In the case of hypoactive sexual desire disorder, a marked difference within a couple often leads to one partner being labeled as having low desire. For example, if one partner is quite happy with sexual relations once a week but the other partner desires sex every day, the latter partner may accuse the former of having low desire and, unfortunately, the former partner might agree. Facilitating better conditions often resolves these misunderstandings. Fortunately, for people with this and more complex sexual dysfunctions, treatments are now available, both psychosocial and medical. Advances in medical treatments, particularly for erectile dysfunction, have been dramatic in just the past few years. We look first at psychosocial treatments; then we examine the latest medical procedures.

Psychosocial Treatments

Among the many advances in our knowledge of sexual behavior, none was more dramatic than the publication in 1970 by William Masters and Virginia Johnson of *Human Sexual Inadequacy*. The procedures outlined in this book literally revolutionized sex therapy by providing a brief, direct, and reasonably successful therapeutic program for sexual dysfunctions. Underscoring again the common basis of most sexual dysfunctions, a similar approach to therapy is taken with all patients, male and female, with slight variations depending on the specific sexual problem (for example, premature ejaculation or orgasmic disorder). This intensive program involves a male and a female therapist to facilitate communication between the dysfunctional partners. (Masters and Johnson were the original male and female therapists.) Therapy is conducted daily over a 2-week period.

The actual program is quite straightforward. In addition to providing basic education about sexual functioning, altering deep-seated myths, and increasing communication, the clinicians'

primary goal is to eliminate psychologically based performance anxiety (refer back to Figure 10.5). To accomplish this, Masters and Johnson introduced *sensate focus* and *nondemand pleasuring*. In this exercise, couples are instructed to refrain from intercourse or genital caressing and simply to explore and enjoy each other's body through touching, kissing, hugging, massaging, or similar kinds of behavior. In the first phase, nongenital pleasuring, breasts and genitals are excluded from the exercises. After successfully accomplishing this phase, the couple moves to genital pleasuring but with a ban on orgasm and intercourse and clear instructions to the man that achieving an erection is not the goal.

At this point, arousal should be reestablished and the couple should be ready to attempt intercourse. So as not to proceed too quickly, this stage is also broken down into parts. For example, a couple might be instructed to attempt the beginnings of penetration; that is, the depth of penetration and the time it lasts are only gradually built up, and both genital and nongenital pleasuring continue. Eventually, full intercourse and thrusting are accomplished. After this 2-week intensive program, recovery was reported by Masters and Johnson for the vast majority of more than 790 sexually dysfunctional patients, with some differences in the rate of recovery depending on the disorder. Close to 100% of individuals with premature ejaculation recovered, whereas the rate for more difficult cases of lifelong generalized erectile dysfunction was closer to 60%.

After these results were published, specialty sexuality clinics based on the pioneering work of Masters and Johnson were established around the country to administer these new treatment techniques. Subsequent research revealed that many of the structural aspects of the program did not seem necessary. For example, one therapist seems to be as effective as two (LoPiccolo, Heiman, Hogan, & Roberts, 1985), and seeing patients once a week seems to be as effective as seeing them every day (Heiman & LoPiccolo, 1983). It has also become clear in the succeeding decades that the results achieved by Masters and Johnson were better than those achieved in clinics around the world using similar procedures. Reasons for this are not entirely clear. One possibility is that they were highly motivated because patients had to take at least 2 weeks off and fly to St. Louis to meet with Masters and Johnson.

Sex therapists have expanded on and modified these procedures over the years to take advantage of recent advances in knowledge (see, for example, Bradford & Meston, 2011; Rosen, 2007; Weiner & Avery-Clark, 2014; Wincze, 2009; Wincze et al., 2008). Results with sex therapy for erectile dysfunction indicate that as many as 60% to 70% of the cases show a positive treatment outcome for at least several years, although results are mixed and there may be some slipping after that (Fröhlauf, Gerger, Schmidt, Munder, & Barth, 2013; Rosen, 2007; Segraves & Althof, 1998). For better treatment of specific sexual dysfunctions, sex therapists integrate specific procedures into the context of general sex therapy. For example, to treat premature ejaculation, most sex therapists use a procedure developed by Semans (1956), sometimes called the *squeeze* technique, in which the penis is stimulated, usually by the partner, to nearly full erection. At this point, the partner firmly squeezes the penis near the top where the head of the penis joins the shaft, which quickly reduces arousal. These steps are repeated until (for heterosexual partners) eventually the

penis is briefly inserted in the vagina without thrusting. If arousal occurs too quickly, the penis is withdrawn and the squeeze technique is employed again. In this way, the man develops a sense of control over arousal and ejaculation. Reports of success with this approach over the past 20 years suggest that 60% to 90% of men benefit, but the success rates drop to about 25% after 3 years or more of follow up (Althof, 2007; Malavige & Jayawickrema, 2015; Polonsky, 2000). Gary, the 31-year-old sales representative, was treated with this method, and his wife was cooperative during the procedures. Brief marital therapy also persuaded Gary that his insecurity over his perception that his wife no longer found him attractive was unfounded. After treatment, he reduced his work hours somewhat, and the couple's marital and sexual relations improved.

Lifelong female orgasmic disorder may be treated with explicit training in masturbatory procedures (Bradford & Meston, 2011). For example, Greta was still unable to achieve orgasm with manual stimulation by her husband, even after proceeding through the basic steps of sex therapy. At this point, following certain standardized treatment programs for this problem (see, for example, Heiman, 2000; Heiman & LoPiccolo, 1988), Greta and Will purchased a vibrator and Greta was taught to let go of her inhibitions by talking out loud about how she felt during sexual arousal, even shouting or screaming if she wanted to. In the context of appropriate genital pleasuring and disinhibition exercises, the vibrator brought on Greta's first orgasm. With practice and good communication, the couple eventually learned how to bring on Greta's orgasm without the vibrator. Although Will and Greta were both delighted with her progress, Will was concerned that Greta's screams during orgasm would attract the attention of the neighbors! Summaries of results from a number of studies suggest 70% to 90% of women will benefit from treatment, and these gains are stable and even improve further over time (Fröhlauf et al., 2013; Heiman, 2007; Heiman & Meston, 1997; Segraves & Althof, 1998).

To treat vaginismus and pain related to penetration in genitopelvic pain/penetration disorder, the woman and, eventually, the partner gradually insert increasingly larger dilators at the woman's pace. After the woman (and then the partner) can insert the largest

dilator, in a heterosexual couple, the woman gradually inserts the man's penis. These exercises are carried out in the context of genital and nongenital pleasuring so as to retain arousal. Close attention must be accorded to any increased fear and anxiety that may be associated with the process, which may trigger memories of early sexual abuse that may have contributed to the onset of the condition. These procedures are highly successful, with a large majority of women (80% to 100%) overcoming vaginismus in a relatively short period (Binik et al., 2007; Leiblum & Rosen, 2000; ter Kuile et al., 2007; ter Kuile, Melles, de Groot, Tuijnman-Raasveld, & van Lankveld, 2013).

