenth-graders, and 16 percent of ninth-graders recently reported that they were currently sexually active (Kann & others, 2016a).

What trends in adolescent sexual activity have occurred in recent decades? From 1991 to 2015, fewer adolescents reported any of the following: ever having had sexual intercourse, currently being sexually active, having had sexual intercourse before the age of 13, and having had sexual intercourse with four or more persons during their lifetime (Kann & others, 2016a) (see Figure 5).

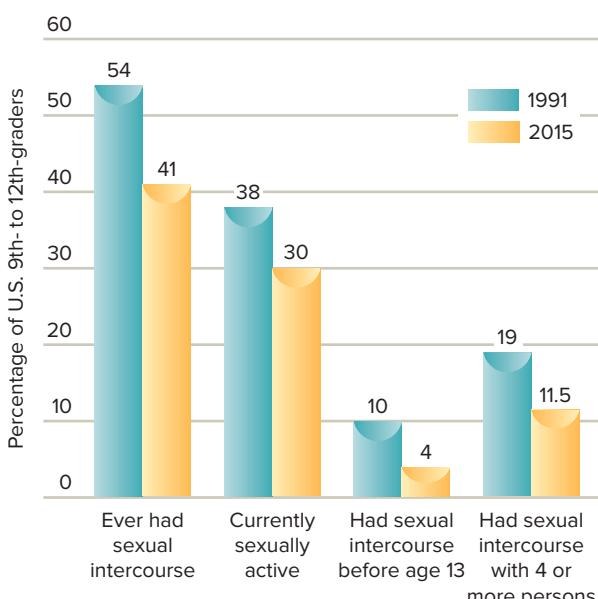

Sexual initiation varies by ethnic group in the United States (Kann & others, 2016a). African Americans are likely to engage in sexual behaviors earlier than other ethnic groups, whereas Asian Americans are likely to engage in them later (Feldman, Turner, & Araujo, 1999). In a more recent national U.S. survey of ninth- to twelfth-graders, 48.5 percent of African Americans, 42.5 percent of Latinos, and 39.9 percent of non-Latino Whites said they had experienced sexual intercourse (Kann & others, 2016a). In this study, 8 percent of African Americans (compared with 5 percent of Latinos and 2.5 percent of non-Latino Whites) said they had their first sexual experience before 13 years of age.

Research indicates that oral sex is now a common occurrence among U.S. adolescents (Fava & Bay-Cheng, 2012; Song & Halpern-Felsher, 2010). In a national survey, 51 percent of U.S. 15- to 19-year-old boys and 47 percent of girls in the same age range said they had engaged in oral sex (Child Trends, 2015). Researchers have also found that among female adolescents who reported having vaginal sex first, 31 percent reported having a teen pregnancy, whereas among those who initiated oral-genital sex first, only 8 percent reported having a teen pregnancy (Reese & others, 2013). Thus, how adolescents initiate their sex lives may have positive or negative consequences for their sexual health.

**FIGURE 5**

**SEXUAL ACTIVITY OF U.S. ADOLESCENTS FROM 1991 TO 2015**

**Risk Factors in Adolescent Sexual Behavior** Many adolescents are not emotionally prepared to handle sexual experiences, especially in early

adolescence (Cai & others, 2018; Donenberg & others, 2018; Ihongbe, Cha, & Masho, 2017). Early sexual activity is linked with risky behaviors such as drug use, delinquency, and school-related problems (Boisvert, Boislard, & Poulin, 2017; Rivera & others, 2018). A recent study of more than 3,000 Swedish adolescents revealed that sexual intercourse before age 14 was linked to risky behaviors such as an increased number of sexual partners, experience of oral and anal sex, negative health behaviors (smoking, drug and alcohol use), and antisocial behavior (being violent, stealing, running away from home) at 18 years of age (Kastbom & others, 2016). Further, a recent study found that early sexual debut (first sexual intercourse before age 13) was associated with sexual risk taking, substance use, violent victimization, and suicidal thoughts/attempts in both sexual minority (in this study, gay, lesbian, and bisexual adolescents) and heterosexual youth (Lowry, Robin, & Kann, 2017). And in a recent study of Korean adolescent girls, early menarche was linked with earlier initiation of sexual intercourse (Kim & others, 2018).

In addition to having sex in early adolescence, other risk factors for sexual problems in adolescence include contextual factors such as socioeconomic status (SES) and poverty, immigration/ethnic minority status, family/parenting and peer factors, and school-related influences (Simons & others, 2016; Warner, 2018). The percentage of sexually active young adolescents is higher in low-income areas of inner cities (Morrison-Beedy & others, 2013). One study revealed that neighborhood poverty concentrations predicted 15- to 17-year-old girls' and boys' sexual initiation (Cubbin & others, 2010). Also, a national survey of 15- to 20-year-olds found that Spanish-speaking immigrant youth were more likely to have a sexual partner age difference of 6 or more years and less likely to use contraception at first sexual intercourse than their native Latino, non-Latino White, and English-speaking Latino immigrant counterparts (Haderxhanaj & others, 2014).

A number of family factors are associated with sexual risk-taking (Ashcraft & Murray, 2017; Ruiz-Casares & others, 2017). For example, a recent study revealed that adolescents who in the eighth grade reported greater parental knowledge and more family rules about dating were less likely to initiate sex from the eighth to tenth grade (Ethier & others, 2016). Also, a recent study revealed that of a number of parenting practices the factor that best predicted a lower level of risky sexual behavior by adolescents was supportive parenting (Simons & others, 2016). Further, one study found that difficulties and disagreements between Latino adolescents and their parents were linked to the adolescents' early sex initiation (Cordova & others, 2014). Also, having older sexually active siblings or pregnant/parenting teenage sisters placed adolescent girls at higher risk for pregnancy (Miller, Benson, & Galbraith, 2001).

Peer, school, sport, and religious contexts provide further information about sexual risk taking in adolescents (Choukas-Bradley & Prinstein, 2016). One study found that adolescents who associated with more deviant peers in early adolescence were likely to have more sexual partners at age 16 (Lansford & others, 2010). Also, a research review found that school connectedness was linked to positive sexuality outcomes (Markham & others, 2010). A study of middle school students revealed that better academic achievement was a protective factor in preventing boys and girls from engaging in early sexual intercourse (Laflin, Wang, & Barry, 2008). Also, a recent study found that adolescent males who play sports engage in a higher level of sexual risk taking, while adolescent females who play sports engage in a lower level of sexual risk taking (Lipowski & others, 2016). And a recent study of African American adolescent girls indicated that those who reported that religion was of low or moderate importance to them had a much earlier sexual debut than their counterparts who said that religion was very important or extremely important to them (George Dalmida & others, 2018).

Cognitive and personality factors are increasingly implicated in sexual risk taking in adolescence. Weak self-regulation (difficulty controlling one's emotions and behavior) and impulsiveness are two such factors. Another longitudinal study found that weak self-regulation at 8 to 9 years of age and

Psychologists are exploring ways to encourage adolescents to make less risky sexual decisions. risk proneness (tendency to seek sensation and make poor decisions) at 12 to 13 years of age set the stage for sexual risk taking at 16 to 17 years of age (Crockett, Raffaelli, & Shen, 2006). Also, a meta-analysis indicated that the link between impulsivity and risky sexual behavior was likely to be more characteristic of adolescent females than males (Dir, Coskunpinar, & Cyders, 2014).

### developmental connection

**Conditions, Diseases, and Disorders**  
What are some good strategies for protecting against HIV and other sexually transmitted infections? Connect to “Physical and Cognitive Development in Early Adulthood.”

**Contraceptive Use** Too many sexually active adolescents still do not use contraceptives, use them inconsistently, or use contraceptive methods that are less effective than others (Chandra-Mouli & others, 2018; Diedrich, Klein, & Peipert, 2017; Fridy & others, 2018; Jaramillo & others, 2017). In 2015, 14 percent of sexually active adolescents did not use any contraceptive method the last time they had sexual intercourse (Kann & others, 2016a). Researchers have found that U.S. adolescents are less likely to use condoms than their European counterparts (Jorgensen & others, 2015).

Recently, a number of leading medical organizations and experts have recommended that adolescents use long-acting reversible contraception (LARC). These include the Society for Adolescent Health and Medicine (2017), the American Academy of Pediatrics and American College of Obstetrics and Gynecology (Allen & Barlow, 2017), and the World Health Organization (2017). LARC consists of the use of intrauterine devices (IUDs) and contraceptive implants, which have a much lower failure rate and are more effective in preventing unwanted pregnancy than birth control pills and condoms (Diedrich, Klein, & Peipert, 2017; Fridy & others, 2018; Society for Adolescent Health and Medicine, 2017).

**Sexually Transmitted Infections** Some forms of contraception, such as birth control pills or implants, do not protect against sexually transmitted infections, or STIs. **Sexually transmitted infections (STIs)** are contracted primarily through sexual contact, including oral-genital and anal-genital contact. Every year more than 3 million American adolescents (about one-fourth of those who are sexually experienced) acquire an STI (Centers for Disease Control and Prevention, 2018). In a single act of unprotected sex with an infected partner, a teenage girl has a 1 percent risk of getting HIV, a 30 percent risk of acquiring genital herpes, and a 50 percent chance of contracting gonorrhea (Glei, 1999). Yet another very widespread STI is chlamydia. We will consider these and other sexually transmitted infections in more detail later.

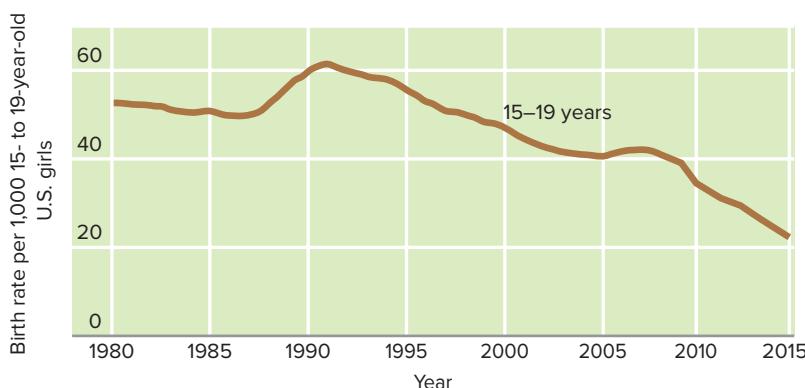

**Adolescent Pregnancy** Adolescent pregnancy is another problematic outcome of sexuality in adolescence and requires major efforts to reduce its occurrence (Brindis, 2017; Chandra-Mouli & others, 2018; Fridy & others, 2018; Marseille & others, 2018; Romero & others, 2017; Tevendale & others, 2017). In cross-cultural comparisons, the United States continues to have one of the highest adolescent pregnancy and childbearing rates in the industrialized world, despite a considerable decline during the 1990s. The U.S. adolescent pregnancy rate is eight times as high as that in the Netherlands. Although U.S. adolescents

are no more sexually active than their counterparts in the Netherlands, their adolescent pregnancy rate is dramatically higher. In the United States, 82 percent of pregnancies in adolescents 15 to 19 years of age are unintended (Koh, 2014). A cross-cultural comparison found that among 21 countries, the United States had the highest adolescent pregnancy rate among 15- to 19-year-olds and Switzerland the lowest (Sedgh & others, 2015).

Despite the negative comparisons of the United States with many other developed countries, there have been some encouraging trends in U.S. adolescent pregnancy rates. In 2015, the U.S. birth rate for 15- to 19-year-olds was 22.3 births per 1,000 females, the lowest rate ever recorded, which represents a dramatic decrease from the 61.8 births for the same age range in 1991 and down even 8 percent from 2014 (Martin & others, 2017) (see Figure 6). There also has been a substantial decrease in adolescent pregnancies across ethnic groups in recent years. Reasons for the decline

include school/community health classes, increased contraceptive use, and fear of sexually transmitted infections such as AIDS.

Ethnic variations characterize birth rates for U.S. adolescents. Latina adolescents are more likely than African American and non-Latina White adolescents to have a child (Martin & others, 2017). Latina and African American adolescent girls who have a child are also more likely to have a second child than are non-Latina White adolescent girls (Rosengard, 2009). And daughters of teenage mothers are at increased risk for teenage childbearing, thus perpetuating an intergenerational cycle (Meade, Kershaw, & Ickovics, 2008).

Adolescent pregnancy creates health risks for both the baby and the mother (Leftwich & Alves, 2017). Infants born to adolescent mothers are more likely to have low birth weights—a prominent factor in infant mortality—as well as neurological problems and childhood illness (Leftwich & Alves, 2017). A recent study assessed the reading and math achievement trajectories of children born to adolescent and non-adolescent mothers with different levels of education (Tang & others, 2016). In this study, higher levels of maternal education were linked to higher academic achievement through the eighth grade. Nonetheless, the achievement of children born to adolescent mothers never reached the levels of children born to adult mothers. Adolescent mothers are more likely to be depressed and to drop out of school than their peers are (Siegel & Brandon, 2014). Although many adolescent mothers resume their education later in life, they generally never catch up economically with women who postpone childbearing until their twenties. Also, a study of African American urban youth found that at 32 years of age, women who had become mothers as teenagers were more likely than non-teen mothers to be unemployed, live in poverty, depend on welfare, and not have completed college (Assini-Meytin & Green, 2015). In this study, at 32 years of age, men who had become fathers as teenagers were more likely than non-teen fathers to be unemployed.

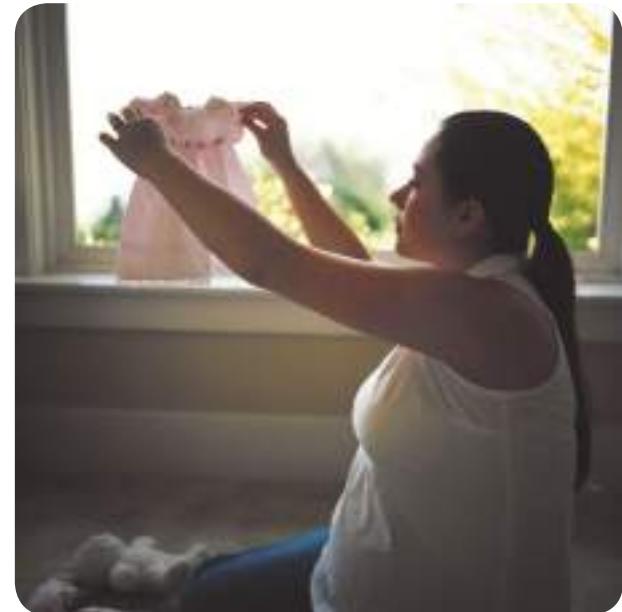

A special concern is repeated adolescent pregnancy. In a recent national study, the percentage of teen births that were repeat births decreased from 2004 (21 percent) to 2015 (17 percent) (Dee & others, 2017). In a recent meta-analysis, use of effective contraception, especially LARC, and education-related factors (higher level of education and school continuation) resulted in a lower incidence of repeated teen pregnancy, while depression and a history of abortion were linked to a higher percentage of repeated teen pregnancy (Maravilla & others, 2017).

Researchers have found that adolescent mothers interact less effectively with their infants than do adult mothers (Leftwich & Alves, 2017). One study revealed that adolescent mothers spent more time negatively interacting and less time in play and positive interactions with their infants than did adult mothers (Riva Crugnola & others, 2014). Also, a recent intervention, “My Baby and Me,” that involved frequent, intensive home visitation coaching sessions with adolescent mothers across three years resulted in improved maternal behavior and child outcomes (Guttentag & others, 2014).

Although the consequences of America’s high rate of adolescent pregnancy are cause for great concern, it often is not pregnancy alone that leads to negative consequences for an adolescent mother and her offspring. Adolescent mothers are more likely to come from low-SES backgrounds (Mollborn, 2017). Many adolescent mothers also were not good students before they became pregnant (Malamitsi-Puchner & Boutsikou, 2006). However, not every adolescent female who bears a child lives a life of poverty and low achievement. Thus, although adolescent pregnancy is a high-risk circumstance, and adolescents who do not become pregnant generally fare better than those who do, some adolescent mothers do well in school and have positive outcomes (Schaffer & others, 2012).

Serious, extensive efforts are needed to help pregnant adolescents and young mothers enhance their educational and occupational opportunities (Carroll, 2018; Craft, Brandt, & Prince, 2016; Mueller & others, 2017; Romero & others, 2017). Adolescent mothers also need help obtaining competent child care and planning for the future.

Adolescents can benefit from age-appropriate family-life education (Barfield, Warner, & Kappeler, 2017; Mueller & others, 2017). Family and consumer science educators teach life skills, such as effective decision making, to adolescents. ### Lynn Blankinship, Family and Consumer Science Educator

Lynn Blankinship is a family and consumer science educator with an undergraduate degree in this field from the University of Arizona. She has taught for more than 20 years, the last 14 at Tucson High Magnet School.

Blankinship has been honored as the Tucson Federation of Teachers Educator of the Year and the Arizona Teacher of the Year. Blankinship especially enjoys teaching life skills to adolescents. One of her favorite activities is having students care for an automated baby that imitates the needs of real babies. She says that this program has a profound impact on students because the baby must be cared for around the clock for the duration of the assignment. Blankinship also coordinates real-world work experiences and training for students in several child-care facilities in the Tucson area.

### Reducing Adolescent Pregnancy

One strategy for reducing adolescent pregnancy, called the Teen Outreach Program (TOP), focuses on engaging adolescents in volunteer community service and stimulates discussions that help adolescents appreciate the lessons they learn through volunteerism.

Girls Inc. has four programs that are intended to increase adolescent girls' motivation to avoid pregnancy until they are mature enough to make responsible decisions about motherhood (Roth & others, 1998). Growing Together, a series of five two-hour workshops for mothers and adolescents, and Will Power/Won't Power, a series of six two-hour sessions that focus on assertiveness training, are for 12- to 14-year-old girls. For older adolescent girls, Taking Care of Business provides nine sessions that emphasize career planning as well as information about sexuality, reproduction, and contraception. Health Bridge coordinates health and education services—girls can participate in this program as one of their club activities. Girls who participated in these programs were less likely to get pregnant than girls who did not participate (Girls Inc., 1991).

In 2010, the U.S. government launched the Teen Pregnancy Prevention (TPP) program under the direction of the newly created Office of Adolescent Health (Koh, 2014). Currently, a number of studies are being funded by the program in an effort to find ways to reduce the rate of adolescent pregnancy.

The sources and the accuracy of adolescents' sexual information are linked to adolescent pregnancy. Adolescents can get information about sex from many sources, including parents, siblings, schools, peers, magazines, television, and the Internet. A special concern is the accuracy of sexual information to which adolescents have access on the Internet.

Currently, a major controversy in sex education is whether schools should have an abstinence-only program or a program that emphasizes contraceptive knowledge (Erkut & others, 2013; MacKenzie, Hedge, & Enslin, 2017). Recent research reviews have concluded that abstinence-only programs do not delay the initiation of sexual intercourse and do not reduce HIV risk behaviors (Denford & others, 2017; Jaramillo & others, 2017; Santelli & others, 2017).

Despite the evidence that favors comprehensive sex education, there recently has been an increase in government funding for abstinence-only programs (Donovan, 2017). Also, in some states (Texas and Mississippi, for example), many students still either get abstinence-only or no sex education at all (Campbell, 2016; Pollock, 2017).

Recently, there also has been an increased emphasis in abstinence-only-until-marriage (AOUM) policies and programs. However, a major problem with such policies and programs is that a very large majority of individuals engage in sexual intercourse at some point in adolescence or emerging adulthood while the age of marriage continues to go up (27 for females, 29 for males in the United States) (Society for Adolescent Medicine, 2017).

## 3 Issues in Adolescent Health

Adolescent Health

**LG3**

Identify adolescent problems related to health, substance use and abuse, and eating disorders.

Substance Use and Abuse

Eating Disorders

Many health experts argue that whether adolescents are healthy depends primarily on their own behavior. To improve adolescent health, adults should aim to (1) increase adolescents' *health-enhancing* behaviors, such as eating nutritious foods, exercising, wearing seat belts, and getting adequate sleep; and (2) reduce adolescents' *health-compromising* behaviors, such as drug abuse, violence, unprotected sexual intercourse, and dangerous driving.

### ADOLESCENT HEALTH

Adolescence is a critical juncture in the adoption of behaviors that are relevant to health (Coore Desai, Reece, & Shakespeare-Pellington, 2017; Devenish, Hooley, & Mellor, 2017; Oldfield & others, 2018; Yap & others, 2017). Many of the behaviors that are linked to poor health habits and early death in adults begin during adolescence (Blake, 2017; Donatelle & Ketcham, 2018). Conversely, the early formation of healthy behavior patterns, such as regular exercise and a preference for foods low in fat and cholesterol, not only has immediate health benefits but helps in adulthood to delay or prevent disability and mortality from heart disease, stroke, diabetes, and cancer (Hales, 2018; Powers & Dodd, 2017).

**Nutrition and Exercise** Concerns are growing about adolescents' nutrition and exercise habits (Donatelle, 2019; Powers & Dodd, 2017; Schiff, 2017, 2019; Smith & Collene, 2019). National data indicated that the percentage of overweight U.S. 12- to 19-year-olds increased from 11 percent in the early 1990s to nearly 20.5 percent in 2014 (Centers for Disease Control and Prevention, 2016). In another study, 12.4 percent of U.S. kindergarten children were obese, but by 14 years of age, 20.8 percent were obese (Cunningham, Kramer, & Narayan, 2014).

A special concern in American culture is the amount of fat we consume. Many of today's adolescents virtually live on fast-food meals, which are high in fat. A comparison of adolescents in 28 countries found that U.S. and British adolescents were more likely to eat fried food and less likely to eat fruits and vegetables than adolescents in most other countries that were studied (World Health Organization, 2000). The National Youth Risk Survey found that U.S. high school students showed a linear decrease in their intake of fruits and vegetables from 1999 through 2015 (Kann & others, 2016a).

Being obese in adolescence predicts obesity in emerging adulthood. For example, a longitudinal study of more than 8,000 adolescents found that obese adolescents were more likely to develop severe obesity in emerging adulthood than were overweight or normal-weight adolescents (The & others, 2010). In another longitudinal study, the percentage of overweight individuals increased from 20 percent at 14 years of age to 33 percent at 24 years of age (Patton & others, 2011).

*What are some characteristics of adolescents' exercise patterns?*

©Tom Stewart/Corbis/Getty Images

Researchers have found that individuals become less active as they reach and progress through adolescence (Alberga & others, 2012). A national study of U.S. adolescents revealed that physical activity increased until 13 years of age in boys and girls but then declined through 18 years of age (Kahn & others, 2008). A recent national study also found that adolescent girls were much less likely to have engaged in 60 minutes or more of vigorous exercise per day in 5 of the last 7 days (61 percent) than were boys (42 percent) (YRBSS, 2016). Ethnic differences in exercise participation rates of U.S. adolescents also occur, and these rates vary by gender. In the national study just mentioned, non-Latino White boys exercised the most, African American and Latino girls the least (YRBSS, 2016).

Positive physical outcomes of exercise in adolescence include a lower rate of obesity, reduced triglyceride levels, lower blood pressure, and a lower incidence of type II diabetes (Barton & others, 2017; Powers & Howley, 2018; Son & others, 2017; Walton-Fisette & Wuest, 2018; Xie & others, 2017). Also, one study found that adolescents who were high in physical fitness had better connectivity between brain regions than adolescents who were low in physical fitness (Herting & others, 2014). Exercise in adolescence also is linked to other positive outcomes. Higher levels of exercise are related to fewer depressive symptoms in adolescents (Gosmann & others, 2015). In a recent study, a high-intensity exercise program reduced depressive symptoms and improved the moods of depressed adolescents (Carter & others, 2016). In another study, young adolescents who exercised regularly had higher academic achievement (Hashim, Freddy, & Rosmatunisah, 2012). And in a recent research review, among a number of cognitive factors, memory was the factor that most often was improved by exercise in adolescence (Li & others, 2017).

Adolescents' exercise is increasingly being found to be associated with parenting and peer relationships (Mason & others, 2017; Michaud & others, 2017). One study revealed that family meals during adolescence protected against becoming overweight or obese in adulthood (Berge & others, 2015). Another study revealed that female adolescents' physical activity was linked to their male and female friends' physical activity, while male adolescents' physical activity was associated with their female friends' physical activity (Sirard & others, 2013).

Researchers have found that screen time is associated with a number of adolescent health problems, including a lower rate of exercise and a higher rate of sedentary behavior (Pearson & others, 2017). In one research review, a higher level of screen-based sedentary behavior was associated with being overweight, having sleep problems, being depressed, and having lower levels of physical activity/fitness and psychological well-being (higher stress levels, for example (Costigan & others, 2013).

What types of interventions and activities have been successful in reducing overweight in adolescents and emerging adults? Research indicates that dietary changes and regular exercise are key components of weight reduction in adolescence and emerging adulthood (Fukerson & others, 2018; Lipsky & others, 2017; Martin & others, 2018; Powers & Howley, 2018). For example, a recent study found that a combination of regular exercise and a diet plan resulted in weight loss and enhanced executive function in adolescents (Xie & others, 2017).

**Sleep** Like nutrition and exercise, sleep is an important influence on well-being. Might changing sleep patterns in adolescence contribute to adolescents' health-compromising behaviors? Recently there has been a surge of interest in adolescent sleep patterns (Hoyt & others, 2018; Meltzer, 2017; Palmer & others, 2018; Reddy & others, 2017; Seo & others, 2017; Wheaton & others, 2018). A longitudinal study in which adolescents completed a 24-hour diary every 14 days in ninth, tenth, and twelfth grades found that regardless of how much students studied each day, when the students sacrificed sleep time to study more than usual they had difficulty understanding what was taught in class and were more likely to struggle with class assignments the next day (Gillen-O'Neil, Huynh, & Fuligni, 2013). Also, a recent experimental study indicated that when adolescents' sleep was restricted to five hours for five nights, then returned to ten hours for two nights, their sustained attention was negatively affected (especially in the early morning) and did not return to baseline levels during recovery (Agostini & others, 2017). Further, researchers have found that adolescents who get less than 7.7 hours of sleep per night on average have more emotional and peer-related problems, higher anxiety, and a higher level of suicidal ideation (Sarchiapone & others, 2014). And a recent national study of more than 10,000 13- to 18-year-olds revealed that later weeknight bedtime, shorter weekend bedtime delay, and both short and long periods of weekend oversleep were linked to increased rates of anxiety, mood, substance abuse, and behavioral disorders (Zhang & others, 2017). Further, in a four-year longitudinal study beginning at 12 years of age, poor sleep patterns (for example, shorter sleep duration and greater

daytime sleepiness) at age 12 was associated with an increased likelihood of drinking alcohol and using marijuana at 16 years of age (Miller, Janssen, & Jackson, 2017). Also, recent Swedish studies revealed that adolescents with a shorter sleep duration were more likely to have more school absences, while shorter sleep duration and greater sleep deficits were linked to having a lower grade point average (Hysing & others, 2015, 2016).

In a recent national survey of youth, only 27 percent of U.S. adolescents got eight or more hours of sleep on an average school night (Kann & others, 2016a). In this study, the percentage of adolescents getting this much sleep on an average school night decreased as they got older (see Figure 7). Also, in other research with more than 270,000 U.S. adolescents from 1991–2012, adolescents were getting less sleep in recent years than in the past (Keyes & others, 2015).

The National Sleep Foundation (2006) conducted a U.S. survey of adolescent sleep patterns. Those who got inadequate sleep (eight hours or less) on school nights were more likely to feel tired or sleepy, to be cranky and irritable, to fall asleep in school, to be in a depressed mood, and to drink caffeinated beverages than their counterparts who got optimal sleep (nine or more hours). Also, a longitudinal study of more than 6,000 adolescents found that sleep problems were linked to subsequent suicidal thoughts and attempts in adolescence and early adulthood (Wong & Brower, 2012). Further, one study found that adolescents who got less than 7.7 hours of sleep per night on average had more emotional and peer-related problems, higher anxiety, and a higher level of suicidal ideation than their peers who got 7.7 hours of sleep or more (Sarchiapone & others, 2014).

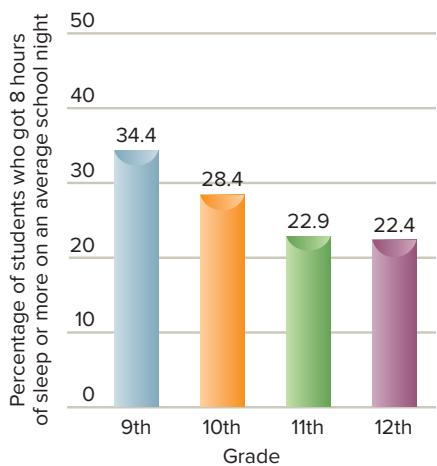

Why are adolescents getting too little sleep? Among the reasons given are those involving electronic media, caffeine, and changes in the brain coupled with early school start times (Bartel, Scheeren, & Gradisar, 2018; Owens, 2014). In one study, adolescents averaged engaging in four electronic activities (in some cases, this involved simultaneous use of different devices) after 9 p.m. (Calamaro, Mason, & Ratcliffe, 2009). Engaging in these electronic activities in the evening can replace sleep time, and such media use may increase sleep-disrupting arousal (Cain & Gradisar, 2010). Also, a study of fourth- and seventh-graders found that sleeping near small screens (smartphones, for example), sleeping with a TV in the room, and more screen time were associated with shorter sleep duration in both children and adolescents (Falbe & others, 2015).

Caffeine intake by adolescents appears to be related to inadequate sleep (Owens, 2014). Greater caffeine intake as early as 12 years of age is linked to later sleep onset, shorter sleep duration, and increased daytime sleepiness (Carskadon & Tarokh, 2014). Further, researchers have yet to study the connection between adolescent sleep patterns and high levels of caffeine intake from energy drinks.

Mary Carskadon and her colleagues (2004, 2005, 2011a, b; Crowley & Carskadon, 2010; Tarokh & Carskadon, 2010) have conducted a number of research studies on adolescent sleep patterns. They found that when given the opportunity, adolescents will sleep an average of 9 hours and 25 minutes a night. Most get considerably less than nine hours of sleep, however, especially during the week. This shortfall creates a sleep deficit, which adolescents often attempt to make up on the weekend. The researchers also found that older adolescents tend to be sleepier during the day than younger adolescents. They theorized that this sleepiness was not due to academic work or social pressures. Rather, their research suggests that adolescents' biological clocks undergo a shift as they get older, delaying their period of sleepiness by about one hour. A delay in the nightly release of the sleep-inducing hormone melatonin, which is produced in the brain's pineal gland, seems to underlie this shift. Melatonin is secreted at about 9:30 p.m. in younger adolescents and approximately an hour later in older adolescents.

Carskadon concludes that early school starting times may cause grogginess, inattention in class, and poor performance on tests. Based on her research, school officials in Edina, Minnesota, decided to start classes at 8:30 a.m. rather than the usual 7:25 a.m. Since then there have been fewer referrals for discipline problems, and the number of students who report being ill or depressed has decreased. The school system reports that test scores have improved for high school students but not for middle school students. This finding supports Carskadon's suspicion that early start times are likely to be more stressful for older than for younger adolescents.

One study found that just a 30-minute delay in school start time was linked to improvements in adolescents' sleep, alertness, mood, and health (Owens, Belon, & Moss, 2010). In another study, early school start times were

In Mary Carskadon's sleep laboratory at Brown University, an adolescent girl's brain activity is being monitored. Carskadon (2005) says that in the morning, sleep-deprived adolescents' "brains are telling them it's night time . . . and the rest of the world is saying it's time to go to school" (p. 19).

linked to a higher vehicle crash rate in adolescent drivers (Vorona & others, 2014). The American Academy of Pediatrics recommends that schools institute start times from 8:30 to 9:30 a.m. to improve adolescents' academic performance and quality of life (Adolescent Sleep Working Group, AAP, 2014).

Do sleep patterns change in emerging adulthood? Research indicates that they do (Galambos, Howard, & Maggs, 2011). One study revealed that more than 60 percent of college students were categorized as poor-quality sleepers (Lund & others, 2010). In this study, the weekday bedtimes and rise times of first-year college students were approximately 1 hour and 15 minutes later than those of seniors in high school (Lund & others, 2010). However, the first-year college students had later bedtimes and rise times than third- and fourth-year college students, indicating that at about 20 to 22 years of age, a reverse in the timing of bedtimes and rise times occurs. In another study, consistently low sleep duration in college students was associated with less effective attention the next day (Whiting & Murdock, 2016). Also, in a recent study of college students, a higher level of text messaging (greater number of daily texts, awareness of nighttime cell phone notifications, and compulsion to check nighttime notifications) was linked to a lower level of sleep quality (Murdock, Horissian, & Crichtlow-Ball, 2017).

**Leading Causes of Death in Adolescence** The three leading causes of death in adolescence are unintentional injuries, homicide, and suicide (National Center for Health Statistics, 2018). Almost half of all deaths from 15 to 24 years of age are due to unintentional injuries, the majority of them involving motor vehicle accidents. Risky driving habits, such as speeding, tailgating, and driving under the influence of alcohol or other drugs, may be more important contributors to these accidents than lack of driving experience (White & others, 2018; Williams & others, 2018). In about 50 percent of motor vehicle fatalities involving adolescents, the driver has a blood alcohol level of 0.10 percent—twice the level at which a driver is designated as “under the influence” in some states. Of growing concern is the increasingly common practice of mixing alcohol and energy drinks, which is linked to a higher rate of driving while intoxicated (Wilson & others, 2018). A high rate of intoxication is also found in adolescents who die as pedestrians or while using vehicles other than automobiles.

Homicide is the second leading cause of death in adolescence, especially among African American males (National Center for Health Statistics, 2018). Also notable is the adolescent suicide rate, which has tripled since the 1950s. Suicide accounts for 6 percent of deaths in the 10-to-14 age group and 12 percent of deaths in the 15-to-19 age group. We will discuss suicide in more detail later.

## SUBSTANCE USE AND ABUSE

Each year since 1975, Lloyd Johnston and his colleagues at the Institute of Social Research at the University of Michigan have monitored the drug use of America's high school seniors in a wide range of public and private high schools. Since 1991, they also have surveyed drug use by eighth- and tenth-graders. In 2017, the study surveyed approximately 45,000 secondary school students in 380 public and private schools (Johnston & others, 2018).

In the University of Michigan study, drug use among U.S. secondary school students declined in the 1980s but began to increase in the early 1990s before declining again in the early part of the first decade of the 21st century. However, from 2006 through 2017, overall use of illicit drugs began increasing again, due mainly to an increase in marijuana use by adolescents. In 2006, 36.5 percent of twelfth-graders reported annual use of an illicit drug but in 2017 that figure had increased to 39.9 percent. However, if marijuana use is subtracted from the annual use figures, there has been a significant decline in drug use by adolescents. When marijuana use is deleted, in 2006, 19.2 percent of twelfth-graders used an illicit drug annually, but that figure showed a significant decline to 13.3 percent in 2017 (Johnston & others, 2018). Marijuana is the most widely used illicit drug by adolescents.

The United States continues to have one of the highest rates of adolescent drug use of any industrialized nation. Because of the increased legalization of marijuana use for adults in a number of states, youth are likely to have increased access to the drug and it is expected that marijuana use by adolescents will increase in the future.

**Alcohol** How extensive is alcohol use by U.S. adolescents? Sizable declines in adolescent alcohol use have occurred in recent years (Johnston & others, 2018). The percentage of U.S.

eighth-graders who reported having had any alcohol to drink in the past 30 days fell from a 1996 high of 26 percent to 8.0 percent in 2017. The 30-day prevalence fell among tenth-graders from 39 percent in 2001 to 19.7 percent in 2017 and among high school seniors from 72 percent in 1980 to 33.2 percent in 2017. Binge drinking (defined in the University of Michigan surveys as having five or more drinks in a row in the last two weeks) by high school seniors declined from 41 percent in 1980 to 19.1 percent in 2015. Binge drinking by eighth- and tenth-graders also has dropped significantly in recent years. A consistent gender difference occurs in binge drinking, with males engaging in this behavior more than females do (Johnston & others, 2018).

A special concern is adolescents who drive while they are under the influence of alcohol or other substances (White & others, 2018; Williams & others, 2018; Wilson & others, 2018). In the University of Michigan Monitoring the Future Study, 30 percent of high school seniors said they had been in a vehicle with a drugged or drinking driver in the past two weeks (Johnston & others, 2008). And in a national study, one in four twelfth-graders reported that they had consumed alcohol mixed with energy drinks in the last 12 months, and this combination was linked to their unsafe driving (Martz, Patrick, & Schulenberg, 2015).

**Smoking** Cigarette smoking (in which the active drug is nicotine) has been one of the most serious yet preventable health problems among adolescents and emerging adults (McKelvey & Halpern-Felsher, 2017). Cigarette smoking among U.S. adolescents peaked in 1996 and has declined significantly since then (Johnston & others, 2018). Following peak use in 1996, smoking rates for U.S. eighth-graders have fallen by 50 percent. In 2017, the percentage of twelfth-graders who reported having smoked cigarettes in the last 30 days was 9.7 percent, an 8 percent decrease from 2011, while the rate for tenth-graders was 5.0 percent and the rate for eighth-graders was 1.9 percent. Since the mid-1990s an increasing percentage of adolescents have reported that they perceive cigarette smoking as dangerous, that they disapprove of it, that they are less accepting of being around smokers, and that they prefer to date nonsmokers (Johnston & others, 2018).

E-cigarettes—battery-powered devices with a heating element—produce a vapor that users inhale. In most cases the vapor contains nicotine, but the specific contents of “vape” formulas are not regulated (Barrington-Trimis & others, 2017; Gorukanti & others, 2017). While adolescent cigarette use has decreased significantly in recent years, a substantial number of U.S. adolescents are now vaping nicotine. In the national study just described, in 2017, 11.0 percent of twelfth-graders, 8.2 percent of tenth-graders, and 3.5 percent of eighth-graders vaped nicotine (Johnston & others, 2018). Thus, adolescents currently are vaping nicotine more than they are smoking cigarettes. Also, in a recent meta-analysis of longitudinal studies, it was concluded that when adolescents use e-cigarettes they are at increased risk for subsequently smoking cigarettes (Soneji & others, 2018).

### The Roles of Development, Parents, Peers, and Education

There are serious consequences when adolescents begin to use drugs early in adolescence or even in childhood (Donatelle & Ketcham, 2018). For example, a study revealed that the onset of alcohol use before age 11 was linked to a higher risk of alcohol dependence in early adulthood (Guttmannova & others, 2012). Another study found that early onset of drinking and a quick progression to drinking to intoxication were linked to drinking problems in high school (Morean & others, 2014). Further, a longitudinal study found that earlier age at first use of alcohol was linked to increased risk of heavy alcohol use in early adulthood (Liang & Chikritzhs, 2015). And another study indicated that early- and rapid-onset trajectories of alcohol, marijuana, and substance use were associated with substance abuse in early adulthood (Nelson, Van Ryzin, & Dishion, 2015).

Parents play an important role in preventing adolescent drug abuse (Cruz & others, 2018; Garcia-Huidobro & others, 2018; Pena & others, 2017). Positive relationships with parents and others can reduce adolescents' drug use (Chassin & others, 2016; Eun & others, 2018). Researchers have found that parental monitoring is linked with a lower incidence of drug use (Wang & others, 2014). For example, a recent study revealed that parental monitoring

## What Can Families Do to Reduce Drinking and Smoking by Young Adolescents?

Experimental studies have been conducted to determine whether family programs can reduce drinking and smoking by young adolescents. In one experimental study, 1,326 families with 12- to 14-year-old adolescents living in various parts of the United States were interviewed (Bauman & others, 2002). After the baseline interviews, participants were randomly assigned either to go through the Family Matters program (experimental group) or not to experience the program (control group) (Bauman & others, 2002).

The families assigned to the Family Matters program received four mailings of booklets. Each mailing was followed by a telephone call from a health educator to “encourage participation by all family members, answer any questions, and record information” (Bauman & others, 2002, pp. 36–37). The first booklet focused on the negative consequences of adolescent substance abuse to the family. The second emphasized “supervision, support, communication skills, attachment, time spent together, educational achievement, conflict reduction, and how well adolescence is understood.” The third booklet asked parents to list things they do that might inadvertently encourage their child’s use of tobacco or alcohol, identify rules that might influence the child’s use, and consider ways to monitor use. Then adult family members and the child met “to agree upon rules and sanctions related to adolescent use.” Booklet four dealt with “what the child can do to resist peer and media pressures for use.”

Two follow-up interviews with the parents and adolescents were conducted three months and one year after the experimental group had completed the program. Adolescents in the Family Matters program reported lower alcohol and cigarette use at three months and at one year after the program had been completed. Figure 8 shows the results for alcohol.

**FIGURE 8**

### YOUNG ADOLESCENTS’ REPORTS OF ALCOHOL USE IN THE FAMILY MATTERS PROGRAM.

Note that at baseline (before the program started) the young adolescents in the Family Matters program (experimental group) and their counterparts who did not go through the program (control group) reported approximately the same lifetime use of alcohol (slightly higher use by the experimental group). However, three months after the program ended, the experimental group reported lower alcohol use, and this reduction was still present one year after the program had ended, although at a reduced level.

The topics covered in the second booklet underscore the importance of parental influence earlier in development. For instance, staying actively involved and establishing an authoritative, as opposed to a neglectful, parenting style early in children’s lives will better ensure that children have a clear understanding of the parents’ level of support and expectations when the children reach adolescence.

was linked to a lower level of polysubstance use by adolescents (Chan & others, 2017). Also, in a recent intervention study, Latino parents who participated in a program that emphasized the importance of parental monitoring had adolescents with a lower level of drug use than a control group of adolescents whose parents did not participate in the program (Estrada & others, 2017). A research review concluded that the more frequently adolescents ate dinner with their families, the less likely they were to have substance abuse problems (Sen, 2010).

Along with parents, peers play a very important role in adolescent substance use (Cambron & others, 2018; Choukas-Bradley & Prinstein, 2016; Strong & others, 2017). For example, a large-scale national study of adolescents indicated that friends’ use of alcohol was a stronger influence on adolescent alcohol use than parental use (Deutsch, Wood, & Slutske, 2018).

Academic success is also a strong buffer for the emergence of drug problems in adolescence (Kendler & others, 2018). In one study, early educational achievement considerably reduced the likelihood that adolescents would develop drug problems (Bachman & others, 2008). But what can families do to educate themselves and their children and reduce adolescent drinking and smoking behavior? To find out, see *Connecting Through Research*.

## EATING DISORDERS

Let's now examine two eating problems—anorexia nervosa and bulimia nervosa—that are far more common in adolescent girls than boys.

**Anorexia Nervosa** Although most U.S. girls have been on a diet at some point, slightly less than 1 percent ever develop anorexia nervosa. **Anorexia nervosa** is an eating disorder that involves the relentless pursuit of thinness through starvation. It is a serious disorder that can lead to death (Pinhas & others, 2017; Westmoreland, Krantz, & Mehler, 2016). Four main characteristics apply to people suffering from anorexia nervosa: (1) weight below 85 percent of what is considered normal for their age and height; (2) an intense fear of gaining weight that does not decrease with weight loss; (3) a distorted image of their body shape (Revile, O'Connor, & Frampton, 2016), and (4) *amenorrhea* (lack of menstruation) in girls who have reached puberty.

Obsessive thinking about weight and compulsive exercise also are linked to anorexia nervosa (Simpson & others, 2013). Even when they are extremely thin, they see themselves as too fat (Cornelissen & others, 2015). They never think they are thin enough, especially in the abdomen, buttocks, and thighs. They usually weigh themselves frequently, often take their body measurements, and gaze critically at themselves in mirrors.

Anorexia nervosa typically begins in the early to middle adolescent years, often following an episode of dieting and some type of life stress (Fitzpatrick, 2012). It is about 10 times more likely to occur in females than males. When anorexia nervosa does occur in males, the symptoms and other characteristics (such as a distorted body image and family conflict) are usually similar to those reported by females who have the disorder (Ariceli & others, 2005).

Most anorexics are non-Latina White adolescent or young adult females from well-educated middle- and upper-income families and are competitive and high-achieving (Darcy, 2012). They set high standards, become stressed about not being able to reach the standards, and are intensely concerned about how others perceive them (Murray & others, 2017; Stice & others, 2017). Unable to meet these high expectations, they turn to something they can control: their weight. Offspring of mothers with anorexia nervosa are at risk for becoming anorexic themselves (Machado & others, 2014). Problems in family functioning are increasingly being found to be linked to the appearance of anorexia nervosa in adolescent girls (Dimitropoulos & others, 2018; Espie & Eisler, 2015), and research indicates that family therapy is often an effective treatment for adolescent girls with anorexia nervosa (Ganci & others, 2018; Hail & Le Grange, 2018; Hughes & others, 2018).

Biology and culture are involved in anorexia nervosa. Genes play an important role in anorexia nervosa (Meyre & others, 2018). Also, the physical effects of dieting may change neural networks and thus sustain the disordered pattern (Scaife & others, 2017). The thin fashion-model image in U.S. culture likely contributes to the incidence of anorexia nervosa (Cazzato & others, 2016). The media portray thin as beautiful in their choice of fashion models, whom many adolescent girls strive to emulate. Social media may also fuel the relentless pursuit of thinness by making it easier for anorexic adolescents to find each other online. A recent study found that having an increase in Facebook friends across two years was linked to enhanced motivation to be thin (Tiggemann & Slater, 2017).

**Bulimia Nervosa** Whereas anorexics control their weight by restricting food intake, most bulimics cannot. **Bulimia nervosa** is an eating disorder in which the individual consistently follows a binge-and-purge pattern. The bulimic goes on an eating binge and then purges by self-inducing vomiting or using a laxative. Although many people binge and purge occasionally and some experiment with it, a person is considered to have a serious bulimic disorder only if the episodes occur at least twice a week for three months (Castillo & Weiselberg, 2017).

As with anorexics, most bulimics are preoccupied with food, have a strong fear of becoming overweight, are depressed or anxious, and have a distorted body image (Murray & others, 2017; Stice & others, 2017). One study found that bulimics have difficulty controlling their emotions (Lavender & others, 2014). Like adolescents who are anorexic, bulimics are highly perfectionistic (Lampard & others, 2012). Unlike anorexics, individuals who binge and purge typically fall within a normal weight range, which makes bulimia more difficult to detect.

**anorexia nervosa** An eating disorder that involves the relentless pursuit of thinness through starvation.

**bulimia nervosa** An eating disorder in which the individual consistently follows a binge-and-purge pattern.

Approximately 1 to 2 percent of U.S. women are estimated to develop bulimia nervosa, and about 90 percent of bulimics are women. Bulimia nervosa typically begins in late adolescence or early adulthood. Many women who develop bulimia nervosa were somewhat overweight before the onset of the disorder, and the binge eating often began during an episode of dieting. As with anorexia nervosa, about 70 percent of individuals who develop bulimia nervosa eventually recover from the disorder (Agras & others, 2004). Drug therapy and psychotherapy have been effective in treating anorexia nervosa and bulimia nervosa (Agras & others, 2017). Cognitive behavior therapy has especially been helpful in treating bulimia nervosa (Abreu & Cangelli Filho, 2017; Hail & Le Grange, 2018; Peterson & others, 2017).

**LG4** Explain cognitive changes in adolescence.

Piaget's Theory

Adolescent Egocentrism

Information Processing

Adolescents' developing power of thought opens up new cognitive and social horizons. Let's examine some explanations of how their power of thought develops, beginning with Piaget's theory (1952).

### PIAGET'S THEORY

Jean Piaget proposed that around 7 years of age children enter the *concrete operational stage* of cognitive development. They can reason logically about concrete events and objects, and they make gains in their ability to classify objects and to reason about the relationships between classes of objects. Around age 11, according to Piaget, the fourth and final stage of cognitive development—the formal operational stage—begins.

**The Formal Operational Stage** What are the characteristics of the formal operational stage? Formal operational thought is more abstract than concrete operational thought. Adolescents are no longer limited to actual, concrete experiences as anchors for thought. They can conjure up make-believe situations, abstract propositions, and events that are purely hypothetical, and can try to reason logically about them.

The abstract quality of thinking during the formal operational stage is evident in the adolescent's verbal problem-solving ability. Whereas the concrete operational thinker needs to

see the concrete elements A, B, and C to be able to make the logical inference that if A = B and B = C, then A = C, the formal operational thinker can solve this problem merely through verbal presentation.

Another indication of the abstract quality of adolescents' thought is their increased tendency to think about thought itself. One adolescent commented, "I began thinking about why I was thinking what I was. Then I began thinking about why I was thinking about what I was thinking about what I was." If this sounds abstract, it is, and it characterizes the adolescent's enhanced focus on thought and its abstract qualities.

Accompanying the abstract nature of formal operational thought is thought full of idealism and possibilities, especially during the beginning of the formal operational stage, when assimilation dominates. Adolescents engage in extended speculation about ideal characteristics—qualities they desire in themselves and in others. Such thoughts often lead adolescents to compare themselves with others in regard to such ideal standards. And their thoughts are often fantasy flights into future possibilities.

At the same time that adolescents think more abstractly and idealistically, they also think more logically. Children are likely to solve problems through trial and error; adolescents begin to think more as a scientist thinks, devising plans to solve problems and systematically testing solutions. This type of problem solving requires **hypothetical-deductive reasoning**, which involves creating a hypothesis and deducing its implications, steps that provide ways to test the hypothesis. Thus, formal operational thinkers develop hypotheses about ways to solve problems and then systematically deduce the best path to follow to solve the problem.

**Evaluating Piaget's Theory** Researchers have challenged some of Piaget's ideas about the formal operational stage (Reyna & Zayas, 2014). Among their findings is that there is much more individual variation than Piaget envisioned: Only about one in three young adolescents is a formal operational thinker, and many American adults (and adults in other cultures) never become formal operational thinkers.

Furthermore, education in the logic of science and mathematics promotes the development of formal operational thinking. This point recalls a criticism of Piaget's theory that suggests culture and education exert stronger influences on cognitive development than Piaget maintained (Petersen & others, 2017; Wagner, 2018).

Piaget's theory of cognitive development has been challenged on other points as well. Children's cognitive development is not as stage-like as Piaget envisioned (Siegler, 2017; Wu & Scerif, 2018). Because some cognitive abilities have found to emerge earlier than Piaget thought, and others later, children do not appear to move neatly from one stage to another (Bauer, 2018; Liu & Spelke, 2017). Other evidence casting doubt on the stage notion is that children often show more understanding on one task than on another, similar task.

Despite these challenges to Piaget's ideas, we owe him a tremendous debt (Miller, 2016). Piaget was the founder of the present field of cognitive development, and he developed a long list of masterful concepts of enduring power and fascination: assimilation, accommodation, object permanence, egocentrism, conservation, and others. Psychologists also owe him the current vision of children as active, constructive thinkers. And they are indebted to him for creating a theory that has generated a huge volume of research on children's cognitive development (Miller, 2016).

Piaget also was a genius when it came to observing children. His careful observations demonstrated inventive ways to discover how children act on and adapt to their world. He showed us how children need to make their experiences fit their schemes yet simultaneously adapt their schemes to accommodate their experiences. And Piaget revealed how cognitive change is likely to occur if the context is structured to allow gradual movement to the next higher level.

## ADOLESCENT EGOCENTRISM

**Adolescent egocentrism** is the heightened self-consciousness of adolescents. David Elkind (1976) points out that adolescent egocentrism has two key components—the imaginary audience and personal fable. The **imaginary audience** is reflected in adolescents' belief that others are as

interested in them as they themselves are, as well as attention-getting behavior—attempts to be noticed, visible, and “on stage.” For example, an eighth-grade boy might walk into a classroom and think that all eyes are riveted on his spotty complexion. Adolescents sense that they are “on stage” in early adolescence, believing they are the main actors and all others are the audience.

According to Elkind, the **personal fable** is the part of adolescent egocentrism involving a sense of uniqueness and invincibility (or invulnerability). For example, 13-year-old Adrienne says this about herself: “No one understands me, particularly my parents. They have no idea of what I am feeling.” Adolescents’ sense of personal uniqueness makes them believe that no one can understand how they really feel. As part of their effort to retain a sense of personal uniqueness, adolescents might craft a story about the self that is filled with fantasy, immersing themselves in a world that is far removed from reality. Personal fables frequently show up in adolescent diaries.

Adolescents often have been portrayed as having a sense of invincibility or invulnerability. For example, during a conversation

with a girl who is the same age, 14-year-old Margaret says, “Are you kidding? I won’t get pregnant.” This sense of invincibility may lead adolescents to believe that they themselves are invulnerable to dangers and catastrophes (such as deadly car wrecks) that happen to other people. As a result, some adolescents engage in risky behaviors such as drag racing, drug use, suicide attempts, and having sexual intercourse without using contraceptives or barriers against STIs (Alberts, Elkind, & Ginsberg, 2007).