A variety of treatment procedures have also been developed for low sexual desire (see, for example, Pridal & LoPiccolo, 2000; Wincze, 2009; Wincze & Weisberg, 2015). At the heart of these treatments are the standard reeducation and communication phases of traditional sex therapy with, possibly, the addition of masturbatory training and exposure to erotic material. Each case may require individual strategies. Remember Mrs. C., who was sexually abused by her cousin? Therapy involved helping the couple understand the impact of the repeated, unwanted sexual experiences in Mrs. C.'s past and to approach sex so that Mrs. C. was more comfortable with foreplay. She gradually lost the idea that once sex was started she had no control. She and her husband worked on starting and stopping sexual encounters. Cognitive restructuring was used to help Mrs. C. interpret her husband's amorousness in a positive rather than a skeptical light. In general, approximately 50% to 70% of individuals with low sexual desire benefit from sex therapy, at least initially (Basson, 2007; Brotto, 2006).

Medical Treatments

A variety of pharmacological and surgical techniques have been developed in recent years to treat sexual dysfunction, almost all focusing on male erectile disorder. The drug Viagra, introduced in 1998, and similar drugs such as Levitra and Cialis, introduced subsequently, are the best known. We look at the four most popular procedures: oral medication, injection of vasoactive substances directly into the penis, surgery, and vacuum device therapy. Before we begin, note that it is important to combine any medical treatment with a comprehensive educational and sex therapy program to ensure maximum benefit.

In 1998, the drug sildenafil (trade name Viagra) was introduced for erectile dysfunction. Approval from the Food and Drug Administration occurred early in 1998, and results from several clinical trials suggested that between 50% and 80% of a large number of men benefit from this treatment (Conti, Pepine, & Sweeney, 1999; Goldstein et al., 1998) in that erections become sufficient for intercourse, compared with approximately 30% who benefit from placebo. Results are similar with Cialis and Levitra (Carrier et al., 2005). As many as 30% of men may suffer severe headaches as a side effect, however, particularly at higher doses (Rosen, 2000, 2007; Virag, 1999), and reports of sexual satisfaction are not optimal. For example, Virag (1999) evaluated a large number of men treated with Viagra and found that 32% of the men were successful if success was defined as an erection sufficient to engage in intercourse and satisfaction of at least 7 on the 0-to-10 scale. Results

were categorized as fair for 29% who reported adequate erection but satisfaction from 4 to 6, and unsatisfactory for 39% with inadequate erection and satisfaction rated as 0 to 3. Thus, erections were sufficiently firm for intercourse in 61% of the men, consistent with other studies, but only 32% rated the results as at least good, suggesting the need for, perhaps, additional drug or psychological treatment. If men are particularly anxious about sex, results are not as good with the drug (Rosen et al., 2006). Also, the large majority of men stop using the drug after a trial of several months or a year, indicating less than satisfactory long-term results (Rosen, 2007). To address this issue, Bach, Barlow, and Wincze (2004) evaluated the addition of cognitive-behavioral treatment (CBT) to treatment with Viagra. Results were encouraging because couples reported greater satisfaction and increased sexual activity after combined drug therapy and CBT, compared with a period when only the drug was used.

There was also some hope that Viagra would be useful for dysfunction in postmenopausal women, but results were disappointing (Bradford & Meston, 2011; Kaplan et al., 1999). Now interest has centered on a new drug, flibanserin, as a possible treatment for hypoactive sexual desire in women. Indeed initial research findings suggest that this medication may be effective since there is preliminary evidence for increases in sexual desire and reduced distress associated with hypoactive sexual desire in women, (DeRogatis et al., 2012; Katz et al., 2013). These findings are also very controversial since the data show that the effects of what has been called "pink Viagra" are very modest so as to be relatively unnoticeable for many women leading some to question whether pharmaceutical companies may be misleading the public in order to cash in on a sexual enhancement drug for women given the enormous profits associated with Viagra and similar drugs for men (Brotto, 2015; Laan & Tiefer, 2014; Levine, 2015). This research is still in its infancy.

For some time, testosterone (Schiavi, White, Mandeli, & Levine, 1997) has been used to treat erectile dysfunction. But although it is safe and has relatively few side effects, only negligible effects on erectile dysfunction have been reported (Forti, Corona, Vignozzi, & Maggi, 2012; Mann et al., 1996). Some urologists teach patients to inject vasodilating drugs such as *papaverine* or *prostaglandin* directly into the penis when they want to have sexual intercourse. These drugs dilate the blood vessels, allowing blood to flow to the penis and thereby producing an erection within 15 minutes that can last from 1 to 4 hours (Rosen, 2007; Segraves & Althof, 1998). Because this procedure is a bit painful (although not as much as one might think), a substantial number of men, usually 50% to 60%, stop using it after a short time. In one study, 50 of 100 patients discontinued papaverine for various reasons (Lakin, Montague, Vanderbrug Medendorp, Tesar, & Schover, 1990; Segraves & Althof, 1998). A soft capsule that contains papaverine (called MUSE [Medical Urethral System for Erections]) can be inserted directly into the urethra, but this is somewhat painful, is less effective than injections, and remains awkward and artificial enough to preclude wide acceptance (Delizonna, Wincze, Litz, Brown, & Barlow, 2001). Insertion of *penile prostheses* or implants has been a surgical option for almost 100 years; only recently have they become good enough to approximate normal sexual functioning. One procedure involves implanting a semirigid silicone

An inflatable penile implant may be used for men with inadequate sexual functioning.

the pump outside the rod. However, surgical implants fall short of restoring presurgical sexual functioning or assuring satisfaction in most patients (Gregoire, 1992; Kim & Lipshultz, 1997); they are now generally used only if other approaches don't work. On the other hand, this procedure has proved useful for men who must have a cancerous prostate removed, because this surgery often causes erectile dysfunction, although newer "nerve-sparing" surgeries lessen the effect to some extent (Ramsawh, Morgentaler, Covino, Barlow, & DeWolf, 2005).

Another approach is *vacuum device therapy*, which works by creating a vacuum in a cylinder placed over the penis. The vacuum draws blood into the penis, which is then trapped by a specially designed ring placed around the base of the penis. Although using the vacuum device is rather awkward, between 70% and 100% of users report satisfactory erections, particularly if psychological sex therapy is ineffective (Segraves & Althof, 1998; Witherington, 1988). The procedure is also less intrusive than surgery or injections, but it remains awkward and artificial (Delizonna et al., 2001). However, in recent years, this therapy has gained traction as a first-line therapy for men who have been treated for prostate cancer (Pahlajani, Raina, Jones, & Zippe, 2012).

Summary

Treatment programs, both psychosocial and medical, offer hope to most people who suffer from sexual dysfunctions. Unfortunately, such programs are not readily available in many locations because few health and mental health professionals are trained to apply them, although the availability of drugs for male erectile dysfunction is widespread. Further, government agencies such as the NIH have been slow to fund research dedicated to understanding sexual dysfunctions and their treatments since any research focused on sex has occasionally proved to be controversial among some members of Congress serving on oversight committees for NIH funding. Psychological treatment of sexual arousal disorders requires further improvement, and treatments for low sexual desire are largely untested. Most treatments are still intrusive and clumsy, although drugs such as Viagra and Levitra exhibit some success for erectile dysfunction. New medical developments including medications, topical creams, and gene therapy are under investigation as potential treatments, but research on these interventions is just beginning.

rod that can be bent by the male into correct position for intercourse and maneuvered out of the way at other times. In a more popular procedure, the male squeezes a small pump that is surgically implanted into the scrotum, forcing fluid into an inflatable cylinder and thus producing an erection. A newer penile prosthetic device is an inflatable rod that contains the pumping device, which is more convenient than having

Unfortunately, most health professionals tend to ignore the issue of sexuality in older adults. Along with the usual emphasis on communication, education, and sensate focus, appropriate lubricants for women and a discussion of methods to maximize the erectile response in men should be a part of any sexual counseling for older couples. More important, even with reduced physical capabilities, continued sexual relations, not necessarily including intercourse, should be an enjoyable and important part of an aging couple's relationship. Further research and development in the treatment of sexual dysfunction must address all these issues. Nevertheless, the overwhelming consensus is that a combination of psychological and drug treatment, when indicated, will continue to be the treatment strategy of choice.

Concept Check 10.2

Determine whether the following statements are true (T) or false (F) in regard to the causes and treatments of sexual dysfunctions.

1. _____ Many physical and medical conditions and their treatments (for example, prescription medications) contribute to sexual dysfunction; however, many doctors are unaware of the connection.
2. _____ Anxiety always decreases or even eradicates sexual arousal.
3. _____ Sexual dysfunctions can result from a growing dislike for a partner, traumatic sexual events, or childhood lessons about the negative consequences of sexual behavior.
4. _____ A simple, effective treatment for many disorders is education.
5. _____ All sexual dysfunctions are treated with the same psychosocial technique.
6. _____ Most surgical and pharmacological treatments of recent years have focused on erectile disorder.

Paraphilic Disorders: Clinical Descriptions

If you are like most people, your sexual interest is directed to other physically mature adults (or late adolescents), all of whom are capable of freely offering or withholding their consent. But what if you are sexually attracted to something or somebody other than another adult, such as animals (particularly horses and dogs; Williams & Weinberg, 2003) or a vacuum cleaner? (Yes, it does happen!) Or what if your only means of obtaining sexual satisfaction is to commit a brutal murder? Such patterns of sexual arousal and countless others exist in a large number of individuals, causing untold human suffering both for them and, if their behavior involves other people, for their victims. As

noted in the beginning of the chapter, these disorders of sexual arousal, if they cause distress or impairment to the individual, or cause personal harm, or the risk of harm to others are called **paraphilic disorders**. It is important to note that *DSM-5* does not consider a paraphilia a disorder unless it is associated with distress and impairment or harm or the threat of harm to others. Thus, unusual patterns of sexual attraction are not considered to be sufficient to meet criteria for a disorder. This is a controversial change in *DSM-5* (see *DSM Controversies* box on page 399).

Over the years, we have assessed and treated a large number of individuals with paraphilic disorders, ranging from the slightly eccentric and sometimes pitiful cases to some of the most dangerous killer-rapists encountered anywhere. As noted above, there are many harmless aberrations, such as some fetishistic arousal patterns (see next section), which harm no one, are not distressful or impairing, and therefore do not meet criteria for a disorder. We begin by describing briefly the major types of paraphilic disorders, using in all instances cases from our own files. As with sexual dysfunctions, it is unusual for an individual to have just one paraphilic pattern of sexual arousal (Bradford & Meston, 2011; Krueger & Kaplan, 2015; Laws & O'Donohue, 2008; Seto, Kingston, & Bourget, 2014). Many of our patients may present with two, three, or more patterns, although one is usually dominant (Abel, Becker, Cunningham-Rathner, Mittelman, & Rouleau, 1988; Brownell, Hayes, & Barlow, 1977; American Psychiatric Association, 2013). Furthermore, it is not uncommon for individuals with paraphilic disorder to also suffer from comorbid mood, anxiety, and substance abuse disorders (Kafka & Hennen, 2003; Krueger & Kaplan, 2015; Raymond, Coleman, Ohlerking, Christenson, & Miner, 1999). Although paraphilic disorders are not widely prevalent and estimates of their frequency are hard to come by, some disorders, such as transvestic disorder (cross-dressing, discussed later), seem relatively common (Bancroft, 1989; Mason, 1997). You may have been the victim of **frotteuristic disorder** in a large city, typically on a crowded subway or bus. (We mean really crowded, with people packed in like sardines.) In this situation, women have been known to experience more than the usual jostling and pushing from behind. What they discover, much to their horror, is a male with a frotteuristic arousal

pattern rubbing against them until he is stimulated to the point of ejaculation. Because the victims cannot escape easily, the frotteuristic act is usually successful (Lussier & Piché, 2008).

Fetishistic Disorder

In **fetishistic disorder**, a person is sexually attracted to nonliving objects. There are almost as many types of fetishes as there are objects, although women's undergarments and shoes are popular (Darcangelo, 2008; Kafka, 2010). Fetishistic arousal is associated with two classes of objects or activities: (1) an inanimate object or (2) a source of specific tactile stimulation, such as rubber, particularly clothing made out of rubber. Shiny black plastic is also used (Bancroft, 1989; Junginger, 1997). Most of the person's sexual fantasies, urges, and desires focus on this object. A third source of attraction (sometimes called *partialism*) is a part of the body, such as the foot, buttocks, or hair.

In one U.S. city for several months, bras hung out on a woman's backyard clothesline disappeared. The women in the neighborhood soon began talking to each other and discovered that bras were missing from every clothesline for blocks around. A police stakeout caught the perpetrator, who turned out to have a strong fetish for brassieres. As another example of fetishistic behavior

Criteria for Genito-Pelvic Pain/Penetration Disorder

- DSM 5**
- A.** Persistent or recurrent difficulties with one (or more) of the following:
 1. Vaginal penetration during intercourse.
 2. Marked vulvovaginal or pelvic pain during vaginal intercourse or penetration attempts.
 3. Marked fear or anxiety about vulvovaginal or pelvic pain in anticipation of, during, or as a result of vaginal penetration.
 4. Marked tensing or tightening of the pelvic floor muscles during attempted vaginal penetration.
 - B.** The symptoms in Criterion A have persisted for a minimum duration of approximately 6 months.
 - C.** The symptoms in Criterion A cause clinically significant distress in the individual.
 - D.** The sexual dysfunction is not better explained by a nonsexual mental disorder or as a consequence of severe relationship distress or other significant stressors and is not attributable to the effects of a substance/medication or another medical condition.

related to tactile stimulation, it is relatively common for a urologist to be called to the emergency room to remove surgically a long thin object, such as a pencil or the arm of an eyeglass frame, from a man's urethra. Men who insert such objects think that partially blocking the urethra in this way can increase the intensity of ejaculation during masturbation. If the entire object slips into the penis, however, major medical intervention is required.

Voyeuristic and Exhibitionistic Disorders

Voyeuristic disorder is the practice of observing, to become aroused, an unsuspecting individual undressing or naked. **Exhibitionistic disorder**, by contrast, is achieving sexual arousal and gratification by exposing genitals to unsuspecting strangers (Långström, 2010). Consider the case of Robert.

Robert... Outside the Curtains

Robert, a 31-year-old, married, blue-collar worker, reported that he first started "peeping" into windows when he was 14. He rode around the neighborhood on his bike at night, and when he spotted a female through a window he stopped and stared. During one of these episodes, he felt the first pangs of sexual arousal. Eventually he began masturbating while watching, thereby exposing his genitals, although out of sight. When he was older, he drove around until he spotted some prepubescent girls. He parked his car near them, unzipped his fly, called them over, and attempted to carry on a nonsexual conversation. Later he was sometimes able to talk a girl into mutual masturbation and *fellatio*, or oral stimulation of the penis. Although he was arrested several times, paradoxically, the threat of arrest increased his arousal (Barlow & Wincze, 1980). •

Remember that anxiety actually increases arousal under some circumstances. Many voyeurs just don't get the same satisfaction from attending readily available strip shows at a local bar. Exhibitionistic disorder is often associated with lower levels of education, but not always. Note again that the thrilling element of risk is an important part of exhibitionistic disorder.