Might social media be an amplification tool for adolescent egocentrism? Earlier generations of adolescents did not have social media to connect with large numbers of people; instead, they connected with fewer people, either in person or via telephone. Might today’s teens be drawn to social media and its virtually unlimited friend base to express their imaginary audience and sense of uniqueness? One analysis concluded that amassing a large number of friends (audience) may help to validate adolescents’ perception that their life is on stage and everyone is watching them (Psychster Inc, 2010). A recent meta-analysis concluded that a greater use of social networking sites was linked to a higher level of narcissism (Gnambs & Appel, 2018).

What about having a sense of invulnerability—is that aspect of adolescent egocentrism as accurate as Elkind argues? An increasing number of research studies suggest that rather than perceiving themselves to be invulnerable, adolescents tend to portray themselves as vulnerable to experiencing a premature death (Reyna & Rivers, 2008). For example, in one study, 12- to 18-year-olds were asked about their chances of dying in the next year and prior to age 20 (Fischhoff & others, 2010). The adolescents greatly overestimated their chance of dying prematurely.

## INFORMATION PROCESSING

Deanna Kuhn (2009) identified some important characteristics of adolescents’ information processing and thinking. In her view, in the later years of childhood and continuing in adolescence, individuals approach cognitive levels that may or may not be achieved, in contrast to the largely universal cognitive levels that young children attain. By adolescence, considerable variation in cognitive functioning is present across individuals. This variability supports the argument that adolescents are producers of their own development to a greater extent than are children.

Kuhn (2009) further argues that the most important cognitive change in adolescence is improvement in *executive function*—an umbrella-like concept that consists of a number of higher-level cognitive processes linked to the development of the prefrontal cortex (Crone, Peters, & Steinbeis, 2018; Gerst & others, 2017). Executive function involves managing one’s thoughts to engage in goal-directed behavior and to exercise self-control (Bardikoff & Sabbagh, 2017; Knapp & Morton, 2017; Wiebe & Karbach, 2018). Our further coverage of executive function in adolescence focuses on cognitive control, decision making, and critical thinking.

**personal fable** The part of adolescent egocentrism that involves an adolescent's sense of uniqueness and invincibility (or invulnerability).

**Cognitive Control** Earlier you read about the increase in cognitive control that occurs in middle and late childhood. Recall that **cognitive control** involves effective control in a number of areas, including controlling attention, reducing interfering thoughts, and being cognitively flexible (Stewart & others, 2017). Cognitive control continues to increase in adolescence and emerging adulthood (Chevalier, Dauvier, & Blaye, 2018; Romer, Reyna, & Satterthwaite, 2017; Somerville, 2016).

Think about all the times adolescents need to engage in cognitive control, such as the following situations (Galinsky, 2010):

- making a real effort to stick with a task, avoiding interfering thoughts or environmental events, and instead doing what is most effective;
- stopping and thinking before acting to avoid blurting out something that a minute or two later they wished they hadn't said;
- continuing to work on something that is important but boring when there is something a lot more fun to do, inhibiting their behavior and doing the boring but important task, saying to themselves, "I have to show the self-discipline to finish this."

**Control Attention and Reduce Interfering Thoughts** Controlling attention is a key aspect of learning and thinking in adolescence and emerging adulthood (Lau & Waters, 2017; Mueller & others, 2017). Distractions that can interfere with attention in adolescence and emerging adulthood come from the external environment (other students talking while the student is trying to listen to a lecture, or the student turning on a laptop or tablet PC during a lecture and looking at a new friend request on Facebook, for example) or intrusive distractions from competing thoughts in the individual's mind. Self-oriented thoughts, such as worrying, self-doubt, and intense emotionally laden thoughts may especially interfere with focusing attention on thinking tasks (Gillig & Sanders, 2011).

**Be Cognitively Flexible** *Cognitive flexibility* involves being aware that options and alternatives are available and adapting to the situation (Buttelmann & Karbach, 2017; Wang, Ye, & Degol, 2017). Before adolescents and emerging adults adapt their behavior in a situation, they must be aware that they need to change their way of thinking and be motivated to do so (Gopnik & others, 2018). Having confidence in their ability to adapt their thinking to a particular situation, an aspect of *self-efficacy*, also is important in being cognitively flexible (Bandura, 2012).

**Decision Making** Adolescence is a time of increased decision making—which friends to choose; which person to date; whether to have sex, buy a car, go to college, and so on (Helm & Reyna, 2018; Meschkow & others, 2018; Reyna, 2018; Romer, Reyna, & Satterthwaite, 2017; Steinberg & others, 2018; van den Bos & Hertwig, 2017). How competent are adolescents at making decisions? Older adolescents are described as more competent than younger adolescents, who in turn are more competent than children (Keating, 1990). Compared with children, young adolescents are more likely to generate different options, examine a situation from a variety of perspectives, anticipate the consequences of decisions, and consider the credibility of sources.

Most people make better decisions when they are calm than when they are emotionally aroused. That may especially be true for adolescents, who have a tendency to be emotionally intense (Cohen & Casey, 2017). The same adolescent who makes a wise decision when calm may make an unwise decision when emotionally aroused. In the heat of the moment, emotions may overwhelm decision-making ability (Goddings & Mills, 2017).

The social context plays a key role in adolescent decision making (Breiner & others, 2018; Sherman, Steinberg, & Chein, 2018; Silva & others, 2017). For example, adolescents' willingness to make risky decisions is more likely to occur in contexts where substances and other temptations are readily available (Helm & Reyna, 2018; Meschkow & others, 2018; Reyna, 2018; Reyna & Rivers, 2008). Recent research reveals that the presence of peers in risk-taking situations increases the likelihood that adolescents will make risky decisions (Silva & others, 2017; Steinberg, 2015a, b). In a recent study,

What are some different aspects of cognitive control that can benefit adolescents' development?

adolescents took greater risks and showed stronger preference for immediate rewards when they were with three same-aged peers than when they were alone (Silva, Chein, & Steinberg, 2016).

To better understand adolescent decision making, Valerie Reyna and her colleagues (Helm & Reyna, 2018; Meschkow & others, 2018; Reyna, 2018; Reyna & Farley, 2006; Reyna & others, 2011, 2015, 2017; Romer, Reyna, & Satterthwaite, 2017) have proposed the **fuzzy-trace theory dual-process model**, which states that decision making is influenced by two cognitive systems—“verbatim” analytical (literal and precise) and gist-based intuition (simple bottom-line meaning)—which operate in parallel. Basing judgments and decisions on simple gist is viewed as more beneficial than analytical thinking to adolescents’ decision making. In this view, adolescents don’t benefit from engaging in reflective, detailed, higher-level cognitive analysis about a decision, especially in high-risk, real-world contexts where they would get bogged down in trivial detail. In such contexts, adolescents need to rely on their awareness that some circumstances are simply so dangerous that they must be avoided at all costs.

In risky situations it is important for an adolescent to quickly get the *gist*, or meaning, of what is happening and glean that the situation is a dangerous context, which can cue personal values that will protect the adolescent from making a risky decision (Helm, McCormick, & Reyna, 2018; Helm & Reyna, 2018; Meschkow & others, 2018; Rahimi-Golkhandan & others, 2017; Reyna, 2018; Reyna & others, 2011, 2015; Romer, Reyna, & Satterthwaite, 2017). An experiment showed that encouraging gist-based thinking about risks (along with factual information) reduced self-reported risk taking up to one year after exposure to the curriculum (Reyna & Mills, 2014). However, some experts on adolescent cognition argue that in many cases adolescents benefit from both analytical and experiential systems (Kuhn, 2009).

Adolescents need more opportunities to practice and discuss realistic decision making. Many real-world decisions on matters such as sex, drugs, and daredevil driving occur in an atmosphere of stress that includes time constraints and emotional involvement. One strategy for improving adolescent decision making is to provide more opportunities for them to engage in role playing and peer group problem solving.

**Critical Thinking** Adolescence is an important transitional period in the development of critical thinking (Keating, 1990). In one study of fifth-, eighth-, and eleventh-graders, critical thinking increased with age but still occurred in only 43 percent of even the eleventh-graders, and many adolescents showed self-serving biases in their reasoning.

If fundamental skills (such as literacy and math skills) are not developed during childhood, critical-thinking skills are unlikely to mature in adolescence. For the subset of adolescents who lack such fundamental skills, potential gains in adolescent thinking are unlikely. For other adolescents, however, cognitive changes that allow improved critical thinking in adolescence include the following: (1) increased speed, automaticity, and capacity of information processing, which free cognitive resources for other purposes; (2) more breadth of content knowledge in a variety of domains; (3) increased ability to construct new combinations of knowledge; and (4) a greater range and more spontaneous use of strategies or procedures for applying or obtaining knowledge, such as planning, considering alternatives, and cognitive monitoring.

**fuzzy-trace theory dual-process model**  
States that decision making is influenced by two systems—“verbatim” analytical (literal and precise) and gist-based intuition (simple bottom-line meaning)—which operate in parallel; in this model, gist-based intuition benefits adolescent decision making more than analytical thinking does.

Service Learning

What is the transition from elementary to middle or junior high school like? What are the characteristics of effective schools for adolescents? How can adolescents benefit from service learning?

### THE TRANSITION TO MIDDLE OR JUNIOR HIGH SCHOOL

The first year of middle school or junior high school can be difficult for many students (Wigfield, Rosenzweig, & Eccles, 2017; Wigfield, Tonks, & Klauda, 2016). For example, in one study of the transition from sixth grade in an elementary school to seventh grade in a junior high school, adolescents' perceptions of the quality of their school life plunged in the seventh grade (Hirsch & Rapkin, 1987). Compared with their earlier feelings as sixth-graders, the seventh-graders were less satisfied with school, were less committed to school, and liked their teachers less. The drop in school satisfaction occurred regardless of how academically successful the students were. The transition to middle or junior high school is less stressful when students have positive relationships with friends and go through the transition in team-oriented schools where 20 to 30 students take the same classes together (Hawkins & Berndt, 1985).

The transition to middle or junior high school takes place at a time when many changes—in the individual, in the family, and in school—are occurring simultaneously (Wigfield & others, 2015; Wigfield, Rosenzweig, & Eccles, 2017; Wigfield, Tonks, & Klauda, 2016). These changes include puberty and related concerns about body image; the emergence of at least some aspects of formal operational thought and changes in social cognition; increased responsibility and decreased dependency on parents; change to a larger, more impersonal school structure; change from one teacher to many teachers and from a small, homogeneous set of peers to a larger, more heterogeneous set of peers; and an increased focus on achievement and performance. Moreover, when students make the transition to middle or junior high school, they experience the **top-dog phenomenon**, moving from being the oldest, biggest, and most powerful students in the elementary school to being the youngest, smallest, and least powerful students in the middle or junior high school.

The transition to middle or junior high school also can have positive aspects. Students are more likely to feel grown up, have more subjects from which to select, have more opportunities to spend time with peers and locate compatible friends, and enjoy increased independence from direct parental monitoring. They also may be more challenged intellectually by academic work.

The transition from elementary to middle or junior high school occurs at the same time as a number of other developmental changes. *What are some of these other developmental changes?*

### EFFECTIVE SCHOOLS FOR YOUNG ADOLESCENTS

Critics argue that middle and junior high schools should offer activities that reflect a wide range of individual differences in biological and psychological development among young adolescents. In 1989 the Carnegie Corporation issued an extremely negative evaluation of U.S. middle schools. It concluded that most young adolescents attended massive, impersonal schools; were taught from irrelevant curricula; trusted few adults in school; and lacked access to health care and counseling. It recommended that the nation develop smaller "communities" or "houses" to lessen the impersonal nature of large middle schools, have lower student-to-counselor ratios (10 to 1 instead of several hundred to 1), involve parents and community leaders in schools, develop new curricula, have teachers team teach in more flexibly designed curriculum blocks that integrate several disciplines, boost students' health and fitness with more in-school programs, and help students who need public health care to get it. Twenty years later, experts are still finding that middle schools throughout the nation need a major redesign if they are to be effective in educating adolescents (Roeser, 2016; Wigfield & others, 2015).

## Katherine McMillan Culp, Research Scientist at an Educational Center

Katherine McMillan Culp wanted mainly to live in New York City when she graduated from college and became a receptionist at a center that focused on children and technology. More than 20 years later she is leading research projects at the center (Center for Children and Technology). Not long after her receptionist job, she combined work at the center with graduate school at Columbia University. Culp became especially interested in how content and instruction can best be created to link with the developmental level of children and adolescents.

Today she holds the position of principal research scientist at Education Development Center, directing a number of projects. One

of her main current interests is middle school students' science learning. In this area, she consults with game designers, teachers, and policy makers to improve their understanding of how adolescents think and learn.

Her advice to anyone wanting to do this type of work outside of academia is to get the best education and training possible, then become connected with schools, work with teachers, and obtain experience related to practical problems involved with schools and learning (Culp, 2012).

## HIGH SCHOOL

Just as there are concerns about U.S. middle school education, so are there concerns about U.S. high school education (Kitsantas & Cleary, 2016). A recent analysis indicated that only 25 percent of U.S. high school graduates have the academic skills to succeed in college (Bill & Melinda Gates Foundation, 2017). Not only are many high school graduates poorly prepared for college, they also are poorly prepared for the demands of the modern, high-performance workplace (Bill & Melinda Gates Foundation, 2018).

Critics stress that in many high schools expectations for success and standards for learning are too low. Critics also argue that too often high schools foster passivity and that schools should create a variety of pathways for students to achieve an identity. Many students graduate from high school with inadequate reading, writing, and math skills—including many who go on to college and must enroll in remediation classes there. Other students drop out of high school and do not have skills that will allow them to obtain decent jobs, much less to be informed citizens.

The transition to high school can have problems just as the transition to middle school does. For example, high schools are often even larger, more bureaucratic, and more impersonal than middle schools are; there isn't much opportunity for students and teachers to get to know each other, which can lead to distrust; and teachers rarely make content relevant to students' interests (Eccles & Roeser, 2016). Such experiences likely undermine the motivation of students.

Robert Crosnoe's (2011) book, *Fitting In, Standing Out*, highlighted another major problem with U.S. high schools: how the negative social aspects of adolescents' lives undermine their academic achievement. In his view, adolescents become immersed in complex peer group cultures that demand conformity. High school is supposed to be about getting an education, but for many youth it is about navigating the social worlds of peer relations that may or may not value education and academic achievement. Adolescents who fail to fit in, especially those who are obese or gay, become stigmatized. Crosnoe recommends increased school counseling services, expanded extracurricular activities, and improved parental monitoring to reduce such problems (Crosnoe & Benner, 2015).

**Dropout Rates** Yet another concern about U.S. high schools involves students dropping out of school. In the last half of the twentieth century and the first decade of the twenty-first century, U.S. high school dropout rates declined (National Center for Education Statistics, 2017). In the 1940s, more than half of U.S. 16- to 24-year-olds had dropped out of school; by 2015, this figure had decreased to 5.9 percent. The dropout rate of Latino adolescents remains high, although it has been decreasing considerably in the twenty-first century (from 27.8 percent in 2000 to 9.2 percent in 2016). The lowest dropout rate in 2015 was for Asian American adolescents (2.1 percent), followed by non-Latino White adolescents (4.6 percent).

African American adolescents (6.5 percent), and Latino adolescents (9.2 percent) (National Center for Education Statistics, 2017).

National data on Native American adolescents are inadequate because statistics have been collected sporadically and/or from small samples. However, there are some indications that Native American adolescents may have the highest school dropout rate.

Gender differences have characterized U.S. dropout rates for many decades, but they have been narrowing in recent years. In 2015, the dropout rate for males was 6.3 percent and for females it was 5.4 percent (National Center for Education Statistics, 2017).

The average U.S. high school dropout rates just described mask some very high dropout rates in low-income areas of inner cities. For example, in cities such as Detroit, Cleveland, and Chicago, dropout rates are higher than 50 percent. Also, the percentages cited earlier are for 16- to 24-year-olds. When dropout rates are calculated in terms of students who do not graduate from high school within four years, the percentage of students who drop out is also much higher. Thus, in considering high school dropout rates, it is important to examine age, the number of years it takes to complete high school, and various contexts including ethnicity, gender, and school location.

Students drop out of school for many reasons (Dupere & others, 2015). In one study, almost 50 percent of the dropouts cited school-related reasons for leaving school, such as not liking school or being expelled or suspended (Rumberger, 1983). Twenty percent of the dropouts (but 40 percent of the Latino students) cited economic reasons for leaving school. One-third of the female students dropped out for personal reasons such as pregnancy or marriage.

According to a research review, the most effective programs to discourage dropping out of high school provide early intervention for reading problems, tutoring, counseling, and mentoring (Lehr & others, 2003). Clearly, then, early detection of children's school-related difficulties and getting children engaged with school in positive ways are important strategies for reducing the dropout rate (Crosnoe, Bonazzo, & Wu, 2015).

One program that has been very effective in reducing school dropout rates is "I Have a Dream" (IHAD), an innovative, comprehensive, long-term dropout prevention program administered by the National "I Have a Dream" Foundation in New York ("I Have a Dream" Foundation, 2017). It has grown to encompass more than 180 projects in 64 cities and 28 states plus Washington, DC, and New Zealand, serving more than 16,000 children ("I Have a Dream" Foundation, 2017). Local IHAD projects around the country "adopt" entire grades (usually the third or fourth) from public elementary schools, or corresponding age cohorts from public housing developments. These children—"Dreamers"—are then provided with a program of academic, social, cultural, and recreational activities throughout their elementary, middle school, and high school years. Evaluations of IHAD programs have found improvements in grades, test scores, and school attendance, as well as a reduction in behavioral problems among Dreamers (Davis, Hyatt, & Arrasmith, 1998).

## EXTRACURRICULAR ACTIVITIES

Adolescents in U.S. schools usually can choose from a wide array of extracurricular activities in addition to their academic courses. These adult-sanctioned activities typically occur during the after-school hours and can be sponsored either by the school or by the community. They include such diverse activities as sports, academic clubs, band, drama, and math clubs. Researchers have found that participation in extracurricular activities is linked to higher grades, greater school engagement, less likelihood of dropping out of school, improved probability of going to college, higher self-esteem, and lower rates of depression, delinquency, and substance abuse (Denault & Guay, 2017; Simpkins, Fredricks, & Eccles, 2015; Wigfield & others, 2015). A recent study revealed that immigrant adolescents who participated in extracurricular activities improved their

An important educational goal is to increase the high school graduation rate of Native youth. An excellent strategy to accomplish this goal is high quality early childhood educational programs such as this one at St. Bonaventure Indian School on the Navajo Nation in Thoreau, New Mexico.

academic achievement and increased their school engagement (Camacho & Fuligni, 2015). Adolescents gain more benefit from a breadth of extracurricular activities than from focusing on a single extracurricular activity.

Of course, the quality of the extracurricular activities matters (Simpkins, Fredricks, & Eccles, 2015). High-quality extracurricular activities that are likely to promote positive adolescent development provide competent, supportive adult mentors; opportunities for increasing school connectedness; challenging and meaningful activities; and opportunities for improving skills.

## SERVICE LEARNING

**Service learning** is a form of education that promotes social responsibility and service to the community. In service learning, adolescents engage in activities such as tutoring, helping older adults, working in a hospital, assisting at a child-care center, or cleaning up a vacant lot to make a play area. An important goal of service learning is that adolescents become less self-centered and more strongly motivated to help others (Hart, Goel, & Atkins, 2017; Hart & van Goethem, 2017; Hart & others, 2017; Kackar-Cam & Schmidt, 2014). Service learning is often more effective when two conditions are met (Nucci, 2006): (1) giving students some degree of choice in the service activities in which they participate, and (2) providing students opportunities to reflect about their participation.

Researchers have found that service learning benefits adolescents in a number of ways (Hart & others, 2017). Improvements in adolescent development related to service learning include higher grades in school, increased goal setting, higher self-esteem, and a greater sense of being able to make a difference for others (Hart & van Goethem, 2017). Also, one study revealed that adolescents' volunteer activities provided opportunities to explore and reason about moral issues (van Goethem & others, 2012).

## topical connections *looking forward*

From 18 to 25 years of age, individuals make a transition from adolescence to adulthood. This transitional period, called emerging adulthood, is characterized by identity exploration, instability, and awareness of possibilities. Individuals often reach the peak of their physical skills between 19 and 26 years of age, followed by declining physical development during the early thirties. Cognitive development becomes more pragmatic and realistic, as well as more reflective and relativistic. Work becomes a more central aspect of individuals' lives.

## Physical and Cognitive Development in Adolescence

### 1 The Nature of Adolescence

LG1

Discuss the nature of adolescence.

- Many stereotypes of adolescents are too negative. Most adolescents today successfully negotiate the path from childhood to adulthood. However, too many of today's adolescents are not provided with adequate opportunities and support to become competent adults. It is important to view adolescents as a heterogeneous group because different portraits of adolescents emerge, depending on the particular set of adolescents being described.
- Social policy regarding adolescents too often has focused on health-compromising behaviors and not enough on strength-based approaches. Adolescents need more caring adults in their lives.

### 2 Physical Changes

Puberty

The Brain

Adolescent Sexuality

LG2

Describe the changes involved in puberty, as well as changes in the brain and sexuality during adolescence.

- Puberty is a period of rapid physical maturation involving hormonal and bodily changes that occur primarily during early adolescence. Determinants of pubertal timing include nutrition, health, and heredity. The pubertal growth spurt begins at an average age of 9 years for girls and 11 for boys, reaching a peak at 11½ for girls and 13½ for boys. Individual variation in pubertal changes is substantial.
- Adolescents show considerable interest in their body image, with girls having more negative body images than boys do. For boys, early maturation brings benefits, at least during early adolescence. Early-maturing girls are vulnerable to a number of risks.
- Changes in the brain during adolescence involve the thickening of the corpus callosum and a gap in maturation between the limbic system and the prefrontal cortex, which functions in reasoning and self-regulation.
- Adolescence is a time of sexual exploration and sexual experimentation. Having sexual intercourse in early adolescence is associated with negative developmental outcomes.
- Contraceptive use by adolescents is increasing. About one in four sexually experienced adolescents acquires a sexually transmitted infection (STI). The adolescent pregnancy rate is higher in the United States than in other industrialized nations, but the U.S. rate of adolescent pregnancy has been decreasing in recent years.

### 3 Issues in Adolescent Health

Adolescent Health

Substance Use and Abuse

Eating Disorders

LG3

Identify adolescent problems related to health, substance use and abuse, and eating disorders.

- Adolescence is a critical juncture in health because many of the factors related to poor health habits and early death in the adult years begin during adolescence. Poor nutrition, lack of exercise, and inadequate sleep are concerns. The three leading causes of death in adolescence are unintentional injuries, homicide, and suicide.
- Despite recent declines, the United States has one of the highest rates of adolescent illicit drug use of any industrialized nation. Alcohol abuse is a major adolescent problem, although its rate has been dropping in recent years, as has the rate of cigarette smoking. Parents, peers, social support, and educational success play important roles in determining whether adolescents take drugs.
- Eating disorders have increased in adolescence, along with the percentage of adolescents who are overweight. Two eating disorders that may emerge in adolescence are anorexia nervosa and bulimia nervosa. Anorexia nervosa typically starts in the early to middle adolescent years following a dieting episode and involves the relentless pursuit of thinness through starvation. Bulimia nervosa involves a binge-and-purge pattern, and bulimics (unlike anorexics) typically fall within a normal weight range.

## 4 Adolescent Cognition

Piaget's Theory

Adolescent Egocentrism

Information Processing

LG4

Explain cognitive changes in adolescence.

- During the formal operational stage, Piaget's fourth stage of cognitive development, thinking becomes more abstract, idealistic, and logical than during the concrete operational stage. However, many adolescents are not formal operational thinkers but are consolidating their concrete operational thought.
- Elkind describes adolescent egocentrism as the heightened self-consciousness of adolescents that consists of two parts: the imaginary audience and the personal fable. Recent research questions whether adolescents perceive themselves to be invulnerable.
- Adolescence is characterized by a number of advances in executive function. Cognitive control involves effective control and flexible thinking in a number of areas, including controlling attention, reducing interfering thoughts, remaining cognitively flexible, making decisions, and thinking critically.

## 5 Schools

The Transition to Middle or Junior High School

Effective Schools for Young Adolescents

High School

Extracurricular Activities

Service Learning

LG5

Summarize some key aspects of how schools influence adolescent development.

- The transition to middle or junior high school coincides with many social, familial, and individual changes in the adolescent's life, and this transition is often stressful. One source of stress is the move from the top-dog position to the lowest position in school.
- Some critics argue that a major redesign of U.S. middle schools is needed. Critics say that U.S. high schools foster passivity and do not develop students' academic skills adequately. Characteristics of effective schools include lower student-to-counselor ratios, involvement of parents and community leaders in schools, team teaching, and efforts to boost students' health and fitness.
- A number of strategies have been proposed for improving U.S. high schools, including raising expectations and providing better support. The overall high school dropout rate declined considerably in the last half of the twentieth century, but the dropout rates among Latino and Native American youth remain very high.
- Participation in extracurricular activities is associated with positive academic and psychological outcomes. Adolescents benefit from participating in a variety of extracurricular activities; the quality of the activities also matters.
- Service learning, a form of education that promotes social responsibility and service to the community, has been linked with positive benefits for adolescents such as higher grades, increased goal setting, and improved self-esteem.

# SOCIOEMOTIONAL DEVELOPMENT IN ADOLESCENCE

## chapter outline

### ① The Self, Identity, and Religious/Spiritual Development

**Learning Goal 1** Discuss self, identity, and religious/spiritual development in adolescence.

- Self-Esteem
- Identity
- Religious/Spiritual Development

### ② Families

**Learning Goal 2** Describe changes that take place in adolescents' relationships with their parents.

- Parental Monitoring and Information Management
- Autonomy and Attachment
- Parent-Adolescent Conflict

### ③ Peers

**Learning Goal 3** Characterize the changes that occur in peer relationships during adolescence.

- Friendships
- Peer Groups
- Dating and Romantic Relationships

### ④ Culture and Adolescent Development

**Learning Goal 4** Explain how culture influences adolescent development.

- Cross-Cultural Comparisons
- Socioeconomic Status and Poverty
- Ethnicity
- Media Use and Screen Time

### ⑤ Adolescent Problems

**Learning Goal 5** Identify adolescent problems in socioemotional development and strategies for helping adolescents with problems.

- Juvenile Delinquency
- Depression and Suicide
- The Interrelation of Problems and Successful Prevention/Intervention Programs

## The mayor of the city says she is “everywhere.”

She persuaded the city’s school committee to consider ending the practice of locking tardy students out of their classrooms. She also swayed a neighborhood group to support her proposal for a winter jobs program. According to one city councilman, “People are just impressed with the power of her arguments and the sophistication of the argument” (Silva, 2005, pp. B1, B4). Who is she? Jewel E. Cash, age 16.

Jewel was raised in one of Boston’s housing projects by her mother, a single parent. As a high school student at Boston Latin Academy, she was a member of the Boston Student Advisory Council, mentored children, volunteered at a women’s shelter, managed and danced in two troupes, and was a member of a neighborhood watch group—among other activities.

Jewel told an interviewer from the *Boston Globe*, “I see a problem and I say, ‘How can I make a difference?’ . . . I can’t take on the world, even though I can try. . . . I’m moving forward but I want to make sure I’m bringing people with me” (Silva, 2005, pp. B1, B4). Jewel is far from typical, but her activities illustrate that cognitive and socioemotional development allows adolescents to be capable, effective individuals. As a young adult, Jewel now works with a public consulting group and has continued helping others as a mentor and community organizer.

### topical connections *looking back*

In middle and late childhood, development of self-understanding and understanding others becomes more sophisticated, emotional understanding improves, and moral reasoning advances. In Erikson’s view, children now are in the industry versus inferiority stage, with their industry expressed as an interest in building things and figuring out how things work. Children now spend more time with peers, but parents continue to play important roles in their development, especially in guiding their academic achievement and managing their opportunities. Peer status and friendship become more important in children’s peer relations, and school takes on a stronger academic focus.

# preview

Significant changes characterize socioemotional development in adolescence. These changes include increased efforts to understand themselves and to find their identity. Changes also occur in the social contexts of adolescents' lives, with transformations occurring in relationships with families and peers in cultural contexts. Adolescents also may develop socioemotional problems such as delinquency and depression.

## 1 The Self, Identity, and Religious/Spiritual Development

LG1

Discuss self, identity, and religious/spiritual development in adolescence.

Self-Esteem

Identity

Religious/Spiritual Development

Jewel's confidence and positive identity sound at least as impressive as her activities. This section examines how adolescents develop characteristics like these. How well did you understand yourself during adolescence, and how did you acquire the stamp of your identity? Is your identity still developing?

### SELF-ESTEEM

Recall that self-esteem is the overall way we evaluate ourselves. Controversy characterizes the extent to which self-esteem changes during adolescence and whether there are gender differences in adolescents' self-esteem (Harter, 2006, 2012, 2013, 2016). In one study, both boys and girls had particularly high self-esteem in childhood, but their self-esteem dropped considerably during adolescence (Robins & others, 2002). In this study, the self-esteem of girls declined more than the self-esteem of boys during adolescence.

Does self-esteem in adolescence foreshadow adjustment and competence in adulthood? A New Zealand longitudinal study assessed the self-esteem of adolescents at 11, 13, and 15 years of age and then assessed the adjustment and competence of the same individuals when they were 26 years old (Trzesniewski & others, 2006). The results revealed that adults with poorer mental and physical health, worse economic prospects, and higher levels of criminal behavior were more likely to have had low self-esteem in adolescence than their better-adjusted, more competent adult counterparts. Also, a recent study found that low self-esteem in early adolescence predicted depressive symptoms in late adolescence and emerging adulthood (Messelink, Van Roekel, & Oldehinkel, 2018).

Some critics argue that developmental changes and gender differences in self-esteem during adolescence have been exaggerated (Harter, 2006, 2012, 2013, 2016). Despite the differing results and interpretations, the self-esteem of girls is likely to decline at least somewhat during early adolescence.

Why would the self-esteem of girls decline during early adolescence? One explanation points to girls' negative body images during pubertal change. Another explanation involves the greater interest young adolescent girls take in social relationships and society's failure to reward that interest (Impett & others, 2008).

Self-esteem reflects perceptions that do not always match reality (Jordan & Zeigler-Hill, 2013). An adolescent's self-esteem might indicate a perception about whether he or she is intelligent and attractive, for example, but that perception may not be accurate. Thus, high self-esteem may refer to accurate, justified perceptions of one's worth as a person and one's successes and accomplishments, but it can also indicate an arrogant, grandiose, unwarranted sense of superiority over others. In the same manner, low self-esteem may suggest either an accurate perception of one's shortcomings or a distorted, even pathological insecurity and inferiority.

**Narcissism** refers to a self-centered and self-concerned approach toward others. Typically, narcissists are unaware of their actual self and how others perceive them (Miller & others, 2017; Thomaes & Brummelman, 2016). This lack of awareness contributes to their adjustment problems. Narcissists are excessively self-centered and self-congratulatory, viewing their own needs and desires as paramount (Kealy & others, 2017).

What are some important dimensions of identity?  
©Art Grafts/The Image Bank/Getty Images

Are today's adolescents and emerging adults more self-centered and narcissistic than their counterparts in earlier generations? Research by Jean Twenge and her colleagues (2008a, b) indicated that compared with Baby Boomers who were surveyed in 1975, twelfth-graders surveyed in 2006 were more self-satisfied overall and far more confident that they would be very good employees, mates, and parents. However, other large-scale analyses have revealed no increase in high school and college students' narcissism from the 1980s through the first decade of the twenty-first century (Roberts, Edmonds, & Grijalva, 2010; Trzesniewski & Donnellan, 2010; Trzesniewski, Donnellan, & Robins, 2008a, b, 2013).

## IDENTITY

Who am I? What am I all about? What am I going to do with my life? What is different about me? How can I make it on my own? These questions reflect the search for an identity. By far the most comprehensive and provocative theory of identity development is Erik Erikson's. In this section, we examine his views on identity. We also discuss contemporary research on how identity develops and how social contexts influence that development.

**What Is Identity?** When identity has been conceptualized and researched, it typically is explored in a broad sense. However, identity is a self-portrait that is composed of many pieces and domains:

- The career and work path the person wants to follow (vocational/career identity)
- Whether the person is conservative, liberal, or middle-of-the-road (political identity)
- The person's spiritual beliefs (religious identity)
- Whether the person is single, married, divorced, and so on (relationship identity)
- The extent to which the person is motivated to achieve and is intellectually oriented (achievement, intellectual identity)
- Whether the person is heterosexual, homosexual, bisexual, or transgendered (sexual identity)
- Which part of the world or country a person is from and how intensely the person identifies with his or her cultural heritage (cultural/ethnic identity)
- The kinds of things a person likes to do, which can include sports, music, hobbies, and so on (interests)
- The individual's personality characteristics, such as being introverted or extroverted, anxious or calm, friendly or hostile, and so on (personality)
- The individual's body image (physical identity)

Currently, too little research attention has been given to developmental changes in specific domains of identity (Galliher, McLean, & Syed, 2017; Negru-Subirica & Pop, 2018).

Synthesizing the identity components can be a long and drawn-out process, with many negations and affirmations of various roles and facets (Hatano, Sugimura, & Schwartz, 2018; Maher, Winston, & Ur, 2017; Meeus, 2017; Negru-Subirica & Pop, 2018; Reece & others, 2017). Identity development takes place in bits and pieces. Decisions are not made once and for all, but have to be made again and again. Identity development does not happen neatly, and it does not happen cataclysmically (Adler & others, 2017; Galliher, McLean, & Syed, 2017; Hatano, Sugimura, & Schwartz, 2018; van Doeselaar & others, 2018).

**Erikson's View** It was Erik Erikson (1950, 1968) who first understood how central questions about identity are to understanding adolescent development. Recall that Erikson's fifth developmental stage, which individuals experience during adolescence, is *identity versus identity confusion*. During this time, said Erikson, adolescents are faced with deciding who they are, what they are all about, and where they are going in life.

The search for an identity during adolescence is aided by a *psychosocial moratorium*, which is Erikson's term for the gap between childhood security and adult autonomy. During this period, society leaves adolescents relatively free of responsibilities and able to try out different identities. Adolescents experiment with different roles and personalities. They may want to pursue one career one month (lawyer, for example) and another career the next month (doctor, actor, teacher, social worker, or astronaut, for example). They may dress neatly one day,

sloppily the next. This experimentation is a deliberate effort on the part of adolescents to find out where they fit in the world. Most adolescents eventually discard undesirable roles.

Youth who successfully cope with conflicting identities emerge with a new sense of self that is both refreshing and acceptable. Adolescents who do not successfully resolve this identity crisis suffer what Erikson calls identity confusion. The confusion takes one of two courses: Individuals either withdraw, isolating themselves from peers and family, or they immerse themselves in the world of peers and lose their identity in the crowd.

**Developmental Changes** Although questions about identity may be especially important during adolescence and emerging adulthood, identity formation neither begins nor ends during these years. What is important about identity development in late adolescence and emerging adulthood is that for the first time, physical development, cognitive development, and socioemotional development advance to the point at which the individual can sort through and synthesize childhood identities and identifications to construct a viable path toward adult maturity.

How do individual adolescents go about the process of forming an identity? Eriksonian researcher James Marcia (1980, 1994) reasons that Erikson's theory of identity development contains four statuses of identity, or ways of resolving the identity crisis: identity diffusion, identity foreclosure, identity moratorium, and identity achievement. What determines an individual's identity status? Marcia classifies individuals based on the existence or extent of their crisis or commitment (see Figure 1). **Crisis** is defined as a period of identity development during which the individual is exploring alternatives. Most researchers use the term *exploration* rather than *crisis*. **Commitment** is personal investment in identity.

The four statuses of identity are described below:

- **Identity diffusion** is the status of individuals who have not yet experienced a crisis or made any commitments. Not only are they undecided about occupational and ideological choices, they are also likely to show little interest in such matters.
- **Identity foreclosure** is the status of individuals who have made a commitment but not experienced a crisis. This occurs most often when parents hand down commitments to their adolescents, usually in an authoritarian way, before adolescents have had a chance to explore different approaches, ideologies, and vocations on their own.
- **Identity moratorium** is the status of individuals who are in the midst of a crisis but whose commitments are either absent or are only vaguely defined.
- **Identity achievement** is the status of individuals who have undergone a crisis and made a commitment.

Some critics argue that the identity status approach does not produce enough depth in understanding identity development (Klimstra & others, 2017). One way that researchers are now examining identity changes in depth is to use a *narrative approach*. This involves asking individuals to tell their life stories and evaluate the extent to which their stories are meaningful and integrated (Adler & others, 2017; Maher, Winston, & Ur, 2017; McLean & others, 2017). The term *narrative identity* "refers to the stories people construct and tell about themselves to define who they are for themselves and others. Beginning in adolescence and young adulthood, our narrative identities are the stories we live by" (McAdams, Josselson, & Lieblich, 2006, p. 4).

Position on Occupation and Ideology	Identity Status				
	Identity Diffusion	Identity Foreclosure	Identity Moratorium	Identity Achievement	
Crisis	Absent	Absent	Present	Present	
Commitment	Absent	Present	Absent	Present	

**FIGURE 1**

**MARCA'S FOUR STATUSES OF IDENTITY.** According to Marcia, an individual's status in developing an identity can be categorized as identity diffusion, identity foreclosure, identity moratorium, or identity achievement. The status depends on the presence or absence of (1) a crisis or exploration of alternatives and (2) a commitment to an identity. *What is the identity status of most young adolescents?*

## developmental connection

### Erikson's Theory

Erikson's stage for middle and late childhood is industry versus inferiority and for early adulthood is intimacy versus isolation. Connect to "Socioemotional Development in Middle and Late Childhood" and "Socioemotional Development in Early Adulthood."

Once formed, an identity furnishes individuals with a historical sense of who they have been, a meaningful sense of who they are now, and a sense of who they might become in the future.

**crisis** Marcia's term for a period of identity development during which the adolescent is exploring alternatives.

**commitment** Marcia's term for the part of identity development in which adolescents show a personal investment in identity.

**identity diffusion** Marcia's term for the status of individuals who have not yet experienced a crisis (explored meaningful alternatives) or made any commitments.

**identity foreclosure** Marcia's term for the status of individuals who have made a commitment but have not experienced a crisis.

**identity moratorium** Marcia's term for the status of individuals who are in the midst of a crisis, but their commitments are either absent or vaguely defined.

**identity achievement** Marcia's term for the status of individuals who have undergone a crisis and have made a commitment.

How does identity change in emerging adulthood?

©Tom Grill/Getty Images

**Emerging Adulthood and Beyond** There is a growing consensus that key changes in identity are more likely to take place in emerging adulthood (18 to 25 years of age) or later than during adolescence (Galliher, McLean, & Syed, 2017; Layland, Hill, & Nelson, 2018). College upperclassmen are more likely to be identity achieved than college freshmen or high school students. Many young adolescents, on the other hand, are identity diffused. One study found that as individuals matured from early adolescence to emerging adulthood, they increasingly pursued in-depth exploration of their identity (Klimstra & others, 2010).

Why might college produce some key changes in identity? Increased complexity in the reasoning skills of college students, combined with a wide range of new experiences that highlight contrasts between home and college and between themselves and others, stimulate them to reach a higher level of integrating various dimensions of their identity (Phinney, 2008). College contexts serve as a virtual “laboratory” for identity development through such experiences as diverse coursework and exposure to peers from diverse backgrounds. Also, one of emerging adulthood’s key themes is not

having many social commitments, which gives individuals considerable independence in developing a life path (Arnett, 2015).

Resolution of the identity issue during adolescence and emerging adulthood does not mean that identity will be stable throughout the remainder of life (Demiray & others, 2018). Many individuals who develop positive identities follow what are called “MAMA” cycles; that is, their identity status changes from moratorium to achievement to moratorium to achievement (Marcia, 1994). These cycles may be repeated throughout life (Francis, Fraser, & Marcia, 1989). Marcia (2002) points out that the first identity is just that—it is not, and should not be expected to be, the final product.

**Cultural and Ethnic Identity** Identity developments is influenced by culture and ethnicity (Kiang & Witkow, 2018; McLean & others, 2018; Umana-Taylor & others, 2018; Yoon & others, 2017). Most research on identity development has historically been based on data obtained from adolescents and emerging adults in the United States and Canada, especially those who are non-Latino Whites (Schwartz & others, 2012, 2015a, b). Many of these individuals have grown up in cultural contexts that value individual autonomy. However, in many countries around the world, adolescents and emerging adults have grown up influenced by a collectivist emphasis on fitting in with the group and connecting with others (Schwartz & others, 2015a, b). The collectivist emphasis is especially prevalent in East Asian countries such as China. Researchers have found that self-oriented identity exploration may not be the main process through which identity achievement is attained in East Asian countries (Schwartz & others, 2015a, b). Rather, East Asian adolescents and emerging adults may develop their identity through identification with and imitation of others in their cultural group (Bosma & Kunnen, 2001).

Identity development may take longer in some countries than in others (Schwartz & others, 2015a, b). For example, research indicates that Italian youth may postpone significant identity exploration beyond adolescence and emerging adulthood, not settling on an identity until their mid-to late twenties (Crocetti, Rabaglietti, & Sica, 2012). This delayed identity development is strongly influenced by many Italian youth living at home with their parents until 30 years of age and older.

Seth Schwartz and his colleagues (2012, 2015a, b) has pointed out that while everyone identifies with a particular “culture,” many individuals in cultural majority groups take their cultural identity for granted. Thus, many adolescents and emerging adults in the cultural majority of non-Latino Whites in the United States likely don’t spend much time thinking of themselves as “White American.” However, for many adolescents and emerging adults who have grown up within an ethnic minority group in the United States or emigrated from another country, cultural dimensions likely are an important aspect of their identity.

Throughout the world, ethnic minority groups have struggled to maintain their ethnic identities while blending in with the dominant culture (Erikson, 1968).

One adolescent girl, 16-year-old Michelle Chin, made these comments about ethnic identity development: “My parents do not understand that teenagers need to find out who they are, which means a lot of experimenting, a lot of mood swings, a lot of emotions and awkwardness. Like any teenager, I am facing an identity crisis. I am still trying to figure out whether I am a Chinese American or an American with Asian eyes.”

**Ethnic identity** is an enduring aspect of the self that includes a sense of membership in an ethnic group, along with the attitudes and feelings related to that membership (Douglass & Umana-Taylor, 2017; Meeus, 2017; Umana-Taylor & Douglass, 2017; Umana-Taylor & others, 2018; White & others, 2018; Yoon & others, 2017). Most adolescents from ethnic minority groups develop a *bicultural identity*. That is, they identify in some ways with their ethnic group and in other ways with the majority culture (Cooper, Gonzales, & Wilson, 2015).

For ethnic minority individuals, adolescence and emerging adulthood are often special junctures in their development (Butler-Barnes & others, 2018; Douglass & Umana-Taylor, 2017; Espinosa & others, 2018; Meeus, 2017). Although children are aware of some ethnic and cultural differences, individuals consciously confront their ethnicity for the first time in adolescence or emerging adulthood. Unlike children, adolescents and emerging adults have the ability to interpret ethnic and cultural information, to reflect on the past, and to speculate about the future. With their advancing cognitive skills of abstract thinking and self-reflection, adolescents (especially older adolescents) increasingly consider the meaning of their ethnicity and also have more ethnic-related experiences.

The indicators of identity change often differ for each succeeding generation (Vedder & Phinney, 2014). First-generation immigrants are likely to be secure in their identities and unlikely to change much; they may or may not develop a new identity. The degree to which they begin to feel “American” appears to be related to whether or not they learn English, develop social networks beyond their ethnic group, and become culturally competent in their new country. Second-generation immigrants are more likely to think of themselves as “American,” possibly because citizenship is granted at birth. Their ethnic identity is likely to be linked to retention of their ethnic language and social networks. In the third and later generations, the issues become more complex. Historical, contextual, and political factors that are unrelated to acculturation may affect the extent to which members of this generation retain their ethnic identities. For non-European ethnic groups, racism and discrimination influence whether ethnic identity is retained.

Recent research indicates that pride in one’s ethnic identity group has positive outcomes (Ikram & others, 2016; Umana-Taylor & others, 2018). For example, in a recent study, having pride in one’s ethnic group and a strong ethnic identity were linked to lower rates of substance use in adolescents (Grindal & Nieri, 2016). And in another recent study, strong ethnic group affiliation and connection served a protective function in reducing risk for psychiatric problems (Anglin & others, 2018). Recent longitudinal studies document that the ethnic identity of adolescents is influenced by positive and diverse friendships (Rivas-Drake & others, 2017; Santos, Kornienko, & Rivas-Drake, 2017).

## RELIGIOUS/SPIRITUAL DEVELOPMENT

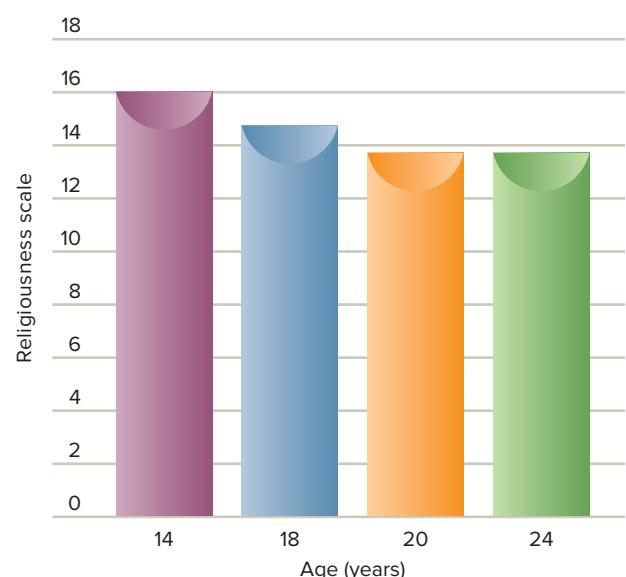

In the chapter on “Physical and Cognitive Development in Adolescence” we described the many benefits of service learning. A number of studies have found that adolescents who are involved in religious institutions are more likely to engage in service learning than their counterparts who don’t participate in religious institutions (Lerner & others, 2015). Let’s explore adolescents’ religious and spiritual experiences.

Religious issues are important to many adolescents, but during the twenty-first century religious interest among adolescents has declined. In a 2010 national study of American college freshmen, 73 percent said they had attended religious services frequently or occasionally during their senior year in high school, down from a high of 85 percent in 1997 (Pryor, DeAngelo, & Blake, 2011).

A developmental study revealed that religiousness declined from 14 to 20 years of age in the United States (Koenig, McGue, & Iacono, 2008) (see Figure 2). In this study, religiousness was assessed with items such as frequency of prayer, frequency of discussing religious teachings, frequency of deciding moral actions for religious reasons, and the overall importance of religion in everyday life. As indicated in Figure 2, more change in religiousness occurred from 14 to 18 years of age than from 20 to 24 years of age. Also in this study, attending religious services declined from 14 to 18 years of age and then began to increase at 20 years of age. And in a recent study, as adolescents got older, their religious service attendance declined and this decline was linked to such factors as becoming employed, leaving home, and engaging in sexual activity.

**ethnic identity** An enduring, basic aspect of the self that includes a sense of membership in an ethnic group and the attitudes and feelings related to that membership.

**FIGURE 2**  
**DEVELOPMENTAL CHANGES IN RELIGIOUSNESS FROM 14 TO 24 YEARS**

**OF AGE.** Note: The religiousness scale ranged from 0 to 32, with higher scores indicating stronger religiousness.

(Hardie, Pearce, & Denton, 2016). Also in this study, parents' religious affiliation and attendance provided some protection against decreasing attendance.

Researchers have found that adolescent girls are more religious than are adolescent boys (King & Boyatzis, 2015). One study of 13- to 17-year-olds revealed that girls are more likely to attend religious services frequently, to perceive that religion shapes their daily lives, to participate in religious youth groups, to pray alone, and to feel closer to God (Smith & Denton, 2005).

Analysis of the World Values Survey of 18- to 24-year-olds revealed that emerging adults in less developed countries were more likely to be religious than their counterparts in more developed countries (Lippman & Keith, 2006). For example, emerging adults' reports that religion was very important in their lives ranged from a low of 0 in Japan to 93 percent in Nigeria, and belief in God ranged from a low of 40 percent in Sweden to a high of 100 percent in Pakistan.

**Religion and Identity Development** As we saw earlier in this chapter, identity development becomes a central focus during adolescence and emerging adulthood (Kroger, 2015). As part of their search for identity, adolescents and emerging adults begin to grapple in more sophisticated, logical ways with such questions as "Why am I on this planet?" "Is there really a God or higher spiritual being, or have I just been believing what my parents and the church imprinted in my mind?" "What really are my religious views?"

**Cognitive Development and Religion in Adolescence** Many of the cognitive changes thought to influence religious development involve Piaget's cognitive developmental theory. More so than in childhood, adolescents think abstractly, idealistically, and logically. The increase in abstract thinking lets adolescents consider various ideas about religious and spiritual concepts. For example, an adolescent might ask how a loving God can possibly exist given the extensive suffering of many people in the world (Good & Willoughby, 2008). Adolescents' increased idealistic thinking provides a foundation for thinking about whether religion provides the best route to a better world. And adolescents' increased logical reasoning gives them the ability to develop hypotheses and systematically sort through different answers to spiritual questions (Good & Willoughby, 2008).

**The Positive Role of Religion in Adolescents' Lives** Researchers have found that various aspects of religion are linked with positive outcomes for adolescents (Longo, Bray, &

Many children and adolescents show an interest in religion, and many religious institutions created by adults (such as this Muslim school in Malaysia) are designed to introduce them to religious benefits and ensure that they will carry on a religious tradition.

Kim-Spoon, 2017; Talib & Abdollahi, 2017). Religion plays a role in adolescents' health and has an influence on whether they engage in problem behaviors (King, Ramos, & Clardy, 2013). A research meta-analysis found that spirituality/religiosity was positively related to well-being, self-esteem, and three of the Big Five factors of personality (conscientiousness, agreeableness, openness) (Yonker, Schnabelrauch, & DeHaan, 2012). In this meta-analysis, lower levels of spirituality/religion were associated with higher levels of risk-taking and depression. Further, a recent study revealed that high school students who reported turning to spiritual beliefs when they were experiencing problems were less likely to engage in substance use (Debnam & others, 2018). And across three countries (England, Scotland, and Canada), adolescents who reported having a higher level of spirituality were more likely to have positive health outcomes (Brooks & others, 2018).

Many religious adolescents also adopt their religion's message about caring and concern for people (Lerner & others, 2015). For example, in one survey religious youth were almost three times as likely to engage in community service as nonreligious youth (Youniss, McLellan, & Yates, 1999).

Describe changes that take place in adolescents' relationships with their parents.

Parental Monitoring and Information Management

Autonomy and Attachment

Parent-Adolescent Conflict

Adolescence typically alters the relationship between parents and their children. Among the most important aspects of family relationships in adolescence are those that involve parental monitoring and information management, autonomy and attachment, and parent-adolescent conflict.

## PARENTAL MONITORING AND INFORMATION MANAGEMENT

In "Socioemotional Development in Middle and Late Childhood," we discussed the importance of parents as managers of children's development. A key aspect of the managerial role of parenting is effective monitoring, which is especially important as children move into the adolescent years (Bendezú & others, 2018; Cope & others, 2017; Kelly, Becker, & Spirito, 2017; Lindsay & others, 2018; Low & Shortt, 2017; Rusby & others, 2018). Monitoring includes supervising adolescents' choice of social settings, activities, and friends, as well as their academic efforts. In a recent study of fifth- to eighth-graders, a higher level of parental monitoring was associated with students having higher grades (Top, Liew, & Luo, 2017). A recent meta-analysis also found that higher levels of parental monitoring and rule enforcement were linked to later initiation of sexual intercourse and increased use of condoms by adolescents (Dittus & others, 2015). Another study revealed that adolescents with high levels of depressed mood

were less likely to engage in drinking when their parents engaged in parental monitoring (Kelly, Becker, & Spirito, 2017). However, in this study, parents with a high level of depressed mood were less likely to monitor their adolescents effectively than their counterparts who were less depressed.

A current interest involving parental monitoring focuses on adolescents' management of their parents' access to information, especially strategies used in disclosing or concealing information about their activities (Rote & Smetana, 2016; Smetana, Robinson, & Rote, 2015). When parents engage in positive parenting practices, adolescents are more likely to disclose information. A study of U.S. and Chinese young adolescents found that adolescents' disclosure to parents was linked with a higher level of academic competence (better learning strategies, autonomous motivation, and better grades) over time (Cheung, Pomerantz, & Dong, 2012). Researchers have found that adolescents' disclosure to parents about their whereabouts, activities, and friends is linked to positive adolescent adjustment (Cottrell & others, 2017; Smetana, Robinson, & Rote, 2015). A recent study of 10- to 18-year-olds found that lower adolescent disclosure to parents was linked to antisocial behavior (Criss & others, 2015).