The Lawyer Who Needed the Bus

Several years ago, a distinguished lawyer reported that he needed help and that his career was on the line. An intelligent, good-looking single man, he noted without bragging that he could have sex with any number of beautiful women in the course of his law practice. The only way he could become aroused, however, was to leave his office, go down to the bus stop, ride around the city until a reasonably attractive young woman got on, expose himself just before the next stop, and then run off the bus, often with people chasing after him. To achieve maximal arousal, the bus could not be full or empty; there had to be just a few people sitting on the bus, and the woman getting on had to be the right age. Sometimes hours would pass before these circumstances lined up correctly. The lawyer observed that if he was not fired for exhibitionism he would be fired for all the time he was missing from work. On several occasions, he had requested a girlfriend to role-play sitting on a bus in his apartment. Although he exposed himself to her, he could not achieve sexual arousal and gratification because the activity just wasn't exciting. •

Although prevalence is unknown (Murphy & Page, 2008), in a random sample of 2,450 adults in Sweden, 31% reported at least one incident of being sexually aroused by exposing their genitals to a stranger, and 7.7% reported at least one incident of being sexually aroused by spying on others having sex (Långström & Seto, 2006). To meet diagnosis for exhibitionistic disorder, the behavior must occur repeatedly and be compulsive or out of control.

Transvestic Disorder

In **transvestic disorder**, sexual arousal is strongly associated with the act of (or fantasies of) dressing in clothes of the opposite sex, or cross-dressing (Blanchard, 2010; Wheeler, Newring, & Draper, 2008). Consider the case of Mr. M.

Mr. M... Strong Man in a Dress

Mr. M., a 31-year-old married police officer, came to our clinic seeking treatment for uncontrollable urges to dress in women's clothing and appear in public. He had been doing this for 16 years and had been discharged from the Marine Corps for cross-dressing. Since then, he had risked public disclosure on several occasions. Mr. M.'s wife had threatened to divorce him because of the cross-dressing, yet she often purchased women's clothing for him and was "compassionate" while he wore them. •

Note that Mr. M. was in the Marine Corps before he joined the police force. It is not unusual for males who are strongly inclined to dress in female clothes to compensate by associating

with so-called macho organizations. Some of our cross-dressing patients have been associated with various paramilitary organizations. Nevertheless, most individuals with this disorder do not seem to display any compensatory behaviors. The same survey in Sweden mentioned earlier found 2.8% of men and 0.4% of women reported at least one episode of transvestistic disorder (Långström & Zucker, 2005). The 3% prevalence rate in males, while a rough estimate, is generally accepted (APA, 2013).

Interestingly, the wives of many men who cross-dress have accepted their husbands' behavior and can be quite supportive if it is a private matter between them. Docter and Prince (1997)

reported that 60% of more than 1,000 men with transvestistic disorder were married at the time of the survey. Some people, both married and single, join cross-dressing clubs that meet periodically or subscribe to newsletters devoted to the topic. If sexual arousal is primarily focused on the clothing itself the diagnostic criteria require a specification "with fetishism." Research suggests that transvestism of this type is indistinguishable from other fetishes in most respects (Freund, Seto, & Kuban, 1996). Another specifier for transvestism describes a pattern of sexual arousal associated not with clothing itself but rather with thoughts or images of oneself as a female. This specifier is called "autogynephilia." Consider the case of Ron, recently seen in our clinic.

Ron and Rhonda... Sexual Confusion

Ron was a 47-year-old divorced male with a 6-year-old son who lived with his son's mother. For the past several years, Ron had been living with his girlfriend and his girlfriend's 7-year-old daughter, mother, and sister. He was large and muscular with a short but full beard. His initial complaint was severe social anxiety, which he felt had interfered with his ability to make friends and advance in his job since he sought out positions that required only limited social interaction. He reported that he loved his girlfriend and wanted to get married and was particularly concerned about being the best father he could be for his son. He was assigned to group treatment for social anxiety, but he showed up for the first session much to our surprise dressed in a jeans miniskirt, knee-high black leather boots, and a blouse. During the session he expressed considerable confusion about his sexuality, and we decided his needs would be better met in individual treatment.

At that point, he requested to be called Rhonda and began volunteering a previous history of cross-dressing and frequenting gay nightclubs from time to time. He reported that his first marriage had ended after his wife discovered photos of him wearing her wedding dress. Presently, the most sexually arousing scenario for him was the image of himself as a woman, such as imagining himself performing domestic chores or activities such as cooking for a male partner while wearing an apron. But he was clear that it was not the clothes that were arousing so much as the image in his own mind of himself as a woman. He also reported engaging in risky sexual behaviors such as unprotected sex, meeting up with strangers to engage in sexual behaviors in parking lots, texting naked/provocative photos of himself to potential partners, and engaging in sexual acts in public places such as the gym shower, all of which would begin with him dressed in his female clothes and assuming the role of a woman. He had kept this behavior from his girlfriend mostly by hiding his clothes in the trunk of his car or in a back closet at work. In spite of this behavior, he maintained a strong and frequent sexual relationship with his girlfriend and was terrified of contracting AIDS and infecting her. He also couldn't imagine giving up the strong relationship with his

son. Treatment focused on eliminating risky sexual behavior and clarifying with him the most important values in his life. He chose his girlfriend and his son and, after a course of treatment and occasional follow-up sessions, reported himself to be at peace with his decision and had given up his risky infidelities with no reports of slips or relapses. •

This specifier is very controversial because the “sexual confusion” experienced by Ron overlaps to some degree with gender dysphoria (described below), and some think this confusion is better captured by the concept of gender dysphoria. Indeed, there is a somewhat greater risk that individuals with this paraphilic disorder will develop gender dysphoria and request transition through sex reassignment surgery (Blanchard, 2010; Lawrence, 2013). But as one can see in the case of Ron/Rhonda, gender dysphoria was not a major component of his presentation, and he did not once consider surgical sex reassignment. Rather, he was very strongly sexually aroused by thoughts and images of himself as a woman.

Sexual Sadism and Sexual Masochism Disorders

Both **sexual sadism** and **sexual masochism** are associated with either inflicting pain or humiliation (sadism) or suffering pain or humiliation (masochism; Hücker, 2008; Krueger, 2010a, 2010b; Yates, Hücker, & Kingston, 2008), and becoming sexually aroused is specifically associated with violence and injury in these conditions (Seto, Lalumiere, Harris, & Chivers, 2012). Although Mr. M. was extremely concerned about his cross-dressing, he was also disturbed by another problem. To maximize his sexual pleasure during intercourse with his wife, he had her wear a collar and leash, tied her to the bed, and handcuffed her. He sometimes tied himself with ropes, chains, handcuffs, and wires, all while he was cross-dressed. Mr. M. was concerned he might injure himself seriously. As a member of the police force, he had heard of cases and even investigated one himself in which an individual was found dead, tightly and completely bound in harnesses, handcuffs, and ropes. In many such cases, something goes wrong and the individual accidentally hangs himself, an event that should be distinguished from the closely related condition called *hypoxiphilia*, which involves self-strangulation to reduce the flow of oxygen to the brain and enhance the sensation of orgasm. It may seem paradoxical that someone has to either inflict or receive pain to become sexually aroused, but these types of cases are not uncommon. On many occasions, the behaviors themselves are quite mild and harmless (Krueger, 2010a; 2010b), but they can become dangerous and costly. It was not unusual that Mr. M. presented with three patterns of deviant arousal—in his case, sexual masochism, sexual sadism, and transvestism.

Sadistic Rape

After murder, rape is the most devastating assault one person can make on another. It is not classified as a paraphilic disorder because most instances of rape are better characterized as an assault by a male (or, quite rarely, a female) whose patterns of sexual arousal are not paraphilic. Instead, many rapists meet criteria for antisocial personality

disorder (see Chapter 12) and may engage in a variety of antisocial and aggressive acts (Bradford & Meston, 2011; Davison & Janca, 2012; McCabe & Wauchope, 2005; Quinsey, 2010). Many rapes could be described as opportunistic, in that an aggressive or antisocial individual with a marked lack of empathy and disregard for inflicting pain on others (Bernat, Calhoun, & Adams, 1999) spontaneously took advantage of a vulnerable and unsuspecting woman. These unplanned assaults often occur during robberies or other criminal events. Rapes can also be motivated by anger and vindictiveness against specific women and may have been planned in advance (Hücker, 1997; McCabe & Wauchope, 2005; Rebocho & Silva, 2014; Quinsey, 2010).

A number of years ago, we determined in our sexuality clinic that certain rapists do closely fit definitions of paraphilic disorder and could probably better be described as sadists, a finding that has since been confirmed (McCabe & Wauchope, 2005; Quinsey, 2010; Seto et al., 2012). We constructed two audiotapes on which were described (1) mutually enjoyable sexual intercourse and (2) sexual intercourse involving force on the part of the male (rape). Each tape was played twice for selected listeners. The nonrapists became sexually aroused to descriptions of mutually consenting intercourse but not to those involving force. Rapists,

however, became aroused by both types of descriptions (Abel, Barlow, Blanchard, & Guild, 1977).

Among the rapists we were evaluating, a subgroup seemed to be particularly aroused when force and acts of cruelty were involved. To assess this reaction more completely, we put together a third audiotape consisting of aggression and assault without any sexual content. A number of individuals displayed strong sexual arousal to nonsexual aggressive themes, as well as to rape, and little or no arousal to mutually enjoyable intercourse. One of our patients was the most brutal rapist we have ever encountered. By his own report, he had raped more than 100 times. His last victim spent 2 weeks in the hospital recovering from various injuries. He would bite his victim's breasts, burn her with cigarettes, beat her with belts and switches, and pull out her pubic hair while shoving objects in her vagina. Although some evidence indicated he had killed at least three of his victims, it was not sufficient to convict him. Nevertheless, he was convicted of multiple assaults and rapes and was about to begin a life sentence in a closely guarded area of the maximum-security state prison. Realizing his behavior was hopelessly out of control, he was eager to get there. He reported that all his waking hours were spent ruminating uncontrollably on sadistic fantasies. He knew he was going to spend the rest of his life in prison, probably in solitary confinement, but he hoped there was something we could do to relieve him of his obsession. By any definition, this man met criteria for sexual sadism disorder.

Pedophilic Disorder and Incest

Perhaps the most tragic sexual deviance is sexual attraction to children (or young adolescents generally aged 13 years or younger), called **pedophilia** (Blanchard, 2010; Seto, 2009, 2012). People around the world have become more aware of this problem following the well-publicized scandal in the Catholic Church, where priests, many of whom undoubtedly met criteria for pedophilic

disorder, abused children repeatedly, only to be transferred to another church and repeat these offences. Individuals with this pattern of arousal may be attracted to male children, female children, or both. In one survey, as many as 12% of men and 17% of women reported being touched inappropriately by adults when they were children (Fagan, Wise, Schmidt, & Berlin, 2002). A more recent study estimated the prevalence of sexual abuse before age 18 to be 10.14% (Pérez-Fuentes et al., 2013). Approximately 90% of abusers are male, and 10% are female (Fagan et al., 2002; Seto, 2009). Much as with adult rape, as many as 40% to 50% of sexual offenders do not have pedophilic arousal patterns and do not meet criteria for pedophilic disorder. Rather, their offenses are associated with brutal antisocial and aggressive opportunistic acts (Blanchard, 2010; Seto, 2009). Child pornography investigations have made much news lately, and individuals convicted of downloading child pornography often defend themselves by pointing out that they were "just looking" and are not pedophiles. But an important study indicates that being charged with a child pornography offense is one of the best diagnostic indications of pedophilic disorder (Seto, Cantor, & Blanchard, 2006).

If the children are the person's relatives, the pedophilia takes the form of **incest**. Although pedophilia and incest have much in common, victims of pedophilic disorder tend to be young children, and victims of incest tend to be girls beginning to mature physically (Rice & Harris, 2002). By using penile strain gauge measures, Marshall, Barbaree, and Christophe (1986) and Marshall (1997) demonstrated that incestuous males are, in general, more aroused by adult women than are males with pedophilic disorder, who tend to focus exclusively on children. Thus, incestuous relations may have more to do with availability and interpersonal issues ongoing in the family than pedophilia, as in the case of Tony.

Tony . . .

More and Less a Father

Tony, a 52-year-old married television repairman, came in depressed. About 10 years earlier, he had begun sexual activity with his 12-year-old daughter. Light kissing and some fondling gradually escalated to heavy petting and, finally, mutual masturbation. When his daughter was 16 years old, his wife discovered the ongoing incestuous relationship. She separated from her husband and eventually divorced him, taking her daughter with her. Soon, Tony remarried. Just before his initial visit to our clinic, Tony visited his daughter, then 22 years old, who was living alone in a different city. They had not seen each other for 5 years. A second visit, shortly after the first, led to a recurrence of the incestuous behavior. At this point, Tony became extremely depressed and told his new wife the whole story. She contacted our clinic with his full cooperation while his daughter sought treatment in her own city. •

We return to the case of Tony later, but several features are worth noting. First, Tony loved his daughter and was bitterly disappointed and depressed over his behavior. Occasionally, a child molester is abusive and aggressive, sometimes killing the victims; in these cases, the disorder is often both sexual sadism and pedophilia. But most child molesters are *not* physically abusive. Rarely is a child physically forced or injured. From the molester's perspective, no harm is done because there is no physical force or threats. Child molesters often rationalize their behavior as "loving" the child or teaching the child useful lessons about sexuality. The child molester almost never considers the psychological damage the victim suffers, yet these interactions often destroy the child's trust and ability to share intimacy. Child molesters rarely gauge their power over the children, who may participate in the molestation without protest yet be frightened and unwilling. Often children feel responsible for the abuse because no outward force or threat was used by the adult, and only after the abused children grow up are they able to understand they were powerless to protect themselves and not responsible for what was done to them.