## AUTONOMY AND ATTACHMENT

With most adolescents, parents are likely to find themselves engaged in a delicate balancing act, weighing competing needs for autonomy and control, for independence and connection.

**Autonomy** The typical adolescent's push for autonomy and responsibility puzzles and angers many parents. Most parents anticipate that their teenager will have some difficulty adjusting to the changes that adolescence brings, but few parents imagine and predict just how strong an adolescent's desires will be to spend time with peers or how intensely adolescents will want to show that it is they—not their parents—who are responsible for their successes and failures.

Adolescents' ability to attain autonomy and gain control over their behavior is acquired through appropriate adult reactions to their desire for control. At the onset of adolescence, the average individual does not have the knowledge to make appropriate or mature decisions in all areas of life. As the adolescent pushes for autonomy, the wise adult relinquishes control in those areas where the adolescent can make reasonable decisions, but continues to guide the adolescent to make reasonable decisions in areas where the adolescent's knowledge is more limited. Gradually, adolescents acquire the ability to make mature decisions on their own. A recent study also found that from 16 to 20 years of age, adolescents perceived that they had increasing independence and improved relationships with their parents (Hadiwijaya & others, 2017).

Gender differences characterize autonomy-granting in adolescence. Boys are given more independence than girls. In one study, this was especially true in U.S. families with a traditional gender-role orientation (Bumpus, Crouter, & McHale, 2001).

Expectations about the appropriate timing of adolescent autonomy often vary across cultures, parents, and adolescents (Romo, Mireles-Rios, & Lopez-Tello, 2014). For example, expectations for early autonomy on the part of adolescents are more prevalent among non-Latino Whites, single parents, and adolescents themselves than they are among Asian Americans or Latinos, married parents, and parents themselves (Feldman & Rosenthal, 1999). Nonetheless, although Latino cultures may place a stronger emphasis on parental authority and restrict adolescent autonomy, one study revealed that regardless of where they were born, Mexican-origin adolescent girls living in the United States expected autonomy at an earlier age than their mothers preferred (Bamaca-Colbert & others, 2012).

**The Role of Attachment** Recall that one of the most widely discussed aspects of socioemotional development in infancy is secure attachment to caregivers (Hoffman & others, 2017; Meins, Bureau, & Ferryhough, 2018). In the past decade, researchers have explored whether secure attachment also might be an important aspect of adolescents' relationships with their parents (Allen & Tan, 2016; Lockhart & others, 2017). Researchers have found that insecurely attached adolescents are more likely than securely attached adolescents to have emotional difficulties and to engage in problem behaviors such as juvenile delinquency and

drug abuse (Hoeve & others, 2012). A recent study involving adolescents and emerging adults from 15 to 20 years of age found that insecure attachment to mothers was linked to becoming depressed and remaining depressed (Agerup & others, 2015). In a longitudinal study, Joseph Allen and his colleagues (2009) found that secure attachment at 14 years of age was linked to a number of positive outcomes at 21 years of age, including relationship competence, financial/career competence, and fewer problematic behaviors. Further, in a recent study of Latino families, a higher level of secure attachment with mothers was associated with less heavy drug use by adolescents (Gattamorta & others, 2017). And in a research review, the most consistent outcomes of secure attachment in adolescence involved positive peer relations and development of the adolescent's capacity to regulate emotions (Allen & Miga, 2010).

Might secure attachment be linked to parenting styles in adolescence? A study of Chinese adolescents revealed that authoritative parenting positively predicted parent-adolescent attachment, which in turn was associated with a higher level of adolescent self-esteem and positive attachment to peers (Cai & others, 2013). And a longitudinal study revealed that secure attachment in adolescence and emerging adulthood was predicted by observations of maternal sensitivity across childhood and adolescence (Waters, Ruiz, & Roisman, 2017).

**Balancing Freedom and Control** We have seen that parents play very important roles in adolescent development (Cope & others, 2017; Low & Shortt, 2017). Although adolescents are moving toward independence, they still need to stay connected with their family (Allen & Tan, 2016; Lansford & others, 2018; Lockhart & others, 2017; Papernow, 2018). The National Longitudinal Study on Adolescent Health surveyed more than 12,000 adolescents and found that those who did not eat dinner with a parent five or more days a week had dramatically higher rates of smoking, drinking, using marijuana, getting into fights, and initiating sexual activity (Council of Economic Advisors, 2000). In another longitudinal study, parental psychological control (extent to which parents use guilt, anxiety, love withdrawal, and other psychologically controlling behaviors) was linked to decreases in adolescents' autonomy and relatedness with friends between 13 and 18 years of age and lower levels of autonomy and relatedness with romantic partners at 18 (Oudekerk & others, 2015).

## PARENT-ADOLESCENT CONFLICT

Although parent-adolescent conflict increases in early adolescence, it does not reach the tumultuous proportions G. Stanley Hall envisioned at the beginning of the twentieth century (Bornstein, Jager, & Steinberg, 2013). Rather, much of the conflict involves the everyday events of family life, such as keeping a bedroom clean, dressing neatly, getting home by a certain time, and not talking endlessly on the phone. The conflicts rarely involve major dilemmas such as drugs or delinquency.

Conflict with parents often escalates during early adolescence and then lessens as the adolescent reaches 17 to 20 years of age. In a recent study of Chinese American families, parent-adolescent conflict increased in early adolescence, peaked at about 16 years of age, and then decreased through late adolescence and emerging adulthood (Juang & others, 2018). Parent-adolescent relationships become more positive if adolescents go away to college than if they attend college while living at home (Sullivan & Sullivan, 1980).

The everyday conflicts that characterize parent-adolescent relationships may actually serve a positive developmental function. These minor disputes and negotiations facilitate the adolescent's transition from being dependent on parents to becoming an autonomous individual. Recognizing that conflict and negotiation can serve a positive developmental function can tone down parental hostility.

The old model of parent-adolescent relationships suggested that as adolescents mature they detach themselves from parents and move into a world of autonomy apart from parents. The old model also suggested that parent-adolescent conflict is intense and stressful throughout adolescence. The new model emphasizes that parents serve as important attachment figures and support systems while adolescents explore a wider, more complex social world. The new model also emphasizes that in most families parent-adolescent conflict is moderate rather than severe and that the everyday negotiations and minor disputes not only are normal but also can serve the positive developmental function of helping the adolescent make the transition from childhood dependency to adult independence (see Figure 3).

According to one adolescent, Stacey Christensen, age 16: "I am lucky enough to have open communication with my parents. Whenever I am in need or just need to talk, my parents are there for me. My advice to parents is to let your teens grow at their own pace, be open with them so that you can be there for them. We need guidance; our parents need to help but not be too overwhelming."

Still, a high degree of conflict characterizes some parent-adolescent relationships (Brouillard & others, 2018; Nguyen & others, 2018; Van Lissa & others, 2017; Smokowski & others, 2017). And this prolonged, intense conflict is associated with various adolescent problems: movement out of the home, juvenile delinquency, depression, school dropout, pregnancy and early marriage, membership in religious cults, and drug abuse (Brook & others, 1990; Delgado & others, 2018; Juang & others, 2018). For example, a recent study found that higher levels of parent-adolescent conflict were associated with higher levels of adolescent anxiety, depression, and aggression, and lower levels of self-esteem (Smokowski & others, 2015). Also, a recent study found that high levels of parent-adolescent conflict were associated with lower levels of empathy in adolescents throughout the six years of the study from 13 to 18 years of age (Van Lissa & others, 2015). And in another study, higher levels of parent-adolescent conflict were related to higher levels of peer-reported aggression and delinquency (Ehrlich, Dykas, & Cassidy, 2012).

Cross-cultural studies reveal that parent-adolescent conflict is lower in some countries than in the United States. Two countries where parent-adolescent conflict is lower than in the United States are Japan and India.

When families emigrate to another country, adolescents typically acculturate more quickly to the norms and values of their new country than do their parents (Nguyen & others, 2018). This likely occurs because of immigrant adolescents' exposure in school to the language and culture of the host country. The norms and values immigrant adolescents experience are especially likely to diverge from those of their parents in areas such as autonomy and romantic relationships (Nair & others, 2018). In a recent study of Chinese American families, parent-adolescent conflict was linked to a sense of alienation between parents and adolescents, which in turn was related to more depressive symptoms, delinquent behavior, and lower levels of academic achievement (Hou, Kim, & Wang, 2016).

## 3 Peers

LG3 Characterize the changes that occur in peer relationships during adolescence.

Friendships

Peer Groups

Dating and Romantic Relationships

Peers play powerful roles in the lives of adolescents (Nesi & others, 2017; Rubin & Barstead, 2018). Peer relations undergo important changes in adolescence, including changes in friendships and in peer groups, as well as the beginning of romantic relationships (Markovic & Bowker, 2017).

### FRIENDSHIPS

For most children, being popular with their peers is a strong motivator. Beginning in early adolescence, however, teenagers typically prefer to have a smaller number of friendships that are more intense and intimate than those of young children.

Harry Stack Sullivan (1953) was the most influential theorist to discuss the importance of adolescent friendships. During adolescence, said Sullivan, friends become increasingly important in meeting social needs. In particular, Sullivan argued, the need for intimacy intensifies during early adolescence, motivating teenagers to seek out close friends. If adolescents fail to develop such close friendships, they experience loneliness and a reduced sense of self-worth.

Many of Sullivan's ideas have withstood the test of time. For example, adolescents report disclosing intimate and personal information to their friends more often than do younger children (Buhrmester, 1998) (see Figure 4). Adolescents also say they depend more on friends than on parents to satisfy their needs for companionship, reassurance of worth, and intimacy. The ups and downs of experiences with friends shape adolescents' well-being (Bagwell & Bukowski, 2018; Laursen, 2018; Nesi & others, 2017; Prinstein & Giletta, 2016). Adolescent girls are more likely to disclose information about problems to a friend than are adolescent boys (Rose & Smith, 2018; Rose & others, 2012).

Although having friends can be a developmental advantage, not all friendships are alike and the quality of friendship matters (Bagwell & Bukowski, 2018; Mason & others, 2017). People differ in the company they keep—that is, who their friends are. It is a developmental disadvantage to have coercive, conflict-ridden, and poor-quality friendships (Raudsepp & Riso, 2017; Rose & Smith, 2018; Rubin & Barstead, 2018; Rubin & others, 2018). A recent study revealed that having friends who engage in delinquent behavior is associated with early onset and more persistent delinquency (Evans, Simons, & Simons, 2016). Another recent study found that adolescents adapted their smoking and drinking behavior to that of their best friends (Wang & others, 2016). Further, a recent study of adolescent girls revealed that friends' dieting predicted whether adolescent girls would engage in dieting or extreme dieting (Balantekin, Birch, & Savage, 2018).

Developmental advantages occur when adolescents have friends who are socially skilled, supportive, and oriented toward academic achievement (Choukas-Bradley & Prinstein, 2016; Ryan & Shin, 2018; Witkow, Rickert, & Cullen, 2017). Positive friendship relationships in adolescence are associated with a host of positive outcomes, including lower rates of delinquency, substance abuse, risky sexual behavior, and bullying victimization, and higher levels of academic achievement (Kindermann & Gest, 2018; Laursen, 2018; Laursen & Adams, 2018; Mason & others, 2017).

Although most adolescents develop friendships with individuals who are close to their own age, some adolescents become best friends with younger or older individuals. Do older friends encourage adolescents to engage in delinquent behavior or early sexual behavior? Adolescents who interact with older youth do engage in more problem behaviors, such as delinquency and early sexual behavior (Poulin & Pedersen, 2007).

To read about strategies for helping adolescents develop friendships, see *Connecting Development to Life*.

### PEER GROUPS

How extensive is peer pressure in adolescence? What roles do cliques and crowds play in adolescents' lives? As we see next, researchers have found that the standards of peer groups and the influence of crowds and cliques become increasingly important during adolescence.

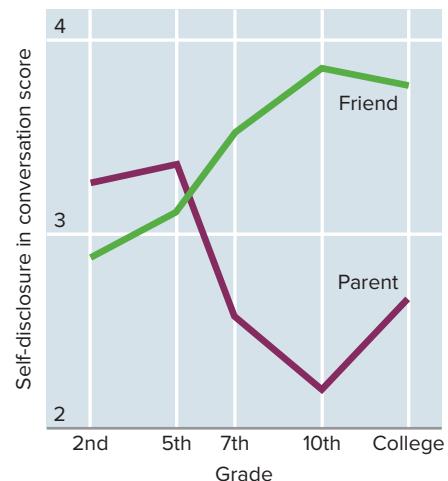

FIGURE 4

**DEVELOPMENTAL CHANGES IN SELF-DISCLOSING CONVERSATIONS.** Self-disclosing conversations with friends increased dramatically in adolescence while declining in an equally dramatic fashion with parents. However, self-disclosing conversations with parents began to pick up somewhat during the college years. The data shown represent the means for each age group.

## Effective and Ineffective Strategies for Making Friends

Here are some strategies for making friends that adults can recommend to adolescents (Wentzel, 1997):

- Initiate interaction. Learn about a friend: Ask for his or her name, age, favorite activities. Use these prosocial overtures: introduce yourself, start a conversation, and invite him or her to do things.
- Be nice. Show kindness, be considerate, and compliment the other person.
- Engage in prosocial behavior. Be honest and trustworthy: Tell the truth, keep promises. Be generous, share, and be cooperative.
- Show respect for yourself and others. Have good manners, be polite and courteous, and listen to what others have to say. Have a positive attitude and personality.
- Provide social support. Show you care.

And here are some inappropriate strategies for making friends that adults can recommend that adolescents avoid using (Wentzel, 1997):

- Be psychologically aggressive. Show disrespect and have bad manners. Use others, be uncooperative, don't share, ignore others, gossip, and spread rumors.
- Present yourself negatively. Be self-centered, snobby, conceited, and jealous; show off; care only about yourself. Be mean, have a bad attitude, be angry, throw temper tantrums, and start trouble.
- Behave antisocially. Be physically aggressive, yell at others, pick on them, make fun of them, be dishonest, tell secrets, and break promises.

**Peer Pressure** Young adolescents conform more to peer standards than children do (Nesi & others, 2017; Prinstein & Giletta, 2016). Around the eighth and ninth grades, conformity to peers—especially to their antisocial standards—peaks (Brown & Larson, 2009; Brown & others, 2008). At this point, adolescents are most likely to go along with a peer to steal hubcaps off a car, draw graffiti on a wall, or steal cosmetics from a store counter. One study found that U.S. adolescents are more likely than Japanese adolescents to put pressure on their peers to resist parental influence (Rothbaum & others, 2000). And a recent study found that boys were more likely to be influenced by peer pressure involving sexual behavior than were girls (Widman & others, 2016).

Which adolescents are most likely to conform to peers? Mitchell Prinstein and his colleagues (Prinstein, 2007; Prinstein & Dodge, 2008; Prinstein & Giletta, 2016) have conducted research that found adolescents who feel uncertain about their social identity, which may be evident in low self-esteem and high social anxiety, are most likely to conform to peers. This uncertainty often increases during times of transition, such as changing circumstances in school and family life. Also, adolescents are more likely to conform to peers whom they perceive to have higher status than they do.

**Cliques and Crowds** Cliques and crowds assume more important roles during adolescence than during childhood (Brown, 2011; Furman & Rose, 2015). **Cliques** are small groups that range from 2 to about 12 individuals and average about 5 or 6 individuals. The clique members are usually of the same sex and about the same age.

Cliques can form because adolescents engage in similar activities, such as belonging to a club or playing on a sports team. Some cliques also form because of friendship. Several adolescents may form a clique because they have spent time with each other, share mutual interests, and enjoy each other's company.

**Crowds** are larger than cliques and less personal. Adolescents are usually members of a crowd based on reputation, and they may or may not spend much time together. Many crowds are defined by the activities adolescents engage in (such as “jocks” who are good at sports or “druggies” who take drugs) (Brown, 2011).

## DATING AND ROMANTIC RELATIONSHIPS

Adolescents spend considerable time either dating or thinking about dating (Furman, 2018; Furman & Rose, 2015; Lantagne & Furman, 2017). Dating can be a form of recreation, a source of status, or a setting for learning about close relationships, as well as a way of finding a mate.

## **Developmental Changes in Dating and Romantic Relationships**

Three stages characterize the development of romantic relationships in adolescence (Connolly & McIsaac, 2009):

1. *Entry into romantic attractions and affiliations at about 11 to 13 years of age.* This initial stage is triggered by puberty. From 11 to 13, adolescents become intensely interested in romance and it dominates many conversations with same-sex friends. Developing a crush on someone is common and the crush often is shared with a same-sex friend. Young adolescents may or may not interact with the individual who is the object of their infatuation. When dating occurs, it usually occurs in a group setting.
2. *Exploring romantic relationships at approximately 14 to 16 years of age.* At this point in adolescence, two types of romantic involvement occur: (a) Casual dating emerges between individuals who are mutually attracted. These dating experiences are often short-lived, lasting a few months at best, and usually endure for only a few weeks. (b) Dating in groups is common and reflects embeddedness in the peer context. Friends often act as third-party facilitators of a potential dating relationship by communicating their friend's romantic interest and determining whether this attraction is reciprocated.
3. *Consolidating dyadic romantic bonds at about 17 to 19 years of age.* At the end of the high school years, more serious romantic relationships develop. This is characterized by strong emotional bonds more closely resembling those in adult romantic relationships. These bonds often are more stable and enduring than earlier bonds, typically lasting one year or more.

Two variations on these stages in the development of romantic relationships in adolescence involve early and late bloomers (Connolly & McIsaac, 2009). *Early bloomers* include 15 to 20 percent of 11- to 13-year-olds who say that they currently are in a romantic relationship and 35 percent who indicate that they have had some prior experience in romantic relationships. One study found that early bloomers externalized problem behaviors through adolescence more than their on-time and later-bloomer counterparts (Connolly & others, 2013). *Late bloomers* comprise approximately 10 percent of 17- to 19-year-olds who say that they have had no experience with romantic relationships and another 15 percent who report that they have not engaged in any romantic relationships that lasted more than four months.

**Dating in Gay and Lesbian Youth** Recently, researchers have begun to study romantic relationships among gay and lesbian youth (Diamond & Alley, 2018; Savin-Williams, 2017). Many sexual minority youth date other-sex peers, which can help them to clarify their sexual orientation or disguise it from others (Savin-Williams, 2018). Most gay and lesbian youth have had some same-sex sexual experience, often with peers who are “experimenting.” Some gay and lesbian youth continue to have a same-sex orientation while others have a primarily heterosexual orientation (Savin-Williams, 2017, 2018).

**Sociocultural Contexts and Dating** The sociocultural context exerts a powerful influence on adolescents’ dating patterns (Yoon & others, 2017). This influence may be seen in differences in dating patterns among ethnic groups within the United States. For example, one study found that Asian American adolescents were less likely to have been involved in a romantic relationship in the past 18 months than African American or Latino adolescents were (Carver, Joyner, & Udry, 2003).

Values, religious beliefs, and traditions often dictate the age at which dating begins, how much freedom in dating is allowed, whether dates must be chaperoned by adults or parents, and the roles of males and females in dating. For example, Latino and Asian American cultures have more conservative standards regarding adolescent dating than does the Anglo-American culture. Dating may become a source of conflict within a family if the parents grew up in cultures where dating begins at a late age, little freedom in dating is allowed, dates are chaperoned, and dating by adolescent girls is especially restricted. When immigrant adolescents choose to adopt the ways of the dominant U.S. culture (such as unchaperoned dating), they often clash with parents and extended-family members who have more traditional values. Also, a recent study found that mother-daughter conflict in Mexican American families was linked to an increase in daughters’ romantic involvement (Tyrell & others, 2016).

How are adolescent romantic relationships linked to adjustment?  
©Pascal Broze/SuperStock

**Dating and Adjustment** Researchers have linked dating and romantic relationships with various measures of how well-adjusted adolescents are (Furman, 2018; Furman & Rose, 2015; Lantagne & Furman, 2017; Rogers & others, 2018). For example, a study of tenth-graders revealed that the more romantic encounters they had experienced, the more likely they were to report high levels of social acceptance, friendship competence, and romantic competence; however, having more romantic experience also was linked with a higher level of substance use, delinquency, and sexual behavior (Furman, Low, & Ho, 2009). In another study conducted among adolescent girls but not adolescent males, having an older romantic partner was linked with an increase in depressive symptoms, largely influenced by an increase in substance use (Haydon & Halpern, 2010).

However, in some cases, romantic relationships in adolescence are linked with positive developmental changes. For example, in a recent study, having a supportive romantic relationship in adolescence was linked to positive outcomes for adolescents who had a negative relationship with their mother (Szwedo, Hessel, & Allen, 2017). In another study, adolescents who engaged

in a higher level of intimate disclosure at age 10 reported a higher level of companionship in romantic relationships at 12 and 15 years of age (Kochendorfer & Kerns, 2017). In this study, those who reported more conflict in friendships had a lower level of companionship in romantic relationships at 15 years of age. And in a recent study, hostile conflict with a romantic partner at age 17 predicted an increase in internalizing behaviors (depression, for example) from 17 to 27 (Kansky & Allen, 2018). Also in this study, romantic partner support at age 17 predicted decreases in externalizing behaviors (high levels of aggression, for example) over time.

Dating and romantic relationships at an early age can be especially problematic (Furman, 2018). One study found that romantic activity was linked to depression in early adolescent girls (Starr & others, 2012). Researchers also have found that early dating and “going with” someone are linked with adolescent pregnancy and problems at home and school (Florsheim, Moore, & Edgington, 2003).

Ethnicity

Media Use and Screen Time

In this section, we will discuss cross-cultural variations in a number of aspects of adolescent development. We also will examine how ethnicity affects U.S. adolescents and influences their development. Further, we discuss the many challenges faced by adolescents who grow up in low-income and impoverished families. And we will explore an important aspect of the cultural worlds of adolescents—the media.

## CROSS-CULTURAL COMPARISONS

What traditions continue to influence the lives of adolescents around the globe? What circumstances are changing adolescents' lives? Depending on the culture, adolescence may involve many different experiences (Chen, Lee, & Chen, 2018).

**Health** Adolescent health and well-being have improved in some respects but not in others. Overall, fewer adolescents around the world die from infectious diseases and malnutrition now than in the past (UNICEF, 2017). However, a number of adolescent health-compromising behaviors (especially illicit drug use and unprotected sex) are increasing in frequency. Extensive increases in the rates of HIV in adolescents have occurred in many sub-Saharan countries (UNICEF, 2017).

**Gender** Around the world, the experiences of male and female adolescents continue to be quite different (Brown & Larson, 2002; Peitzmeier & others, 2016). Except in a few regions, such as Japan, the Philippines, and Western countries, males have far greater access to educational opportunities than females do (UNICEF, 2018). In many countries, adolescent females have less freedom than males to pursue a variety of careers and engage in various leisure activities. Gender differences in sexual expression are widespread, especially in India, Southeast Asia, Latin America, and Arab countries where far more restrictions are placed on the sexual activity of adolescent females than on that of males. These gender differences do appear to be narrowing over time, however. In some countries, educational and career opportunities for women are expanding, and control over adolescent girls' romantic and sexual relationships is weakening.

**Family** In some countries, adolescents grow up in closely knit families with extensive kin networks that retain a traditional way of life. For example, in Arab countries "adolescents are taught strict codes of conduct and loyalty" (Brown & Larson, 2002, p. 6). However, in Western countries such as the United States, parenting is less authoritarian than in the past, and much larger numbers of adolescents are growing up in divorced families and stepfamilies.

In many countries around the world, current trends "include greater family mobility, migration to urban areas, family members working in distant cities or countries, smaller families, fewer extended-family households, and increases in mothers' employment" (Brown & Larson, 2002, p. 7). Unfortunately, many of these changes may reduce the ability of parents to spend time with their adolescents.

**Peers** Some cultures give peers a stronger role in adolescence than other cultures do (Brown & others, 2008). In most Western nations, peers figure prominently in adolescents' lives, in some cases taking on roles that in other cultures are assumed by parents. Among street youth in South America, the peer network serves as a surrogate family that supports survival in dangerous and stressful settings. In other regions of the world, such as in Arab countries, peer relations are restricted, especially for girls (Booth, 2002).

**Time Allocation to Different Activities** Reed Larson and his colleagues (Larson, 2001; Larson & Angus, 2011; Larson & Dawes, 2015; Larson, McGovern, & Orson, 2018; Larson, Orson, & Bowers, 2017; Larson, Shernoff, & Bempechat, 2014; Larson & Verma, 1999; Larson, Walker, & McGovern, 2018) have examined how adolescents spend their time in work, play, and developmental activities such as school. U.S. adolescents spend about 60 percent as much time on schoolwork as East Asian adolescents do, which is mainly due to U.S. adolescents doing less homework (Larson & Verma, 1999).

U.S. adolescents have greater quantities of discretionary time than adolescents in other industrialized countries do (Larson & Dawes, 2015; Larson, McGovern, & Orson, 2018; Larson, Orson, & Bowers, 2017; Larson, Walker, & McGovern, 2018; Larson, Wilson, & Rickman, 2009). About 40 to 50 percent of U.S. adolescents' waking hours (not counting summer vacations) is spent in discretionary activities, compared with 25 to 35 percent in East Asia and 35 to 45 percent in Europe. Whether this additional discretionary time is a liability or an asset for U.S. adolescents, of course, depends on how they use it.

According to Larson (2001), U.S. adolescents may have too much unstructured time because when they are given a choice they typically engage in unchallenging activities such as hanging out and watching TV. Although relaxation and social interaction are important aspects of adolescence, it seems unlikely that spending large numbers of hours per week in unchallenging activities would foster development. Structured voluntary activities may provide more

promise for adolescent development than unstructured time, especially if adults give responsibility to adolescents, challenge them, and provide competent guidance in these activities (Larson & Dawes, 2015; Larson, Orson, & Bowers, 2017; Larson, Walker, & McGovern, 2018).