Paraphilic Disorders in Women

Paraphilic disorders are seldom seen in women and were thought to be absent in women for many years, with the possible exception of sadomasochistic practices. But in recent years, several reports have appeared describing individual cases or small series of cases (Davis, 2014; Seto, 2009). Now estimates suggest that approximately 5% to 10% of all sexual offenders are women (Cortoni & Gannon, 2011; Logan, 2009; Wiegel, 2008). For example, Federoff, Fishell, and Federoff (1999) have reported 12 cases of women with paraphilic disorders seen in their clinic. Although some women had more than one paraphilic disorder, 5 of the 12 presented with pedophilia,

Criteria for Other Specified Paraphilic Disorder

This category applies to presentations in which symptoms characteristic of a paraphilic disorder that cause clinically significant distress or impairment in social, occupational, or other important areas of functioning predominate but do not meet the full criteria for any of the disorders in the paraphilic disorders diagnostic class. Examples include, but are not limited to, telephone scatology (obscene phone calls), necrophilia (corpses), zoophilia (animals), coprophilia (feces), klismaphilia (enemas), and urophilia (urine).

4 presented with exhibitionism, and 3 presented with sadomasochistic tendencies. Female sexual offenders are often treated similarly to male sexual offenders; however, recent work suggests that more attention is needed to understand the differences between these offenders and the best ways to treat them (Cortoni & Gannon, 2016).

To take several examples, one heterosexual woman was convicted of sexually molesting an unrelated 9-year-old boy while she was babysitting. It seems she had touched the boy's penis and asked him to masturbate in front of her while she watched religious programs on television. It is not unusual for individuals with paraphilic disorders to rationalize their behavior by engaging in some other practices that they consider to be morally correct or uplifting at the same time, a practice sometimes referred to as "moral cleansing." Yet another woman came to treatment because of her "uncontrollable" rituals of undressing in front of her apartment window and masturbating approximately five times a month. In addition she would,

occasionally, drive her truck through the neighborhood, where she would attempt to befriend cats and dogs by offering them food. She would then place honey or other food substances on her genital area so that the animals would lick her. As with most people with paraphilic disorders, the woman was horrified by this activity and was seeking treatment to eliminate it, although she found it highly sexually arousing. Wiegel (2008) reported on more than 175 females who admitted sexually abusing children or adolescents.

Causes of Paraphilic Disorders

Although no substitute for scientific inquiry, case histories often provide hypotheses that can then be tested by controlled scientific observations. Let's return to the cases of Robert and Tony to see if their histories contain any clues.

Robert... Revenge on Repression

Robert (who sought help for exhibitionism) was raised by a stern authoritarian father and a passive mother in a small Texas town. His father, who was a firm believer in old-time religion, often preached the evils of sexual intercourse to his family. Robert learned little about sex from his father except that it was bad, so he suppressed any emerging heterosexual urges and fantasies and as an adolescent felt uneasy around girls his own age. By accident, he discovered a private source of sexual gratification: staring at attractive and unsuspecting females through the window. This led to his first masturbatory experience.

Robert reported in retrospect that being arrested was not so bad because it disgraced his father, which was his only way of getting back at him. The courts treated him lightly (which is not unusual), and his father was publicly humiliated, forcing the family to move from their small Texas town (Barlow & Wincze, 1980). •

Tony... Trained Too Young

Tony, who sought help because of an incestuous relationship with his daughter, reported an early sexual history that contained a number of interesting events. Although he was brought up in a reasonably loving and outwardly normal Catholic family, he had an uncle who did not fit the family pattern. When he was 9 or 10, Tony was encouraged by his uncle to observe a game of strip poker that the uncle was playing with a neighbor's wife. During this period, he also observed his uncle fondling a waitress at a drive-in restaurant and shortly thereafter was instructed by his uncle to fondle his young female cousin. Thus, he had an early model for mutual fondling and masturbation and obtained some pleasure from interacting in this way with young girls. Although the uncle never touched Tony, his behavior was clearly abusive. When Tony was about 13, he engaged in

mutual manipulation with a sister and her girlfriend, which he remembers as pleasurable. Later, when Tony was 18, a brother-in-law took him to a prostitute, and he first experienced sexual intercourse. He remembered this visit as unsatisfactory because, on that and subsequent visits to prostitutes, he ejaculated prematurely—a sharp contrast to his early experience with young girls. Other experiences with adult women were also unsatisfactory. When he joined the service and was sent overseas, he sought out prostitutes who were often as young as 12. •

These cases remind us that deviant patterns of sexual arousal often occur in the context of other sexual and social problems. Undesired kinds of arousal may be associated with deficiencies in levels of "desired" arousal with consensual adults; this was certainly true for both Tony and Robert, whose sexual relationships with adults were incomplete. In many cases, an inability to develop adequate social relations with the appropriate people for sexual relationships seems to be associated with a developing of inappropriate sexual outlets (Marshall, 1997). Indeed, integrated theories of the causes of paraphilic disorders all note the presence of disordered relationships during childhood and adolescence with resulting deficits in healthy sexual development (Marshall & Barbaree, 1990; Ward & Beech, 2008). Many people with deficient sexual and social skills do not develop deviant patterns of arousal, however.

Early experience seems to have an effect that may be quite accidental. Tony's early sexual experiences just happened to be of the type he later found sexually arousing. Many individuals with pedophilic disorder also report being abused themselves as children, which turns out to be a strong predictor of later sexual abuse by the victim (Fagan et al., 2002; Nunes, Hermann, Malcom, & Lavoie, 2013). Robert's first erotic experience occurred while he was "peeping." But many of us do not find our early experiences reflected in our sexual patterns.

Another factor may be the nature of the person's early sexual fantasies. For example, Rachman and Hodgson (1968; see also Bancroft, 1989) demonstrated that sexual arousal could become associated with a neutral object—a boot, for example—if the boot was repeatedly presented while the individual was sexually aroused. One of the most powerful engines for developing unwanted arousal may be early sexual fantasies that are repeatedly reinforced through the strong sexual pleasure associated with masturbation (Bradford & Meston, 2011). Before an individual with a pedophilic or sadism disorder ever acts on his behavior, he may fantasize about it thousands of times while masturbating. Expressed as a clinical or operant-conditioning paradigm, this is another example of a learning process in which a behavior (sexual arousal to a specific object or activity) is repeatedly reinforced through association with a pleasurable consequence (orgasm). This mechanism may explain why paraphilic disorders are almost exclusively male disorders. The basic differences in frequency of masturbation between men and women that exist across cultures may contribute to the differential development of paraphilic disorders. As you have seen,

on rare occasions, cases of women with paraphilic disorders do turn up (Cortoni & Gannon, 2011; Federoff et al., 1999; Ford & Cortoni, 2008; Hunter & Mathews, 1997; Logan, 2009), and a comprehensive national study of 175 female child sexual abusers exists (Wiegel, 2008).

However, if early experiences contribute strongly to later sexual arousal patterns, then what about the Sambia males who practice exclusive homosexual behavior during childhood and early adolescence and yet are exclusively heterosexual as adults? In such cohesive societies, the social demands or “scripts” for sexual interactions are stronger and more rigid than in our culture and thus may override the effects of early experiences (Baldwin & Baldwin, 1989).

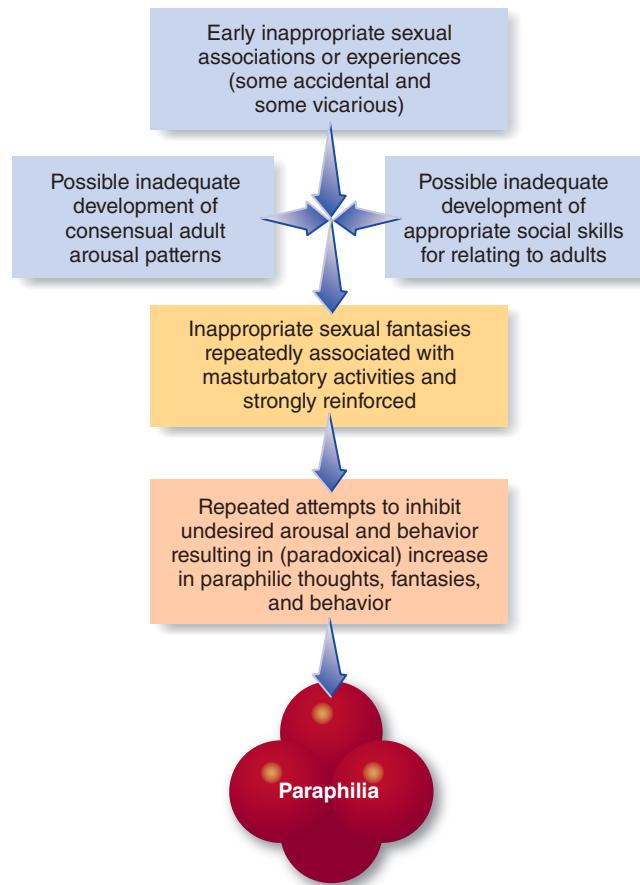

In addition, therapists and sex researchers who work with individuals with paraphilic disorders have observed what seems to be an incredibly strong sex drive. It is not uncommon for some individuals to masturbate three or four times a day. In one case seen in our clinic, a sadistic rapist masturbated approximately every half hour all day long, just as often as it was physiologically possible. We have speculated elsewhere that activity this consuming may be related to the obsessional processes of obsessive-compulsive disorder (Barlow, 2002). In both instances, the very act of trying to suppress unwanted, emotionally charged thoughts and fantasies seems to have the paradoxical effect of *increasing* their frequency and intensity (see Chapter 5). This process is also ongoing in people with eating disorders and addictions, when attempts to restrict strong addictive cravings lead to uncontrollable increases in the undesired behaviors.

Psychopathologists are also becoming interested in the phenomenon of weak inhibitory control across these paraphilic disorders, which may indicate a weak biologically based behavioral inhibition system (BIS) in the brain (Ward & Beech, 2008) that might repress serotonergic functioning. (You may remember from Chapter 5 that the BIS is a brain circuit associated with anxiety and inhibition.)

The model shown in ● Figure 10.6 incorporates the factors thought to contribute to the development of paraphilic disorders. Nevertheless, all speculations, including the hypotheses we have described, have little scientific support at this time. For example, this model does not include the biological dimension. Excess arousal in paraphilic disorders could be biologically based. Before we can make any steadfast conclusions here, more research is needed.

Assessing and Treating Paraphilic Disorders

In recent years, researchers have developed sophisticated methods for assessing specific patterns of sexual arousal (Ponseti et al., 2012; Wincze, 2009; Wincze & Weisberg, 2015). This development is important in studying paraphilic disorder because sometimes even the individual presenting with the problem is not fully aware of what caused arousal. An individual once came in to our clinic complaining of uncontrollable arousal to open-toed white sandals worn by women. He noted that he was irresistibly drawn to any woman wearing such sandals and would follow her for miles. These urges occupied much of his summer.

● FIGURE 10.6

A model of the development of paraphilia.

Subsequent objective assessment revealed that the sandal itself had no erotic value for this individual; rather, he had a strong sexual attraction to women's feet, particularly moving in a certain way. He had no reason to hide this fact; it was just that he did not realize it himself.

Using the model of paraphilic disorders described previously, we assess each patient not only for the presence of paraphilic arousal but also for levels of desired arousal to adults, for social skills, and for the ability to form relationships. Tony had no problems with social skills: He was 52 years old, reasonably happily married, and generally compatible with his second wife. His major difficulty was his continuing strong, incestuous attraction to his daughter. Nevertheless, he loved his daughter and wished strongly to interact in a normal fatherly way with her.

Psychological Treatment

A number of treatment procedures are available for decreasing unwanted arousal. Most are behavior therapy procedures directed at changing the associations and context from arousing and pleasurable to neutral. One procedure, carried out entirely in the imagination of the patient, called **covert sensitization**, was first described by Joseph Cautela (1967; see also Barlow, 2004). In this treatment, patients associate sexually arousing images in

their imagination with some reasons why the behavior is harmful or dangerous. Before treatment, the patient knows about these reasons, but the immediate pleasure and strong reinforcement the sexual activity provides is enough to overcome any thoughts of possible harm or danger that might arise in the future. This process is what happens in much unwanted addictive behavior, where the short-term pleasure outweighs the long-term harm, including bulimia.

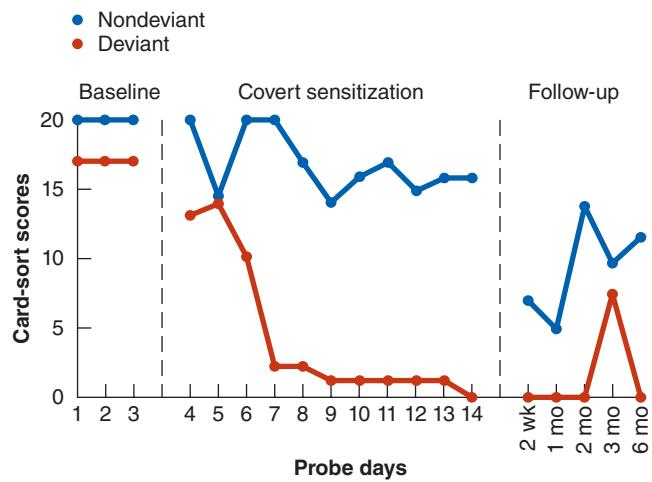

In imagination, harmful or dangerous consequences can be associated quite directly with the unwanted behavior and arousal in a powerful and emotionally meaningful way. One of the most powerful negative aspects of Tony's behavior was his embarrassment over the thought of being discovered by his current wife, other family members, or, most important, the family priest. Therefore, he was guided through the fantasy described here.

Tony... Imagining the Worst

You are alone with your daughter in your trailer. You realize that you want to caress her breasts. So you put your arm around her, slip your hand inside her blouse, and begin to caress her breasts. Unexpectedly the door to the trailer opens and in walks your wife with Father X (the family priest). Your daughter immediately jumps up and runs out the door. Your wife follows her. You are left alone with Father X. He is looking at you as if waiting for an explanation of what he has just seen. Seconds pass, but they seem like hours. You know what Father X must be thinking as he stands there staring at you. You are embarrassed and want to say something, but you can't seem to find the right words. You realize that Father X can no longer respect you as he once did. Father X finally says, "I don't understand this; this is not like you." You both begin to cry. You realize that you may have lost the love and respect of both Father X and your wife, who are important to you. Father X asks, "Do you realize what this has done to your daughter?" You think about this and you hear your daughter crying; she is hysterical. You want to run, but you can't. You are miserable and disgusted with yourself. You don't know if you will ever regain the love and respect of your wife and Father X. •

During six or eight sessions, the therapist narrates such scenes dramatically, and the patient is then instructed to imagine them daily until all arousal disappears. The results of Tony's treatment are presented in Figure 10.7. "Card-sort scores" are a measure of how much Tony wanted sexual interactions with his daughter in comparison with his wish for nonsexual fatherly interactions. His incestuous arousal was largely eliminated after 3 to 4 weeks, but the treatment did not affect his desire to interact with his daughter in a healthier manner. These results were confirmed by psychophysiological measurement of his arousal response. A

return of some arousal at a 3-month follow up prompted us to ask Tony if anything unusual was happening in his life. He confessed that his marriage had taken a turn for the worse, and sexual relations with his wife had all but ceased. A period of marital therapy restored the therapeutic gains (see Figure 10.7). Several years later, after his daughter's therapist decided she was ready, she and Tony resumed a nonsexual relationship, which they both wanted.