**Rites of Passage** Another variation in the experiences of adolescents in different cultures is whether the adolescents go through a rite of passage. Some societies have elaborate ceremonies that signal the adolescent's move to maturity and achievement of adult status (Ember, Ember, & Peregrine, 2015; Miller, 2017). A **rite of passage** is a ceremony or ritual that marks an individual's transition from one status to another. Most rites of passage focus on the transition to adult status. In some traditional cultures, rites of passage are the avenue through which adolescents gain access to sacred adult practices, to knowledge, and to sexuality. These rites often involve dramatic practices intended to facilitate the adolescent's separation from the immediate family, especially the mother. The transformation is usually characterized by some form of ritual death and rebirth, or by means of contact with the spiritual world. Bonds are forged between the adolescent and the adult instructors through shared rituals, hazards, and secrets to allow the adolescent to enter the adult world. This kind of ritual provides a forceful and discontinuous entry into the adult world at a time when the adolescent is perceived to be ready for the change.

An especially rich tradition of rites of passage for adolescents has prevailed in African cultures, especially sub-Saharan Africa. Under the influence of Western industrialized culture, many of these rites are disappearing today, although they are still prevalent in locations where formal education is not readily available.

Do we have such rites of passage for American adolescents? We certainly do not have universal formal ceremonies that mark the passage from adolescence to adulthood. Certain religious and social groups do, however, have initiation ceremonies that indicate that an advance in maturity has been reached: the Jewish bar and bat mitzvah, the Catholic confirmation, and social debuts, for example. School graduation ceremonies come the closest to being culture-wide rites of passage in the United States. The high school graduation ceremony has become nearly universal for middle-class adolescents and increasing numbers of adolescents from low-income backgrounds.

## SOCIOECONOMIC STATUS AND POVERTY

In the chapter on "Socioemotional Development in Middle and Late Childhood" we described many aspects of the challenges faced by children who live in low-income and impoverished families. Here we focus on these challenges that adolescents have to cope with under these circumstances.

Adolescents from low-SES backgrounds are at risk for experiencing low academic achievement and emotional problems, as well as lower occupational attainment in adulthood (Chaudry & others, 2017; Coley & others, 2018). Psychological problems such as smoking, depression, and juvenile delinquency as well as physical illnesses are more prevalent among low-SES adolescents than among economically advantaged adolescents (Simon & others, 2017). For example, a recent study found that of 13 risk factors, low SES was most likely to be associated with smoking initiation in fifth-graders (Wellman & others, 2018). Also, in a recent Chinese study, adolescents in low-income families were more likely to have depressive symptoms (Zhou, Fan, & Yin, 2017). Further, in a U.S. longitudinal study, low SES in adolescence was linked to having a higher level of depressive symptoms at age 54 for females (Pino & others, 2018). And in this study, low-SES females who completed college were less likely to have depressive symptoms at age 54 than low-SES females who did not complete college. In another longitudinal study, low SES in adolescence was a risk factor for having cardiovascular disease 30 years later (Doom & others, 2017). In this study, these factors were found to be involved in the pathway to cardiovascular disease for low-SES individuals: health-compromising behaviors, financial stress, inadequate medical care, and lower educational attainment.

Are there psychological and social factors that predict higher achievement for some of the adolescents living in poverty? A recent study found that higher levels of the following four factors assessed at the beginning of the sixth grade was linked to higher grade point averages at the end of the seventh grade for children living in poverty: (1) academic commitment, (2) emotional control, (3) family involvement and (4) school climate (Li, Allen, & Casillas, 2017).

**rite of passage** A ceremony or ritual that marks an individual's transition from one status to another. Most rites of passage focus on the transition to adult status.

When poverty is persistent and long-standing, it can have especially damaging effects on adolescents (Chaudry & others, 2017; Duncan, Magnuson, & Votruba-Drzal, 2017). A recent study found that 12- to 19-year-olds' perceived well-being was lowest when they had lived in poverty from birth to 2 years of age (compared to 3 to 5, 6 to 8, and 9 to 11 years of age), and each additional year of living in poverty was associated with even lower perceived well-being (Gariepy & others, 2017).

## ETHNICITY

Earlier in this chapter, we explored the identity development of ethnic minority adolescents. Here we will further examine immigration and the relationship between ethnicity and socioeconomic status.

**Immigration** Relatively high rates of immigration are contributing to the growing proportion of ethnic minority adolescents and emerging adults in the United States (Suarez-Oroso, 2018a, b, c; Yoon & others, 2017). Immigrant families are those in which at least one of the parents was born outside the country of residence. Variations in immigrant families involve whether one or both parents are foreign born, whether the child was born in the host country, and the ages at which immigration took place for both the parents and the children (Kim & others, 2018; Titzmann & Gniewosz, 2018). Robert Crosnoe and Andrew Fuligni (2012, p. 1473) concluded:

Some children from immigrant families are doing quite well, some less so, depending on the characteristics of migration itself (including the nation of origin) and their families' circumstances in their new country (including their position in socioeconomic and race-ethnic stratification systems).

What are some of the circumstances immigrants face that challenge their adjustment? Immigrants often experience stressors uncommon to or less prominent among long-time residents, such as language barriers, dislocations and separations from support networks, the dual struggle to preserve identity and to acculturate, and changes in socioeconomic status (Bretzke & Perreira, 2017; Nieto & Bode, 2018; Titzmann, Ferrer-Wreder, & Dmitrova, 2018; Titzmann & Jugert, 2017; Yoshikawa & others, 2017). In a recent study comparing Asian, Latino, and non-Latino White immigrants' adolescents, immigrant Asian adolescents had the highest level of depression, the lowest self-esteem, and were the most likely to report experiencing discrimination (Lo & others, 2017).

Many individuals in immigrant families are dealing with the problem of being undocumented (Beck & others, 2017; Kim & others, 2018; Rojas-Flores & others, 2017). Living in an undocumented family can affect children's and adolescents' developmental outcomes through parents being unwilling to sign up for services for which they are eligible, through conditions linked to low-wage work and lack of benefits, through stress, and through a lack of cognitive stimulation in the home (Cobb & others, 2017). Consequently, when working with adolescents and their immigrant families, counselors need to adapt intervention programs to optimize cultural sensitivity (Calzada & others, 2018; Suarez-Oroso & Suarez-Oroso, 2018; Sue & others, 2017; Wyrick & others, 2017).

The ways in which ethnic minority families deal with stress depend on many factors (Davis & others, 2018; Gonzales-Backen & others, 2017). Whether the parents are native-born or immigrants, how long the family has been in the United States, its socioeconomic status, family values, how competently parents rear their children and adolescents, and their national origin all make a difference (Hou & Kim, 2018; Kim & others, 2018). A recent study of Mexican-origin youth found that when adolescents reported a higher level of familism (giving priority to one's family), they engaged in lower levels of risk taking (Wheeler & others, 2017). Another study revealed that parents' education before migrating was strongly linked to their children's academic achievement (Pong & Landale, 2012).

**Ethnicity and Socioeconomic Status** Much of the research on ethnic minority adolescents has failed to tease apart the influences of ethnicity and socioeconomic status. Ethnicity and socioeconomic status can interact in ways that exaggerate the influence of ethnicity because ethnic minority individuals are overrepresented in the lower socioeconomic levels of American society (Gollnick & Chinn, 2017; Nieto & Bode, 2018). Consequently, researchers too often have given ethnic explanations for aspects of adolescent development that were largely attributable to socioeconomic status.

**FIGURE 5**  
**DEVELOPMENTAL CHANGES IN THE AMOUNT OF TIME U.S. 8- TO 18-YEAR-OLDS SPEND WITH DIFFERENT TYPES OF MEDIA AND ELECTRONIC DEVICES**

Not all ethnic minority families are poor. However, as we saw earlier in this chapter, poverty contributes to the stressful life experiences of many ethnic minority adolescents (Coley & others, 2018; Duncan, Magnuson, & Votruba-Drzal, 2017; Pino & others, 2018; Wadsworth & others, 2016). Thus, many ethnic minority adolescents experience a double disadvantage: (1) prejudice, discrimination, and bias because of their ethnic minority status; and (2) the stressful effects of poverty (Kimmel & Aronson, 2018). Although some ethnic minority youth have middle-income backgrounds, economic advantage does not entirely enable them to escape the prejudice, discrimination, and bias associated with being a member of an ethnic minority group (Macionis, 2017).

## MEDIA USE AND SCREEN TIME

The culture adolescents experience involves not only cultural values, SES, and ethnicity, but also media and screen time influences (Guadagno, 2018; Lever-Duffy & McDonald, 2018; Maloy & others, 2017). Television continues to have a strong influence on children's and adolescents' development, but children's use of other media and information/communication devices has led to the use of the term *screen time*, which includes how much time individuals spend watching television or DVDs, playing video games, and using computers or mobile media such as iPhones (Yan, 2018). A recent study found that nighttime mobile phone use and poor sleep behavior increased from 13 to 16 years of age (Vernon, Modecki, & Barber, 2018). In this study, increased nighttime mobile phone use was linked to increased externalizing problems, as well as decreased self-esteem and coping.

**Prevalence of Media Use and Screen Time** If the amount of time spent in an activity is any indication of its importance, there is no doubt that media use and screen time play important roles in adolescents' lives (Calvert, 2015; Lever-Duffy & McDonald, 2018; Maloy & others, 2017). To better understand various aspects of U.S. adolescents' media use and screen time, the Kaiser Family Foundation funded three national surveys in 1999, 2004, and 2009. The 2009 survey included more than 2,000 8- to 18-year-olds and documented that adolescent media use and screen time had increased dramatically in the previous decade (Rideout, Foehr, & Roberts, 2010). In this survey, in 2009, 8- to 11-year-olds used media 5 hours and 29 minutes a day, 11- to 14-year-olds averaged 8 hours and 40 minutes a day, and 15- to 18-year-olds averaged 7 hours and 58 minutes a day (see Figure 5). Thus, media use jumps more than 3 hours in early adolescence! The largest increases in media use in early adolescence are for TV and video games. TV use by youth increasingly has involved watching TV on the Internet via a notebook computer or cell phone. As indicated in Figure 5, listening to music and using computers also increase considerably among 11- to 14-year-old adolescents. And based on the 2009 survey, adding up the daily media use figures to obtain weekly media use leads to the staggering levels of more than 60 hours a week of media use by 11- to 14-year-olds and almost 56 hours a week by 15- to 18-year-olds!

A major trend in the use of technology is the dramatic increase in media multitasking (Edwards & Shin, 2017; Steinborn & Huestegge, 2017). In the 2009 survey, when the amount of time spent multitasking was included in computing media use, 11- to 14-year-olds spent nearly 12 hours a day (compared with almost 9 hours a day when multitasking was not included) exposed to media (Rideout, Foehr, & Roberts, 2010)! In this survey, 39 percent of seventh- to twelfth-graders said "most of the time" they use two or more media concurrently, such as surfing the Web while listening to music.

In some cases, media multitasking—such as text messaging, listening to an iPod, and updating a YouTube site—is engaged in while doing homework. It is hard to imagine that this allows a student to do homework efficiently, although there is little research on media multitasking. A recent research review concluded that at a general level, digital technologies (surfing the Internet, texting someone) while engaging in a learning task (reading, listening to a lecture) distract learners and result in impaired performance on many tasks (Courage & others, 2015). The same research review also concluded that when driving subtasks such as various perceptual-motor activities (steering control, changing lanes, maneuvering

through traffic, braking, and acceleration) and ongoing cognitive tasks (planning, decision making, or maintaining a conversation with a passenger) are combined with interactive in-vehicle devices (phones, navigation aids, portable music devices), the task of driving becomes more complex and the potential for distraction increases. Also, in a recent study, heavy multimedia multitaskers were less likely than light media multitaskers to delay gratification and more likely to endorse intuitive, but wrong, answers on a cognitive reflection task (Schutten, Stokes, & Arnell, 2017).

**Technology and Digitally Mediated Communication** Culture involves change, and nowhere is that change greater than in the technological revolution individuals are experiencing with increased use of computers and the Internet (Guadagno, 2018; Lever-Duffy & McDonald, 2018). Society still relies on some basic non-technological competencies—for example, good communication skills, positive attitudes, and the ability to solve problems and to think deeply and creatively. But how people pursue these competencies is changing in ways and at speeds that few people had to cope with in previous eras. For youth to be adequately prepared for tomorrow's jobs, technology needs to become an integral part of their lives (Calvert, 2015).

Mobile media, such as cell phones and iPads, are mainly driving the increased media use by adolescents (Yan, 2018). For example, in 2004, 39 percent of adolescents owned a cell phone, a figure that had jumped to 66 percent in 2009 and then to 87 percent in 2016 with a prediction of 92 percent in 2019 (eMarketeer.com, 2016; Rideout & others, 2010).

A recent national survey revealed dramatic increases in adolescents' use of social media and text messaging (Lenhart, 2015). In 2015, 92 percent of U.S. 13- to 17-year-olds reported using social networking sites daily. Twenty-four percent of the adolescents said they go online almost constantly. Much of this increase in going online has been fueled by smartphones and mobile devices. Facebook is the most popular and frequently used social networking site—71 percent reported using Facebook and half said they use Instagram. A recent study found that less screen time was linked to adolescents' better health-related quality of life (Wong & others, 2018). Another recent study indicated that a higher level of social media use was associated with a higher level of heavy drinking by adolescents (Brunborg, Andreas, & Kvaavik, 2017).

Text messaging has become the main way that adolescents connect with their friends, surpassing face-to-face contact, e-mail, instant messaging, and voice calling (Lenhart, 2015; Lenhart & others, 2015). In the national survey and a further update (Lenhart & others, 2015), daily text messaging increased from 38 percent who texted friends daily in 2008 to 55 percent in 2015. However, voice mail was the primary way that most adolescents preferred to connect with parents.

Depression and Suicide

The Interrelation of Problems and Successful Prevention/Intervention Programs

Earlier we described several adolescent problems: substance abuse, sexually transmitted infections, and eating disorders. In this chapter, we will examine the problems of juvenile delinquency, depression, and suicide. We will also explore interrelationships among adolescent problems and describe how such problems can be prevented or remediated.

### JUVENILE DELINQUENCY

The label **juvenile delinquent** is applied to an adolescent who breaks the law or engages in behavior that is considered illegal. Like other categories of disorders, juvenile delinquency is a broad concept, encompassing legal infractions that range from littering to murder.

**Delinquency Rates** Juvenile court delinquency caseloads in the United States increased dramatically from 1960 to 1996 but have decreased slightly since 1996 (Puzzanchera & Robson, 2014). Note that this figure reflects only adolescents who have been arrested and assigned to juvenile court delinquency caseloads and does not include those who were arrested but not assigned to the delinquency caseloads, nor does the figure include youth who committed offenses but were not apprehended. In 2014, there were 975,000 delinquency cases in which juveniles were charged with violating criminal laws—down from 1,400,000 in 2010 but up from 400,000 in 1960 (Hockenberry & Puzzanchera, 2017).

Males are more likely to engage in delinquency than are females. However, U.S. government statistics revealed that the percentage of delinquency cases involving females increased from 19 percent in 1985 to 28 percent in 2014 (Hockenberry & Puzzanchera, 2017).

Delinquency rates among minority groups and lower-socioeconomic-status youth are higher than the proportions of these groups within the general population. However, such groups have less influence over the judicial decision-making process in the United States and therefore may be judged delinquent more readily than their White, middle-socioeconomic-status counterparts who have committed similar offenses.

A distinction is made between early-onset—before age 11—and late-onset—after 11—antisocial behavior. Early-onset antisocial behavior is associated with more negative developmental outcomes than late-onset antisocial behavior (Schulenberg & Zarrett, 2006; Wiecko, 2014). Not only is it more likely to persist into emerging adulthood, but it is also associated with more mental health and relationship problems (Pechorro & others, 2014).

**Causes of Delinquency** Although delinquency is less exclusively a phenomenon of lower socioeconomic status than it was in the past, some characteristics of lower-SES culture might promote delinquency (Dawson-McClure & others, 2015; Macionis, 2017). A recent study of more than 10,000 children and adolescents found that family environments characterized by poverty and child maltreatment were linked to entering the juvenile justice system in adolescence (Vidal & others, 2017). The norms of many lower-SES peer groups and gangs are antisocial, or counterproductive to the goals and norms of society at large. Getting into and staying out of trouble are prominent features of life for some adolescents in low-income neighborhoods. Being “tough” and “masculine” are high-status traits for lower-SES boys, and these traits are often measured by the adolescent’s success in performing and getting away with delinquent acts. And adolescents in communities with high crime rates observe many models who engage in criminal activities. These communities may be characterized by poverty, unemployment, and feelings of alienation toward the middle class. Quality schooling, educational funding, and organized neighborhood activities often are lacking in these communities (Crosnoe & Benner, 2015; Crosnoe & Leventhal, 2014). One study found that youth whose families had experienced repeated poverty were more than twice as likely to be delinquent at 14 and 21 years of age (Najman & others, 2010).

Certain characteristics of families are also associated with delinquency (Ray & others, 2017). Parental monitoring of adolescents is especially important in determining whether an

### Rodney Hammond, Health Psychologist

Rodney Hammond described how his college experiences led to his career choice:

"When I started as an undergraduate at the University of Illinois, Champaign-Urbana, I hadn't decided on my major. But to help finance my education, I took a part-time job in a child development research program sponsored by the psychology department. There, I observed inner-city children in settings designed to enhance their learning. I saw firsthand the contribution psychology can make, and I knew I wanted to be a psychologist" (American Psychological Association, 2003, p. 26).

Rodney Hammond went on to obtain a doctorate in school and community psychology with a focus on children's development. For a number of years, he trained clinical psychologists at Wright State University in Ohio and directed a program to reduce violence in ethnic minority youth. There, he and his associates taught at-risk youth how to use social skills to effectively manage conflict and to recognize situations that could lead to violence. Hammond became the first Director of Violence Prevention at the Centers for Disease Control and Prevention in Atlanta. Following his recent retirement from CDC, he is now Adjunct Professor of Human Development and Counseling at the University of Georgia.

adolescent becomes a delinquent (Bendezu & others, 2018; Dishion & Patterson, 2016). Family discord and inconsistent and inappropriate discipline are also associated with delinquency (Bor, McGee, & Fagan, 2004). And one study found that low rates of delinquency from 14 to 23 years of age were associated with an authoritative parenting style (Murphy & others, 2012). Recent research indicates that family therapy is often effective in reducing delinquency (Darnell & Schuler, 2015; Leve, Chamberlain, & Kim, 2015).

An increasing number of studies have found that siblings can have a strong influence on delinquency (Laursen & others, 2017; Wallace, 2017). Peer relations also can influence delinquency (Prinstein & others, 2018). Adolescents who begin to hang out with delinquent peers are more likely to become delinquent themselves (Dong & Krohn, 2016). And in a recent study of middle school adolescents, peer pressure for fighting and friends' delinquent behavior were linked to adolescents' aggression and delinquent behavior (Farrell, Thompson, & Mehari, 2017).

Lack of academic success is associated with delinquency (Mercer & others, 2016). And a number of cognitive factors such as low self-control, low intelligence, and lack of sustained attention are linked to delinquency (Fine & others, 2016). Further, recent research indicates that having callous-unemotional personality traits predicts an increased risk of engaging in delinquency for adolescent males (Ray & others, 2017).

One individual whose goal is to help at-risk adolescents, such as juvenile delinquents, cope more effectively with their lives is Rodney Hammond. Read about his work in *Connecting with Careers*.

## DEPRESSION AND SUICIDE

What is the nature of depression in adolescence? What causes an adolescent to commit suicide?

**Depression** How widespread is depression in adolescence? Rates of ever experiencing major depressive disorder range from 15 to 20 percent for adolescents (Gruber & Sontag, 2009). Adolescents who are experiencing a high level of stress and/or a loss of some type are

at increased risk for developing depression (Cohen & others, 2018; Luyten & Fonagy, 2018). Also, a recent study found that adolescents who became depressed were characterized by a sense of hopelessness (Weersing & others, 2016).

Adolescent females are far more likely to develop depression than are their male counterparts. In a recent study, at 12 years of age, 5.2 percent of females compared to 2 percent of males had experienced first-onset depression (Breslau & others, 2017). In this study, the cumulative incidence of depression from 12 to 17 years of age was 36 percent for females and 14 percent for males. Among the reasons for this gender difference are that females tend to ruminate in their depressed mood and amplify it; females' self-images, especially their body images, are more negative than males'; females face more discrimination than males do; and puberty occurs earlier for girls than for boys (Bunge & others, 2017).

Is adolescent depression linked to problems in emerging and early adulthood? In one study, researchers initially assessed U.S. adolescents when they were 16 to 17 years of age and then again every two years until they were 26 to 27 years of age (Naicker & others, 2013). In this study, significant effects that persisted after 10 years were depression recurrence, stronger depressive symptoms, migraine headaches, poor self-rated health, and low levels of social support. In another longitudinal study of young people from 14 to 24 years of age, mild to moderate levels of early adolescent depressive behaviors were linked to lower maternal relationship quality, less positive romantic relationships, and greater loneliness in emerging adulthood (Allen & others, 2014).

Genes are linked to adolescent depression (Hannigan, McAdams, & Eley, 2017; Van Assche & others, 2017). One study found that certain dopamine-related genes were associated with depressive symptoms in adolescents (Adkins & others, 2012). And another study revealed that the link between adolescent girls' perceived stress and depression occurred only when the girls had the short version of the serotonin-related gene 5HTTLPR (Beaver & others, 2012).

Certain family factors place adolescents at risk for developing depression (Dardas, van de Water, & Simmons, 2018; Oppenheimer, Hankin, & Young, 2018; Possel & others, 2018). These include having a depressed parent, emotionally unavailable parents, parents who have high marital conflict, and parents with financial problems. One study also revealed that mother-daughter co-rumination (extensively discussing, rehashing, and speculating about problems) was linked to an increase in anxiety and depression in adolescent girls (Waller & Rose, 2010). Also, a recent study found that positive parenting characteristics such as emotional and educational support were associated with lower rates of depression in adolescents (Smokowski & others, 2015).

Poor peer relationships also are associated with adolescent depression (Rose & Smith, 2018; Siennick & others, 2017). A recent study found that adolescents who were isolated from their peers and whose caregivers emotionally neglected them were at significant risk for developing depression (Christ, Kwak, & Lu, 2017). Not having a close relationship with a best friend, having less contact with friends, and being rejected by peers increase depressive tendencies in adolescents (Platt, Kadosh, & Lau, 2013). One study found that relational aggression was linked to depression for girls (Spiker & others, 2012).

Friendship often provides social support. However, whether friendship is linked with a lower level of depression among girls and boys depends on the type of friendship. For example, in one study young adolescents with nondepressed friends were less likely to be depressed than young adolescents without friends, whereas young adolescents with depressed friends were more likely to be depressed (Brendgen & others, 2010). And a study of third- through ninth-graders revealed that girls' co-rumination predicted not only an increase in the positive quality of the friendship, but also an increase in further co-rumination and in depressive and anxiety symptoms (Rose, Carlson, & Waller, 2007). Also, in a recent study, co-rumination with friends was linked to greater peer stress for adolescent girls (Rose & others, 2017). Further, problems in romantic relationships can produce adolescent depression (Furman, 2018).

A recent meta-analysis found that adolescent females who are obese were more likely to have depression (Quek & others, 2017). Being stressed about weight-related concerns is increasingly thought to contribute to the greater incidence of depression in adolescent girls than in adolescent boys (Herpertz-Dahlmann & others, 2015). One study revealed that adolescent girls' higher level of depressive symptoms was linked to a heightened tendency to perceive themselves as overweight and to diet (Vaughan & Halpern, 2010).

Some therapy treatments have been shown to reduce adolescent depression (Bunge & others, 2017). A research review concluded that drug therapy using serotonin reuptake inhibitors, cognitive

behavior therapy, and interpersonal therapy are effective in treating adolescent depression (Maalouf & Brent, 2012). However, in this review, the most effective treatment was a combination of drug therapy and cognitive behavior therapy. Also, a recent research review concluded that Prozac and other SSRIs (selective serotonin reuptake inhibitors) show clinical benefits for adolescents at risk for moderate and severe depression (Cousins & Goodyer, 2015). Other recent research indicates that family therapy also can be effective in reducing adolescent depression (Poole & others, 2018).

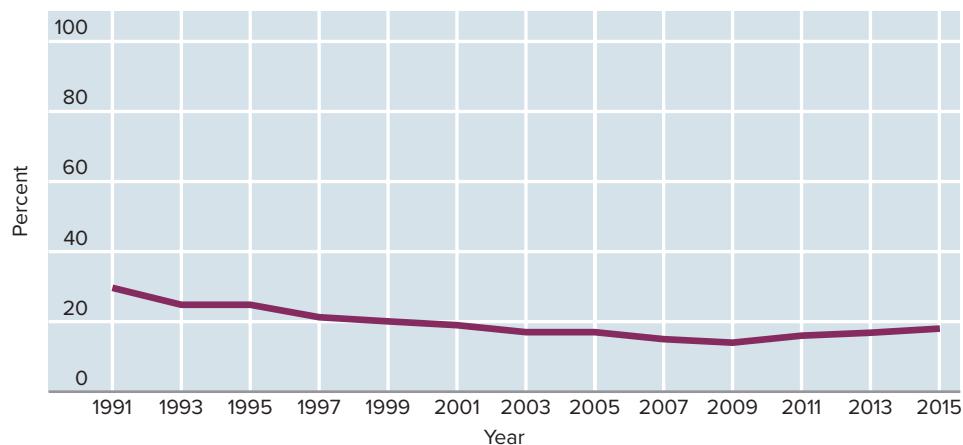

**Suicide** Suicide behavior is rare in childhood but escalates in adolescence and then increases further in emerging adulthood (Park & others, 2006). Suicide is the third-leading cause of death in 10- to 19-year-olds today in the United States (National Center for Health Statistics, 2018). Approximately 4,600 adolescents commit suicide each year (Centers for Disease Control and Prevention, 2018). The rate of suicide among emerging adults is triple that of adolescents (Park & others, 2006).

Although a suicide threat should always be taken seriously, far more adolescents contemplate or attempt it unsuccessfully than actually commit it (Castellvi & others, 2017). As indicated in Figure 6, in the last two decades there has been a considerable decline in the percentage of adolescents who think seriously about committing suicide, although from 2009 to 2015 this percentage increased from 14 to 18 percent (Kann & others, 2016a). In this national study, in 2015, 8.6 percent attempted suicide and 2.8 percent engaged in suicide attempts that required medical attention.

Females are more likely to attempt suicide than males, but males are more likely to succeed in committing suicide (Ivey-Stephenson & others, 2017). Males use more lethal means, such as guns, in their suicide attempts, whereas adolescent females are more likely to cut their wrists or take an overdose of sleeping pills—methods less likely to result in death.

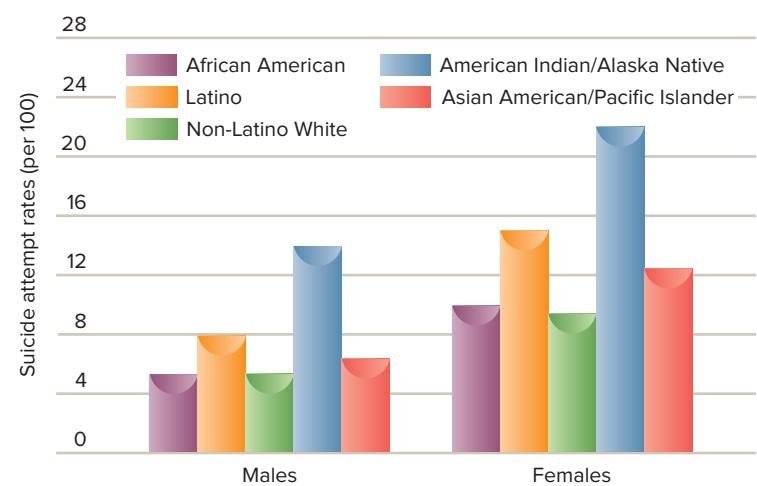

Both earlier and later experiences are linked to suicide attempts, and these can involve family relationships (Bjorkenstam, Kosidou, & Bjorkenstam, 2017; King & others, 2018). The adolescent may have a long-standing history of family instability and unhappiness (Wan & Leung, 2010). Just as a lack of affection and emotional support, high control, and parental pressure for achievement during childhood are related to adolescent depression, such combinations of family experiences also are likely to show up as distal factors in adolescents' suicide attempts. In two recent studies, child maltreatment during the childhood years was linked with suicide attempts in adulthood (Park, 2017; Turner & others, 2017). Further, a recent study indicated that adolescents who were being treated in a suicide clinic experienced lower family cohesion than nonclinical adolescents and adolescents being treated at a general psychiatric clinic (Jakobsen, Larsen, & Horwood, 2017). Recent and current stressful circumstances, such as getting poor grades in school or experiencing the breakup of a romantic relationship, also may trigger suicide attempts (Im, Oh, & Suk, 2017).

Adolescent suicide attempts also vary across ethnic groups in the United States (Wong & others, 2012). As indicated in Figure 6, more than 20 percent of American Indian/Alaska Native (AI/AN) female adolescents reported that they had attempted suicide in the previous year, and suicide accounts for almost 20 percent of AI/AN deaths in 15- to 19-year-olds (Goldston & others, 2008). As indicated in Figure 7, African American and non-Latino White males reported the lowest incidence of suicide attempts. A major risk factor in the high rate of suicide attempts by AI/AN adolescents is their elevated rate of alcohol abuse.

*Note:* Data shown are for one-year rates of self-reported suicide attempts.

Just as genetic factors are associated with depression, they also are associated with suicide (De la Cruz-Cano, 2017; Rao & others, 2017). The closer a person's genetic relationship to someone who has committed suicide, the more likely that person is to also commit suicide.

What is the psychological profile of the suicidal adolescent? Suicidal adolescents often have depressive symptoms (du Roscoät & others, 2016; Thompson & Swartout, 2018). Although not all depressed adolescents are suicidal, depression is the most frequently cited factor associated with adolescent suicide (Thapar & others, 2012). In a recent study, depressed adolescent suicide attempters had greater anhedonia severity (Auerbach & others, 2015). A sense of hopelessness, low self-esteem, and high self-blame also are associated with adolescent suicide (Asarnow & others, 2015; Chang, 2017). Also, in a recent study, a sense of hopelessness predicted an increase in suicidal ideation in depressed adolescents (Wolfe & others, 2018). In another recent study, the most significant factor in a first suicide attempt during adolescence was a major depressive episode, while for children it was child maltreatment (Peyre & others, 2017). Also, in another study, more recent and frequent alcohol use among young adolescents increased the likelihood of suicidal ideation and suicide attempts in African American youth (Tomek & others, 2015). Further, one study found that peer victimization was linked to suicidal ideation and suicide attempts, with cyberbullying more strongly associated with suicidal ideation than traditional bullying (van Geel, Vedder, & Tanilon, 2014).

## THE INTERRELATION OF PROBLEMS AND SUCCESSFUL PREVENTION/INTERVENTION PROGRAMS

We have described some of the major adolescent problems: substance abuse; juvenile delinquency; school-related problems such as dropping out of school; adolescent pregnancy and sexually transmitted infections; eating disorders; depression; and suicide.

The four problems that affect the most adolescents are (1) drug abuse, (2) juvenile delinquency, (3) sexual problems, and (4) school-related problems (Dryfoos, 1990; Dryfoos & Barkin, 2006). The adolescents most at risk have more than one of these problems. Researchers are increasingly finding that problem behaviors in adolescence are interrelated (Marotta, 2017). For example, heavy substance abuse is related to early sexual activity, lower grades, dropping out of school, and delinquency (Belenko & others, 2017). Early initiation of sexual activity and inadequate use of contraception is associated with the use of cigarettes and alcohol, the use of marijuana and other illicit drugs, lower grades, dropping out of school, and delinquency (Lowry & others, 2017). Delinquency is related to early sexual activity, early pregnancy, substance abuse, and dropping out of school (Belenko & others, 2017).

As many as 10 percent of adolescents in the United States have been estimated to engage in all four of these problem behaviors (for example, adolescents who have dropped out of

school are behind in their grade level, are heavy users of drugs, regularly use cigarettes and marijuana, and are sexually active but do not use contraception). In 1990, it was estimated that another 15 percent of high-risk youth engaged in two or three of the four main problem behaviors (Dryfoos, 1990). Sixteen years later, this figure had increased to 20 percent of all U.S. adolescents (Dryfoos & Barkin, 2006).

A review of the programs that have been successful in preventing or reducing adolescent problems found these common components (Dryfoos, 1990; Dryfoos & Barkin, 2006):

1. *Intensive individualized attention.* In successful programs, high-risk adolescents are attached to a responsible adult who gives the adolescent attention and deals with the adolescent's specific needs (Plourde & others, 2017). This theme occurs in a number of programs. In a successful substance-abuse program, a student assistance counselor is available full-time for individual counseling and referral for treatment.
2. *Community-wide multiagency collaborative approaches.* The basic philosophy of community-wide programs is that a

## Which Children Are Most Likely to Benefit from Early Intervention?

Fast Track is an intervention that attempts to lower the risk of juvenile delinquency and other problems (Conduct Problems Prevention Research Group, 2010, 2011, 2013; Dodge, Godwin, & Conduct Problems Prevention Research Group, 2013; Dodge & McCourt, 2010; Dodge & others, 2015; Jones & others, 2010; King & others, 2017; Miller & others, 2010; Zheng & others, 2017). Schools in four areas (Durham, North Carolina; Nashville, Tennessee; Seattle, Washington; and rural central Pennsylvania) were identified as high-risk based on neighborhood crime and poverty data. Researchers screened more than 9,000 kindergarten children in the four schools and randomly assigned 891 of the highest-risk and moderate-risk children to intervention or control groups. The average age of the children when the intervention began was 6.5 years.

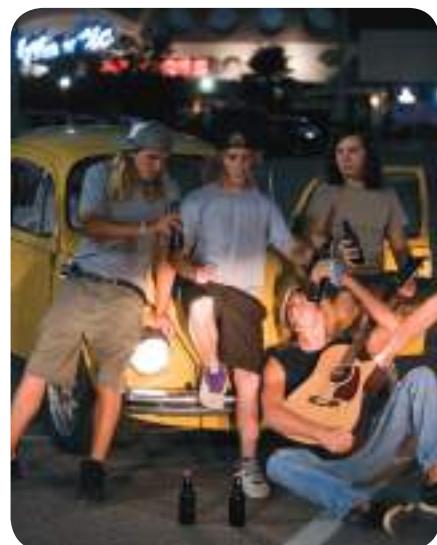

The 10-year intervention consisted of parent behavior management training, child social cognitive skills training, reading tutoring, home visitations, mentoring, and a revised classroom curriculum that was designed to increase socioemotional competence and decrease aggression. Outcomes were assessed in the third, sixth, and ninth grades for conduct disorder (multiple instances of behaviors such as truancy, running away, fire setting, cruelty to animals, breaking and entering, and excessive fighting across a 6-month period), oppositional defiant disorder (an ongoing pattern of disobedient, hostile, and defiant behavior toward authority figures), attention deficit hyperactivity disorder (as described as having one or more of these characteristics over a period of time: inattention, hyperactivity, and impulsivity), any externalizing disorder (presence of any of the three disorders previously described), and self-reported antisocial behavior (a list of 34 behaviors, such as skipping school, stealing, and attacking someone with an intent to hurt them).

The extensive intervention was successful only for children and adolescents who were identified as having the highest risk in kindergarten, lowering their incidence of conduct disorder, attention deficit hyperactivity disorder, any externalized disorder, and antisocial behavior (Dodge & McCourt, 2010). Positive outcomes for the intervention occurred as early as the third grade and continued through the ninth grade. For example, in the ninth grade the intervention reduced the likelihood that the highest-risk kindergarten children would develop conduct disorder by 75 percent, attention deficit hyperactivity disorder by 53 percent, and any externalized disorder by 43 percent. Through age 19, the comprehensive Fast Track early intervention was successful in reducing youth arrest rates (Conduct Problems Prevention Research Group, 2011, 2013; Miller & others, 2010). And at age 25, the early intervention was effective in reducing violent and drug crimes, as well as risky sexual behavior (Dodge & others, 2015). Also, at age 25 those who were given the early intervention had higher well-being scores. Further, one study found that the intervention's impact on adolescents' antisocial behavior was linked to three social cognitive processes: reducing hostile-attribution biases, improving responses to social problems, and devaluing aggression (Dodge, Godwin, & Conduct Problems Prevention Research Group, 2013). And in the most recent research analysis involving this project, approximately one-third of Fast Track's reduction in later crime outcomes in emerging adulthood was attributed to improvements in social and self-regulation skills, such as prosocial behavior, emotion regulation, and problem solving, at 6 to 11 years of age (Sorensen, Dodge, & Conduct Problems Prevention Research Group, 2016).

number of different programs and services have to be in place (Trude & others, 2018). In one successful substance-abuse program, a community-wide health promotion campaign has been implemented that uses local media and community education, in concert with a substance-abuse curriculum in the schools.

3. *Early identification and intervention.* Reaching younger children and their families before children develop problems or at the onset of their problems is a successful strategy (Almy & Cicchetti, 2018). One preschool program provides an excellent model for preventing delinquency, pregnancy, substance abuse, and dropping out of school. Operated by the High/Scope Foundation in Ypsilanti, Michigan, from 1962 to 1967, the Perry Preschool had a long-term positive impact on its students. This enrichment program, directed by David Weikart, served disadvantaged African American children. They attended a high-quality two-year preschool program and received weekly home visits from program personnel. Based on official police records, by age 19, individuals who had attended the Perry Preschool program were less likely to have been arrested and reported fewer adult offenses than a control group did. The Perry Preschool students also were less likely to drop out of high school, and teachers rated their social behavior as more competent than that of a control group who had not received the enriched preschool experience (High/Scope Resource, 2005).

## topical connections *looking forward*

The transitional time frame between adolescence and adulthood that is labeled emerging adulthood occurs between approximately 18 and 25 years of age. Many emerging adults explore their identity and experience instability in different contexts with greater intensity than they did as adolescents. As adults, they benefit from a secure attachment style in close relationships. Love and possibly marriage become central aspects of many young adults' socioemotional development. Many young adults not only are marrying later or not at all but also are having children later than in past decades. Many young adults also cohabit with a romantic partner.

# Socioemotional Development in Adolescence

### 1 The Self, Identity, and Religious/Spiritual Development

**LG1**

Discuss self, identity, and religious/spiritual development in adolescence.

Self-Esteem

Identity

- Some researchers have found that self-esteem declines in early adolescence for both boys and girls, but the drop for girls is greater. Other researchers caution that these declines are often exaggerated and actually are small. Self-esteem reflects perceptions that do not always match reality. Thus, high self-esteem may be justified or it might reflect an arrogant, grandiose self-image that is not warranted. Controversy surrounds the question of whether today's adolescents and emerging adults are more narcissistic than their counterparts in earlier generations.
- Identity development is complex and takes place in bits and pieces. Erikson argues that identity versus identity confusion is the fifth stage of the human life span, which individuals experience during adolescence.
- A psychosocial moratorium during adolescence allows the personality and role experimentation that are important aspects of identity development. James Marcia proposed four identity

statuses—identity diffusion, foreclosure, moratorium, and achievement—that are based on crisis (exploration) and commitment. Increasingly, experts argue that the main changes in identity occur in emerging adulthood rather than adolescence. Individuals often follow moratorium-achievement-moratorium-achievement (MAMA) cycles in their lives. Throughout the world, ethnic minority groups have struggled to maintain their identities while blending into the majority culture.

#### Religious/Spiritual Development

- Many adolescents show an interest in religious and spiritual development. As part of their search for identity, many adolescents and emerging adults begin to grapple with more complex aspects of religion. Various aspects of religion are linked with positive outcomes in adolescent development.

## 2 Families

### Parental Monitoring and Information Management

### Autonomy and Attachment

### Parent-Adolescent Conflict

LG2

Describe changes that take place in adolescents' relationships with their parents.

- A key aspect of parenting an adolescent is effectively monitoring the adolescent's development. Monitoring includes supervising adolescents' choice of social settings, activities, friends, and academic efforts. Adolescents' management of information involves the extent to which adolescents disclose information to parents about their whereabouts. This disclosure, which is more likely when parents engage in positive parenting practices, is linked to positive adolescent adjustment.
- Many parents have a difficult time handling the adolescent's push for autonomy, even though the push is one of the hallmarks of adolescence. Adolescents do not simply move into a world isolated from parents; attachment to parents increases the probability that an adolescent will be socially competent.
- Parent-adolescent conflict increases in adolescence. The conflict is usually moderate rather than severe, and the increased conflict may serve the positive developmental function of promoting autonomy and identity. A subset of adolescents experience high parent-adolescent conflict, which is linked with negative outcomes.

## 3 Peers

### Friendships

### Peer Groups

### Dating and Romantic Relationships

LG3

Characterize the changes that occur in peer relationships during adolescence.

- Harry Stack Sullivan was the most influential theorist to discuss the importance of adolescent friendships. He argued that there is a dramatic increase in the psychological importance and intimacy of close friends in early adolescence. Friends become increasingly important in meeting social needs.
- The pressure to conform to peers is strong during adolescence, especially during the eighth and ninth grades. Cliques and crowds assume more importance in the lives of adolescents than in the lives of children.
- Dating can have many functions. Three stages characterize the development of romantic relationships in adolescence: (1) entry into romantic attractions and affiliations at about 11 to 13 years of age; (2) exploring romantic relationships at approximately 14 to 16 years of age; and (3) consolidating dyadic romantic bonds at about 17 to 19 years of age. Many gay and lesbian youth date other-sex peers, which can help them to clarify their sexual orientation or disguise it from others. Culture can exert a powerful influence on adolescent dating. Dating shows mixed connections with adjustment during adolescence. Early dating is linked with developmental problems.

## 4 Culture and Adolescent Development

### Cross-Cultural Comparisons

LG4

Explain how culture influences adolescent development.

- There are similarities and differences in adolescents across different countries. In some countries, traditions are being continued in the socialization of adolescents, whereas in others, substantial changes in the experiences of adolescents are taking place. Adolescents often fill their time with different activities, depending on the culture in which they live.

- A rite of passage is a ceremony or ritual that marks an individual's transition from one status to another, especially from childhood to adulthood. In primitive cultures, rites of passage are often well defined. In contemporary America, rites of passage to adulthood are ill-defined.
- Low socioeconomic status and poverty can have extremely negative effects on adolescents' development, including lower academic achievement, lower occupational attainment, and more psychological problems.
- Many of the families that have immigrated to the United States in recent decades come from collectivist cultures in which there is a strong sense of family obligation. Much of the research on ethnic minority adolescents has not teased apart the influences of ethnicity and socioeconomic status. Because of this failure, too often researchers have given ethnic explanations for characteristics that were largely due to socioeconomic factors. Although not all ethnic minority families are poor, poverty contributes to the stress experienced by many ethnic minority adolescents.
- In terms of media use and screen exposure, the average U.S. 8- to 18-year-old spends 6½ hours a day using electronic media. If media multitasking is taken into account, adolescents use electronic media 8 hours a day. Adolescents are rapidly increasing the time they spend online. Older adolescents reduce their TV viewing and video game playing and increase their music listening and computer use. Large numbers of adolescents and college students engage in social networking.

## 5 Adolescent Problems

Juvenile Delinquency

Depression and Suicide

The Interrelation of Problems and Successful Prevention/Intervention Programs

**LG5**

Identify adolescent problems in socioemotional development and strategies for helping adolescents with problems.

- A juvenile delinquent is an adolescent who breaks the law or engages in conduct that is considered illegal. Low socioeconomic status, negative family experiences (especially a low level of parental monitoring and having a sibling who is a delinquent), and negative peer influences have been linked to juvenile delinquency.
- Adolescents and emerging adults have higher rates of depression than children do. Female adolescents and emerging adults are more likely to have mood and depressive disorders than their male counterparts. Suicide is the third-leading cause of death in U.S. adolescents.
- Researchers are increasingly finding that problem behaviors in adolescence are interrelated, and at-risk adolescents have one or more of these problems: (1) drug abuse, (2) juvenile delinquency, (3) sexual problems, and (4) school-related problems. Dryfoos found a number of common components in successful programs designed to prevent or reduce adolescent problems: These programs provide individual attention to high-risk adolescents, they develop community-wide intervention strategies, and they include early identification and intervention.

## Early Adulthood

Early adulthood is a time for work and a time for love, sometimes leaving little time for anything else. For some of us, finding our place in adult society and committing to a more stable life take longer than we imagine. We still ask ourselves who we are and wonder if it isn't enough just to be. Our dreams continue and our thoughts are bold, but at some point we become more pragmatic. Sex and love are powerful passions in our lives—at times angels of light, at others fiends of torment. And we possibly will never fully know the love of our parents until we become parents ourselves. This section contains two chapters: “Physical and Cognitive Development in Early Adulthood” and “Socioemotional Development in Early Adulthood.”

**H**e was a senior in college when both of his parents died of cancer within five weeks of each other. What would he do? He and his 8-year-old brother left Chicago to live in California where their older sister was entering law school. Dave would take care of his younger brother, but he needed a job. That first summer, he took a class in furniture painting; then he worked for a geological surveying company, re-creating maps on a computer. Soon, though, he did something very different: with friends from high school, Dave Eggers started *Might*, a satirical magazine for twenty-somethings. It was an edgy, highly acclaimed publication, but not a moneymaker. After a few years, Eggers had to shut down the magazine, and he abandoned California for New York.

This does not sound like a promising start for a career. But within a decade after his parents died, Eggers had not only raised his young brother but had also founded a quarterly journal and Web site, *McSweeney's*, and had written a best-selling book, *A Heartbreaking Work of Staggering Genius*, which received the National Book Critics Circle Award and was nominated for a Pulitzer Prize. It is a slightly fictionalized account of Eggers' life as he helped care for his dying mother, raised his brother, and searched for his own place in the world. Despite the pain of his loss and the responsibility for his brother, Eggers quickly built a record of achievement as a young adult.

## topical connections *looking back* -----

Early adolescence is a time of dramatic physical change as puberty unfolds. Pubertal change also brings considerable interest in one's body image. And pubertal change ushers in an intense interest in sexuality. Although most adolescents develop a positive sexual identity, many encounter sexual risk factors that can lead to negative developmental outcomes. Adolescence also is a critical time in the development of behaviors related to health, such as good nutrition and regular exercise, which are health enhancing, and drug abuse, which is health compromising. Significant changes occur in the adolescent's brain—the early development of the amygdala and the delayed development of the prefrontal cortex—that may contribute to risk taking and sensation seeking. Adolescent thinking becomes more abstract, idealistic, and logical—which Piaget described as the key aspects of formal operational thought. The brain's development and social contexts influence adolescents' decision making.

# preview

In this chapter we will explore many aspects of physical and cognitive development in early adulthood. These include some of the areas that were so important in Dave Eggers' life, such as using his creative talents and pursuing a career. We also will examine changes in physical development, sexuality, and cognitive development. We will begin by addressing the transition from adolescence to adulthood, a time during which Dave Eggers displayed resilience in the face of intense stress.

## 1 The Transition from Adolescence to Adulthood

LG1 Describe the transition from adolescence to adulthood.

Becoming an Adult

The Transition from High School to College

When does an adolescent become an adult? We've discussed that it is not easy to tell when a girl or a boy enters adolescence. The task of determining when an individual becomes an adult is even more difficult.

### BECOMING AN ADULT

For most individuals, becoming an adult involves a lengthy transition period. Recently, the transition from adolescence to adulthood has been referred to as **emerging adulthood**, which occurs from approximately 18 to 25 years of age (Arnett, 2006, 2007, 2010, 2012, 2015a). Experimentation and exploration characterize the emerging adult. At this point in their development, many individuals are still exploring which career path they want to follow, what they want their identity to be, and which lifestyle they want to adopt (for example, single, cohabiting, or married).

**Key Features** Jeffrey Arnett (2006) concluded that five key features characterize emerging adulthood:

- *Identity exploration, especially in love and work.* Emerging adulthood is a time during which key changes in identity take place for many individuals (Layland, Hill, & Nelson, 2018; Vosylis, Erentaite, & Crocetti, 2018).
- *Instability.* Residential changes peak during early adulthood, a time during which instability also is common in love, work, and education.
- *Self-focused.* According to Arnett (2006, p. 10), emerging adults "are self-focused in the sense that they have little in the way of social obligations, little in the way of duties and commitments to others, which leaves them with a great deal of autonomy in running their own lives."
- *Feeling in-between.* Many emerging adults don't consider themselves adolescents or full-fledged adults.
- *The age of possibilities, a time when individuals have an opportunity to transform their lives.* Arnett (2006) describes two ways in which emerging adulthood is the age of possibilities: (1) many emerging adults are optimistic about their future; and (2) for emerging adults who have experienced difficult times while growing up, emerging adulthood presents an opportunity to chart their life course in a more positive direction.

**emerging adulthood** The transition from adolescence to adulthood (occurring from approximately 18 to 25 years of age), which is characterized by experimentation and exploration.

Research indicates that these five aspects characterize not only individuals in the United States as they make the transition from adolescence to early adulthood, but also their counterparts in European countries and Australia (Arnett, 2012, 2015a; Buhl & Lanz, 2007; Sirsch & others, 2009). Although emerging adulthood does not characterize development in all cultures, it does appear to occur in cultures that postpone assuming adult roles and

responsibilities (Kins & Beyers, 2010). The concept of emerging adulthood has been criticized as applying mainly to privileged adolescents and not being a self-determined choice for many young people, especially those in limiting socioeconomic conditions (Cote & Bynner, 2008; Mitchell & Syed, 2015). One study revealed that U.S. at-risk youth entered emerging adulthood slightly earlier than the general population of youth (Lisha & others, 2014).

In a recent analysis, Seth Schwartz (2016) described the two-sided coin of emerging adulthood. As indicated by Arnett, for emerging adults who have experienced troubled times while growing up, emerging adulthood represents a time when they can redirect their lives and move into a more positive developmental trajectory. Indeed, for many individuals, emerging adults have a higher level of well-being than adolescents. But for others, emerging adulthood is a time of increasing anxiety, depression, and problems, as well as considerable worry about one's future. As will be seen later in this chapter, emerging adulthood is a time when many individuals engage in unhealthy behaviors. During this period binge drinking peaks, risky sexual behavior is more frequent than it will be in the late twenties, and poor sleep habits are common. However, as with any period of development, there are clusters of emerging adults who are engaging in health-enhancing behaviors while others are engaging in health-damaging behaviors. In a national longitudinal study of emerging adult health choices, three categories became apparent. The following categories reflected whether individuals smoked or not, engaged in binge drinking or not, were obese or not, and engaged in exercise regularly or were sedentary: (1) consistently healthy lifestyle, (2) consistently unhealthy lifestyle, and (3) shifting lifestyle over time (Daw, Margolis, & Wright, 2017).

But as indicated earlier, an important aspect of emerging adulthood is the resilience that some individuals have shown in moving their life in a positive direction following a troubled adolescence (Leopold, Munz, & Michele-Malkowsky, 2018; Masten, 2017; Masten & Kalstabakken, 2017). A review and analysis of research on resilience in the transition to adulthood concluded that the increased freedom that is available to emerging adults in Western society places a premium on the capacity to plan ahead, delay gratification, and make positive choices (Burt & Paysnick, 2012). Also emphasized in resilient adaptation during emerging adulthood was the importance of forming positive close relationships—to some degree with parents, but more often with supportive romantic partners, close friends, and mentors.

**The Changing Landscape of Emerging and Early Adulthood** In earlier generations, individuals in their mid-twenties at the latest were expected to have finished college, obtained a full-time job, and established their own household, most often with a spouse and a child. However, individuals are now taking much longer to reach these developmental milestones, many of which they are not experiencing until their late twenties or even thirties (Vespa, 2017). It is not surprising that their parents recall having had a much earlier timetable of reaching these developmental milestones.

Consider that for the first time in the modern era, in 2014 living with parents was the most frequent living arrangement for 18- to 34-year-olds (Fry, 2016). Dating all the way back to 1880, living with a romantic partner, whether a spouse or a significant other, was previously the most common living arrangement for emerging and young adults. In 2014, 32.1 percent of 18- to 34-year-olds lived with their parents, followed by 31.6 percent who lived with a spouse or partner in their own home, while 14 percent lived alone. The remaining 22 percent lived in another family member's home, with a non-relative, or in group quarters (a college dorm, for example).

In terms of education, today's emerging and young adults are better educated than their counterparts in the 1970s (Vespa, 2017). For example, they are much more likely to have a college degree today. The biggest reason for this increased educational attainment since the 1970s, though, is a gender difference reversal. In 1975, more young men had college degrees, but today there are more young women than young men who have a college degree.

In terms of work, more young adults are working today than in 1975 (Vespa, 2017). The main reason for this increase also involves a gender change—the significant rise of young women in the workforce, which has increased from slightly below 50 percent to more than two-thirds of young women in the workforce today. In 1975, almost all of the women who were not in the workforce were taking care of their home and family. However, in 2016, less than 50 percent of the women who were not in the workforce were homemakers.

We will further discuss these lifestyle changes in the chapter on “Socioemotional Development in Early Adulthood.”

Parents can play an important role in guiding and preparing adolescents for the changing landscape of emerging adulthood. Joseph and Claudia Allen (2009), authors of *Escaping the Endless Adolescence: How We Can Help Our Teenagers Grow Up Before They Grow Old*, opened their book with a chapter titled, “Is Twenty-five the New Fifteen?” They argue that in recent decades adolescents have experienced a world that places more challenges on maturing into a competent adult. In their words (p. 17),

Generations ago, fourteen-year-olds used to drive, seventeen-year-olds led armies, and even average teens contributed labor and income that helped keep their families afloat. While facing other problems, those teens displayed adult-like maturity far more quickly than today’s, who are remarkably well kept, but cut off from most of the responsibility, challenge, and growth-producing feedback of the adult world. Parents of twenty-somethings used to lament, “They grow up so fast.” But that seems to be replaced with, “Well, . . . Mary’s living at home a bit while she sorts things out.”

The Allens conclude that what is happening to the current generation of adolescents is that after adolescence, they are experiencing “more adolescence” instead of adequately being launched into the adult years. Even many adolescents who have gotten good grades and then as emerging adults continued to achieve academic success in college later find themselves in their mid-twenties not having a clue about how to find a meaningful job, manage their finances, or live independently. In a recent study, maturity fears among undergraduate students were assessed from 1982 to 2012 (Smith & others, 2017). Both male and female undergraduates’ maturity fears increased across time. Thus, recent cohorts of emerging adults seem more reluctant to mature than earlier cohorts were.

The Allens offer the following suggestions for helping adolescents become more mature on their way to adulthood:

- *Provide them with opportunities to be contributors.* Help them move away from being consumers by creating more effective work experiences (quality work apprenticeships, for example), or service learning opportunities that allow adolescents to make meaningful contributions.
- *Give candid, quality feedback to adolescents.* Don’t just shower praise and material things on them, but let them see how the real world works. Don’t protect them from criticism, constructive or negative. Protecting them in this way only leaves them ill-equipped to deal with the ups and downs of the real world of adulthood.
- *Create positive adult connections with adolescents.* Many adolescents deny that they need parental support or attachment to parents, but to help them develop maturity on the way to adulthood, they do. Exploring a wider social world than in childhood, adolescents need to be connected to parents and other adults in positive ways to be able to handle autonomy maturely.
- *Challenge adolescents to become more competent.* Adults need to do fewer things for adolescents that they can accomplish for themselves. Providing adolescents with opportunities to engage in tasks that are just beyond their current level of ability stretches their minds and helps them to make progress along the road to maturity.

**Markers of Becoming an Adult** In the United States, the most widely recognized marker of entry into adulthood is holding a more or less permanent, full-time job, which usually happens when an individual finishes school—high school for some, college for others, graduate or professional school for still others. However, other criteria are far from clear. Economic independence is one marker of adult status, but achieving it is often a long process. College graduates are increasingly returning to live with their parents as they attempt to establish themselves economically. However, one study revealed that continued co-residence with parents during emerging adulthood slowed down the process of becoming a self-sufficient and independent adult (Kins & Beyers, 2010).

Other studies suggest that taking responsibility for oneself may be an important marker of adult status for many individuals (Smith & others, 2017). In one study, both parents and

college students agreed that taking responsibility for one's actions and developing emotional control are important aspects of becoming an adult (Nelson & others, 2007). And in a recent study of Danish emerging adults, the most widely described markers of emerging adulthood were accepting self-responsibility, making independent decisions, and becoming financially independent (Arnett & Padilla-Walker, 2015). In this study the least-described markers were the traditional transition events of getting married and avoiding getting drunk. Also, a recent U.S. study of community college students found that they believed adulthood would mean being able to care for themselves and others (Katsiaficas, 2017).

What we have identified as markers of adult status mainly characterize individuals in developed countries, especially the United States. Are the criteria for adulthood the same in developing countries as they are in the United States? In developing countries, marriage is more often a significant marker for entry into adulthood, and this usually occurs much earlier than the adulthood markers in the United States (Arnett, 2004, 2015b). In one study, the majority of 18- to 26-year-olds in India felt that they had achieved adulthood (Seiter & Nelson, 2011).

## THE TRANSITION FROM HIGH SCHOOL TO COLLEGE

For many individuals in developed countries, graduating from high school and going to college is an important aspect of the transition to adulthood (Eagan & others, 2017). Just as the transition from elementary school to middle or junior high school involves change and possible stress, so does the transition from high school to college. The two transitions have many parallels. Going from being a senior in high school to being a freshman in college replays the top-dog phenomenon of transferring from the oldest and most powerful group of students to the youngest and least powerful group of students that occurred as adolescence began. For many students, the transition from high school to college involves movement to a larger, more impersonal school structure; interaction with peers from more diverse geographical and sometimes more diverse ethnic backgrounds; and increased focus on achievement and its assessment. And like the transition from elementary to middle or junior high school, the transition from high school to college can involve positive features. Students are more likely to feel grown up, have more subjects from which to select, have more time to spend with peers, have more opportunities to explore different lifestyles and values, enjoy greater independence from parental monitoring, and be challenged intellectually by academic work (Halonen & Santrock, 2013; Staley, 2019).

Over the past three decades, the Higher Education Research Institute at UCLA has surveyed first-year college students regarding their backgrounds, experiences, and views on a number of topics. In recent years, traditional-aged college students have shown an increased concern for personal well-being and a decreased concern for the well-being of others, especially for the disadvantaged (Eagan & others, 2017). Today's college freshmen are more strongly motivated to be well-off financially and less motivated to develop a meaningful philosophy of life than were their counterparts of 40 years ago. In 2016, 82.4 percent of students (the highest percent ever in this survey) viewed becoming well-off financially as an "essential" or a "very important" objective compared with only 42 percent in 1971.

There are, however, some signs that U.S. college students are shifting toward a stronger interest in the welfare of society. In the survey just described, interest in developing a meaningful philosophy of life increased from 39 percent to 46.8 percent of U.S. college freshmen from 2001 through 2016 (Eagan & others, 2017).

An increasing number of first-year college students also report having higher levels of stress and depression. In the national survey just described, 41 percent of first-year college students said they frequently or occasionally felt overwhelmed with all they had to do, 12 percent indicated they were depressed, and 34.5 percent reported feeling anxious (Eagan & others, 2017).

Most college campuses have a counseling center that provides access to mental health professionals who can help students learn effective ways to cope with stress. Counselors can provide good information about coping with stress and dealing with academic challenges. To read about the work of college counselor Grace Leaf, see *Connecting with Careers*.

The transition from high school to college often involves positive as well as negative features. In college, students are likely to feel grown up, be able to spend more time with peers, have more opportunities to explore different lifestyles and values, and enjoy greater freedom from parental monitoring. However, college involves a larger, more impersonal school structure and an increased focus on achievement and its assessment.

Eating and Weight

Regular Exercise

Substance Abuse

As more information becomes available about healthy lifestyles and how they contribute to a longer life span, emerging and young adults are increasingly interested in learning about physical performance, health, nutrition, exercise, and addiction.

## PHYSICAL PERFORMANCE AND DEVELOPMENT

Most of us reach our peak levels of physical performance before the age of 30, often between the ages of 19 and 26. This peak of physical performance occurs not only for the average young adult but for outstanding athletes as well. Different types of athletes, however, reach their peak performances at different ages. Most swimmers and gymnasts peak in their late teens. Golfers and marathon runners tend to peak in their late twenties. In other areas of

athletics, peak performance often occurs in the early to mid-twenties. However, in recent years, some highly conditioned athletes—such as Dana Torres (Olympic swimming) and Tom Brady (football)—have stretched the upper age limits of award-winning performances.

Not only do we reach our peak in physical performance during early adulthood, but it is also during this age period that we begin to decline in physical performance. Muscle tone and strength usually begin to show signs of decline around the age of 30. Sagging chins and protruding abdomens also may begin to appear for the first time. The lessening of physical abilities is a common complaint among the just-turned thirties.

## HEALTH

Emerging adults have more than twice the mortality rate of adolescents (Park & others, 2006). As indicated in Figure 1, males are mainly responsible for the higher mortality rate of emerging adults. Further, compared with adolescents, emerging adults engage in more health-compromising behaviors, have more chronic disorders, are more likely to be obese, and are more likely to have a mental disorder than are adolescents (Irwin, 2010). In a more recent analysis, most health care indicators had changed little across the previous decade for adolescents and emerging adults (Park & others, 2014).

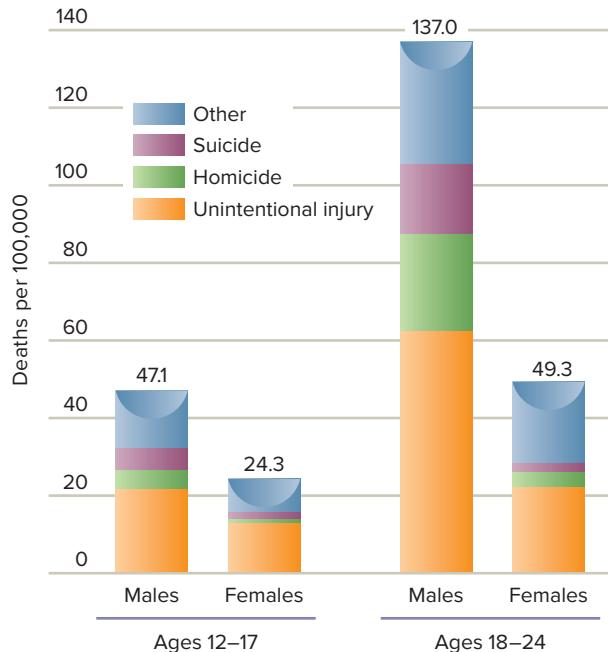

Although most college students know what it takes to prevent illness and promote health, they don't fare very well when it comes to applying this information to themselves. In many cases, emerging adults are not as healthy as they seem (Fatusi & Hindin, 2010; Powers & Howley, 2018). One study revealed that college students from low-SES backgrounds engaged in lower levels of physical activity, ate more fast food and fewer fruits/vegetables, and used more unhealthy weight control methods than their higher-SES counterparts did (VanKim & Laska, 2012).

A longitudinal study revealed that most bad health habits that were engaged in during adolescence increased in emerging adulthood (Harris & others, 2006). Inactivity, poor diet, obesity, substance abuse, inadequate reproductive health care, and use of health care facilities worsened in emerging adulthood. For example, when they were 12 to 18 years of age, only 5 percent of the study participants reported no weekly exercise, but when they became 19 to 26 years of age, 46 percent said they did not exercise during a typical week. Also, a more recent study found that rates of being overweight or obese increased from 25.6 percent for college freshmen to 32 percent for college seniors (Nicoteri & Miskovsky, 2014).

In emerging and early adulthood, few individuals consider how their personal lifestyles will affect their health later in their adult lives. As emerging adults, many of us develop a pattern of not eating breakfast, not eating regular meals, and relying on snacks as our main food source during the day, overeating to the point where we exceed the normal weight for our age, smoking moderately or excessively, drinking moderately or excessively, failing to exercise, getting by with only a few hours of sleep at night, and engaging in risky sexual behavior (Lipson & Sonnevile, 2017; Schlarb, Friedrich, & Clausen, 2017; Schulenberg & others, 2017). These lifestyles are associated with poor health, which in turn diminishes life satisfaction (Faris & others, 2017; Kilwein & Looby, 2017; Powers & Howley, 2018). In the Berkeley Longitudinal Study—in which individuals were evaluated over a period of 40 years—physical health at age 30 predicted life satisfaction at age 70, more so for men than for women (Mussen, Honzik, & Eichorn, 1982).

One study explored links between health behavior and life satisfaction in more than 17,000 individuals 17 to 30 years of age in 21 countries (Grant, Wardle, & Steptoe, 2009). The young adults' life satisfaction was positively related to not smoking, exercising regularly, using sun protection, eating fruit, and limiting fat intake, but was not related to alcohol consumption and fiber intake.

The health profile of emerging and young adults can be improved by reducing the incidence of certain health-impairing lifestyles, such as overeating, and by engaging in health-improving lifestyles that include good eating habits, regular exercise, abstaining from drugs, and getting adequate sleep (Donatelle, 2019; Powers & Howley, 2018; Schiff, 2017, 2019; Smith & Collene,

Recent research indicates that traditional-age freshman college students go to bed more than one hour later than high school seniors but by their third or fourth years of college, their bedtimes begin to get earlier. Connect to “Physical and Cognitive Development in Early Adulthood.”

2019; Sorte, Daeschel, & Amador, 2017; Walton-Fisette & Wuest, 2018). For example, a study of college students found that regularly engaging in moderate or vigorous physical activity was linked to adequate daily fruit and vegetable consumption, healthy body mass index, not smoking, being less depressed, having a lower incidence of binge drinking, being less likely to have multiple sex partners, and getting adequate sleep (Dinger, Brittain, & Hutchinson, 2014). Another study found a bidirectional link between sleep quality/duration and adjustment (depression, stress, and self-esteem) (Tavernier & Willoughby, 2014).

Recent research indicates that 70 percent of college students do not get adequate sleep and that 50 percent of them report daytime sleepiness (Hershner & Chervin, 2015). In a recent study, higher energy drink consumption was linked to more sleep problems in college students (Faris & others, 2017). College students are not the only ones who are getting inadequate sleep. Many adults in their late twenties and thirties don’t get enough either (Brimah & others, 2013). A statement by the American Academy of Sleep Medicine and Sleep Research Society (Luyster & others, 2012) emphasized that chronic sleep deprivation may contribute to cardiovascular disease and a shortened life span, and also result in cognitive and motor impairment that increases the risk of motor vehicle crashes and work-related accidents.

The average American adult gets just under seven hours of sleep a night. How much sleep do adults need to function optimally the next day? An increasing number of experts note that eight hours of sleep or more per night are necessary for optimal performance the next day. These experts argue that many adults have become sleep deprived (Brimah & others, 2013). Work pressures, school pressures, family obligations, and social obligations often lead to long hours of wakefulness and irregular sleep/wake schedules.

Professional guidelines for adolescents and emerging adults recommend annual preventive medical visits with screening and guidance for health-related behaviors. One study examined the delivery of preventive health-care services to emerging adults 18 to 26 years of age (Lau & others, 2013). In this study, rates of preventive services utilized by emerging adults were generally low. Females were more likely to receive health care services than males were.

## EATING AND WEIGHT

Earlier we discussed aspects of overweight children’s lives and examined the eating disorders of anorexia nervosa and bulimia nervosa in adolescence. Now we will turn our attention to obesity and the extensive preoccupation that many young adults have with dieting.

**Obesity** Obesity is not only a problem for many children and adolescents but also a serious and pervasive problem for many adults (Schiff, 2017, 2019; Smith & Collene, 2019; Sorte, Daeschel, & Amador, 2017; Thompson, Manore, & Vaughan, 2017). In a recent U.S. survey conducted in 2013–2014, 37.7 percent of adults were classified as obese (35 percent of men; 40 percent of women) (Flegal & others, 2016). In this survey, 34 percent of 20- to 39-year-olds were obese. Also, one analysis predicted that 42 percent of U.S. adults will be obese in 2030 (Finkelstein & others, 2012). In a recent international comparison of 33 countries, the United States had the highest percentage of obese adults (38.2 percent) and Japan the lowest percentage (3.7); the average of the countries was 19.5 percent of the population being obese (OECD, 2017).

Being overweight or obese is linked to increased risk of hypertension, diabetes, and cardiovascular disease (Aune & others, 2018; Young & others, 2018). Overweight and obesity also are associated with mental health problems, especially depression (Docherty, 2017; Hong & Hur, 2017; Rajan & Menon, 2017; Zhang & others, 2018).

What factors determine whether a person becomes obese? Possible influences include both heredity and environmental conditions, and dieting.

**Heredity** Until recently, the genetic component of obesity was underestimated by scientists. Some individuals inherit a tendency to be overweight (Campbell Am, 2017; Kleinert & others, 2018; Xu & others, 2018). Researchers have documented that animals can be inbred to have a propensity for obesity (Ratner & others, 2015). Further, identical human twins have similar weights, even when they are reared apart (Zhou & others, 2015). However, a recent study found that a high level of activity reduced the degree of genetic linkage for obesity in same-sex twins (Horn & others, 2015).

**Environmental Factors** Environmental factors play an important role in obesity (DeBruyne & Pinna, 2017; Donatelle, 2017, 2019; Kimura & others, 2018). The human genome

has not changed markedly in the last century, yet obesity has noticeably increased. The obesity rate has doubled in the United States since 1900. This dramatic increase in obesity likely is due to greater availability of food (especially food high in fat), greater reliance on energy-saving devices, and declining physical activity.

Sociocultural factors are involved in obesity, which is six times more prevalent among women with low incomes than among women with high incomes. Americans also are more obese than Europeans and people in many other areas of the world. In recent international comparisons of 33 countries, the average obesity rate was 23.2 percent. The United States had the highest adult obesity rate (35.3 percent) and Japan had the lowest rate (3.7 percent) (OECD, 2017).

**Dieting** With obesity on the rise, dieting has become an obsession with many Americans (Donatelle & Ketcham, 2018; Schiff, 2017, 2019). Although many Americans regularly embark on a diet, few are successful in keeping weight off over the long term and many dieters risk becoming fatter (Meule, Richard, & Platte, 2017; Smith & Collene, 2019). A research review of the long-term outcomes of calorie-restricting diets revealed that one-third to two-thirds of dieters regain more weight than they lost on their diets (Mann & others, 2007). However, some individuals do lose weight and maintain the loss (Miller, Nagaraja, & Weinhold, 2015; Smithson & Hill, 2017). How often this occurs and whether some diet programs work better than others are still open questions.

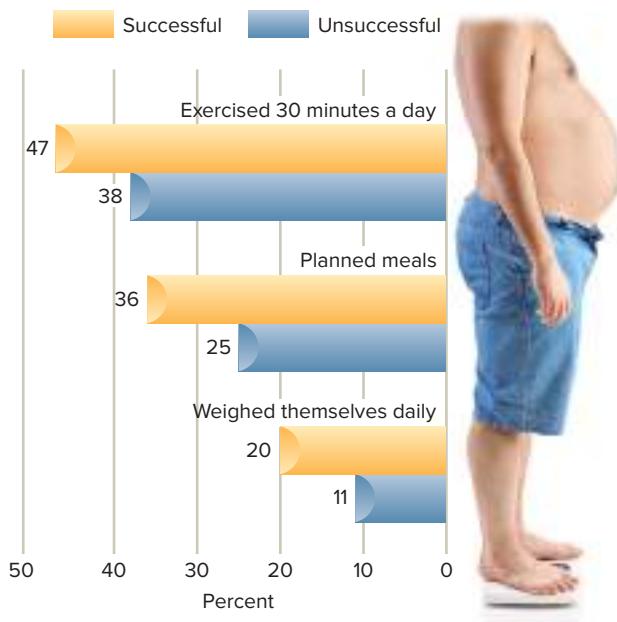

What we *do* know about losing weight is that the most effective programs include exercise (Kwon, Nam, & Park, 2017; Walton-Fisette & Wuest, 2018). A research review concluded that adults who engaged in diet-plus-exercise programs lost more weight than those who relied on diet-only programs (Wu & others, 2009). A study of approximately 2,000 U.S. adults found that exercising 30 minutes a day, planning meals, and weighing themselves daily were the main strategies used by successful dieters as compared with unsuccessful dieters (Kruger, Blanck, & Gillespie, 2006) (see Figure 2). Another study also revealed that daily weigh-ins are linked to maintaining weight loss (Wing & others, 2007).

**Binge Eating Disorder (BED)** In the chapter on “Physical and Cognitive Development in Adolescence,” we discussed the eating problems of anorexia nervosa and bulimia. Here we discuss another eating problem, **binge eating disorder (BED)**, which involves frequent binge eating without compensatory behavior like the purging that characterizes bulimics. Individuals with BED engage in recurrent episodes of eating large quantities of food, during which they feel a lack of control over eating (Browley & others, 2017; Dakanalis & others, 2018; Stice & others, 2017). Because they don’t purge, individuals with BED are frequently overweight (Wilfley, Fitzsimmons-Craft, & Eichen, 2017). For the first time, binge eating disorder was included by the American Psychiatric Association in the fifth edition of its classification of psychiatric disorders in 2013. As with anorexia nervosa and bulimia disorder, BED is far more common in females than males.

Researchers are examining the role of biological and psychological factors in BED (Kornstein, 2017; Marzilli, Cerniglia, & Cimino, 2018; Mitchison & others, 2018). Genes play a role, as does dopamine, the neurotransmitter related to reward pathways in the brain (O’Connor & others, 2017). Also, a recent study found that adolescents with BED were more likely to live in families with less effective family functioning, especially in the area of emotional involvement (Tetzlaff & others, 2016). Cognitive behavior therapy and interpersonal therapy are the most strongly supported interventions for BED (Grilo, 2017).

## REGULAR EXERCISE

One of the main reasons health experts want people to exercise is that it helps to prevent chronic disorders such as heart disease and diabetes (O’Driscoll & others, 2017; Walton-Fisette & Wuest, 2018). Many health experts recommend that young adults engage in 30 minutes or more of aerobic exercise daily. **Aerobic exercise** is sustained exercise—jogging, swimming, or cycling, for example—that stimulates heart and lung activity. Most health experts recommend

raising your heart rate to at least 60 percent of your maximum heart rate. Only about one-fifth of adults, however, achieve these recommended levels of physical activity.

A national poll in the United States found that 51.6 percent of individuals 18 years of age and older exercised for 30 or more minutes 3 or more days a week (Gallup, 2013). In this survey, young adults 18 to 29 years of age (56.8 percent) were the most likely to exercise of all adult age groups. Also in this survey, men were more likely to exercise than women were.

Researchers have found that exercise is linked not only to physical health, but mental health as well. In particular, exercise is associated with a higher self-concept, as well as lower anxiety and depression (Paolucci & others, 2018; Schuch & others, 2016a; Werneck, Oyeyemi, & Silva, 2018). In a recent meta-analysis, adults with major depressive disorder engaged in low levels of physical activity and high levels of sedentary behavior (Schuch & others, 2017b). Also, in a recent study, adults who regularly exercised had lower levels of anxiety and depression (Khanzada, Soomro, & Khan, 2015). Further, data from a national survey revealed that individuals with higher levels of physical activity and cardiovascular fitness were less likely to have depressive symptoms (Loprinzi & others, 2017).

Recent research also indicates that exercise reduces depressive symptoms (Paolucci & others, 2018; Schuch & others, 2017a; Werneck, Oyeyemi, & Silva, 2018). Meta-analyses have shown that exercise can be as effective in reducing depression as psychotherapy (Netz, 2017; Richardson & others, 2005). For example, in a recent meta-analysis, moderate and vigorous aerobic exercise was effective in reducing major depressive disorder (Schuch & others, 2016b). Also, a recent research review concluded that studies in which individuals are randomly assigned to engage in exercise have found that exercise and pharmacological treatments are equally effective in the treatment of depression (Netz, 2017). Here are some helpful strategies for making exercise part of your life:

- **Reduce screen time.** Heavy screen viewing (TV, Internet, and so on) is linked to poor health and obesity. A recent study found that higher screen time by parents was linked to parents' and children's higher waist-to-height ratio (Dong & others, 2017). Another study revealed that compared with individuals who watch no TV, watching TV 6 hours a day reduces life expectancy by 4.8 years (Veerman & others, 2012). And yet another study indicated that mortality risk decreased when screen time was replaced by an increase in daily activity levels (Wijndaele & others, 2017). Replace some of your screen time with exercise.
- **Chart your progress.** Systematically recording your exercise workouts will help you to chart your progress. This strategy is especially helpful over the long term.
- **Get rid of excuses.** People make up all kinds of excuses for not exercising. A typical excuse is "I don't have enough time." You likely do have enough time to exercise 30 minutes per day.
- **Imagine the alternative.** Ask yourself whether you are too busy to take care of your own health. What will your life be like if you lose your health?

## SUBSTANCE ABUSE

Earlier we explored substance abuse in adolescence. Fortunately, by the time individuals reach their late twenties, many have begun reducing their use of alcohol and drugs. That is the conclusion reached by John Schulenberg and his colleagues (2017), who have collected extensive data on individuals as they age from secondary school through early adulthood. As in adolescence, male college students and young adults are more likely to take drugs than their female counterparts (Schulenberg & others, 2017). One study revealed that only 20 percent of college students reported abstaining from alcohol (Huang & others, 2009).

Let's take a closer look at alcohol consumption and nicotine use by young adults and consider how this activity may become an **addiction**, which is a behavior pattern characterized by an overwhelming involvement with a drug and a preoccupation with securing its supply.

**Alcohol** Two problems associated with excessive alcohol consumption are binge drinking and alcoholism.

**Binge Drinking** Heavy binge drinking often occurs in college, and it can take its toll on students (Wombacher & others, 2018). Chronic binge drinking is more common among college

men, especially those who live in fraternity houses (Schulenberg & others, 2017).

In 2016, 32.4 percent of U.S. college students reported having had five or more drinks in a row at least once in the last two weeks (Schulenberg & others, 2017). The term *extreme binge drinking* (also called high-intensity drinking) describes individuals who had 10 or more drinks in a row or 15 or more drinks in a row in the last two weeks (Patrick & others, 2017a, b, c; Schulenberg & Patrick, 2018). In 2016, 12 percent of college students reported having 10 or more drinks in a row in the last two weeks and 4 percent reported having 15 or more drinks in a row in the last two weeks (Schulenberg & others, 2017). While drinking rates among college students have remained high, overall levels of drinking, including binge drinking, in this age group have declined in recent years. For example, binge drinking declined from 37.4 percent in 2012 to 32.4 percent in 2016 (Schulenberg & others, 2017).

In a national survey of drinking patterns on 140 campuses, almost half of the binge drinkers reported problems that included absence from classes, physical injuries, troubles with police, and unprotected sex (Wechsler & others, 2002). For example, binge-drinking college students were 11 times as likely to fall behind in school, 10 times as likely to drive after drinking, and twice as likely to have unprotected sex as college students who did not engage in binge drinking. Further, in another study, college men who frequently engaged in binge drinking had vascular changes in blood flow that are a precursor for developing arteriosclerosis (hardening of the arteries) and other cardiovascular problems such as having a heart attack or a stroke (Goslawski & others, 2013). And a longitudinal study revealed that frequent binge drinking and marijuana use during the freshman year of college predicted delayed college graduation (White & others, 2018).