Two major areas in Tony's life needed treatment: deviant (incestuous) sexual arousal and marital problems. Most individuals with paraphilic arousal patterns need a great deal of attention to family functioning or other interpersonal systems in which they operate (Fagan et al., 2002; Rice & Harris, 2002). In addition, many require intervention to help strengthen appropriate desired patterns of arousal. In **orgasmic reconditioning**, patients are instructed to masturbate to their usual fantasies but to substitute more desirable ones just before ejaculation. With repeated practice, patients should be able to begin the desired fantasy earlier in the masturbatory process and still retain their arousal. This technique, first described by Gerald Davison (1968), has been used with some success in a variety of settings (Brownell et al., 1977; Maletsky, 2002). Finally, as with most strongly pleasurable but undesirable behaviors (including addiction), care must be taken to provide the patient with coping skills to prevent slips or relapses. **Relapse prevention** treatment created for addictions (Laws & O'Donohue, 1997) does just that. Patients are taught to recognize the early signs of temptation and to institute a variety of self-control procedures before their urges become too strong.

Evidence on the effects of psychological treatments for sexual offenders is decidedly mixed at this time. For sexual offenders who have come into contact with the legal system, including those who are incarcerated (obviously a very severe group), the results are modest at best in terms of preventing later occurrences of offending (termed recidivism). Reviews of large numbers of studies with

these populations are hampered because of the substantially different methods and procedures in accessing recidivism rates. But several large surveys following up sexual offenders for a period of 4 to 5 years indicate reductions in sexual recidivism (that is, reoffending) among patients who have received psychological treatments of up to 11% to 20% over what would be expected with the usual and customary treatment, with cognitive-behavioral programs proving to be the most effective in reducing recidivism (Hanson et al., 2002; Lösel & Schmucker, 2005). On the other hand, a large study from the state of California with participants who were incarcerated for their sexual offense showed very little effect of any intervention in rates of sexual or violent offending over an 8-year follow-up period after these individuals were released (Marques, Wiederanders, Day, Nelson, & van Ommeren, 2005). Recently, new techniques have been incorporated to psychological treatments for sex offenders, including techniques to enhance motivation (motivational interviewing) described in Chapter 11, and a focus on the patient's strengths, with the hope that the addition of these techniques will increase the efficacy of treatment; however, more research is needed (Marshall & Marshall, 2014).

For outpatients, on the other hand, there is at least some evidence for success when treatment is carried out by an experienced professional. For example, Barry Maletzky, a psychiatrist at the University of Oregon Medical School, and his staff reported on the treatment of more than 8,000 sexual offenders of numerous types over 20 years (Maletzky, 2002). A variety of procedures were used in a program of 3 to 4 months in a clinic devoted exclusively to this type of treatment. What makes the report notable is that Maletzky collected objective physiological outcome measures using the penile strain gauge described earlier with almost every participant in the program, in addition to patients' reports of progress. In many cases, he also obtained corroborating information from families and legal authorities.

In his follow up of these patients, Maletzky (2002) defined a treatment as successful when someone had (1) completed all treatment sessions, (2) demonstrated no deviant sexual arousal on objective physiological testing at any annual follow-up testing session, (3) reported no deviant arousal or behavior at any time since treatment ended, and (4) had no legal record of any charges of deviant sexual activity, even if unsubstantiated. He defined as a treatment failure anyone who was not a success. Any offender who did not complete treatment for any reason was counted as a failure, even though some may well have benefited from the partial treatment and gone on to recover. Using this criteria, from 75% to 95% of individuals, depending on the type of sexual offense (such as pedophilia, rape, or voyeurism), had a successful outcome. Maletzky's results were not derived from a scientifically controlled clinical trial, however.

Men who rape had the lowest success rate among all offenders with a single diagnosis (75%), and individuals with multiple paraphilic disorders had the lowest success rate of any group. Maletzky (2002) also examined factors associated with failure. Among the strongest predictors were a history of unstable social relationships, an unstable employment history, strong denial the problem exists, a history of multiple victims, and a situation in which the offender continues to live with a victim (as might be typical in cases of

incest). Many of these problems characterize the presumably more severe incarcerated population mentioned above.

Nevertheless, other groups using similar treatment procedures have achieved comparable success rates (Abel, 1989; Becker, 1990; Fagan et al., 2002). Therapist knowledge and expertise seem to be important in successfully carrying out these treatments to prevent future sexual offenses among patients.

Judith Becker used the procedures described previously in a program for adolescent sexual offenders in an inner-city setting (see, for example, Becker, 1990; Morenz & Becker, 1995). Results indicate that a relatively low 10% of those who completed treatment had committed further sex crimes. These findings were important both because many adolescent offenders carry the AIDS virus and literally are putting their victims' lives in danger and because the recidivism rate of sexual offenders without treatment is high (see, for example, Hanson, Steffy, & Gauthier, 1993; Nagayama Hall, 1995), just as it is for all pleasurable but undesirable behavior, including substance abuse. More recently, an important study found that intervening with aggressive, victimizing, or highly inappropriate sexual behavior in children aged 5 to 12 with a CBT was effective in preventing sexual offending once they reached adolescence and adulthood 10 years later compared to a group receiving play therapy (Carpentier, Silovsky, & Chaffin, 2006). Only 2% of children receiving CBT had future sexual offenses. Preventing adult sexual offending would be an important advance if these results were replicated.

Drug Treatments

The most popular drug used to treat individuals with paraphilic disorders is an antiandrogen called *cypertropon acetate* (Bradford, 1997; Assumpção, Garcia, Garcia, Bradford, & Thibaut, 2014; Seto, 2009). This "chemical castration" drug eliminates sexual desire and fantasy by reducing testosterone levels dramatically, but fantasies and arousal return as soon as the drug is removed. A second drug is *medroxyprogesterone* (Depo-Provera is the injectable form), a hormonal agent that reduces testosterone (Assumpção et al., 2014; Fagan et al., 2002). These drugs may be useful for dangerous sexual offenders who do not respond to alternative treatments or to temporarily suppress sexual arousal in patients who require it, but it is not always successful. In an earlier report of the Maletzky series (1991), only 8 of approximately 5,000 patients required the drug because they showed no response whatsoever to psychological treatments. Rösler and Witztum (1998) report successful "chemical castration" of 30 men with severe long-standing paraphilic disorders using triptorelin, which inhibits gonadotropin secretion in men. This drug appears to be somewhat more effective than the other drugs mentioned here with fewer side effects, based on this one study. Of course, the drug is only effective if taken regularly, but most individuals, facing prison as the alternative, are highly motivated to comply with treatment. In another study, Maletzky, Tolan, and McFarland (2006) found that among sexual offenders released from prison for whom medication was considered to be possibly useful, a subset who actually received the medication had significantly fewer subsequent sexual offences than a group who, for a variety of reasons, did not receive the medication.

Summary

Based on evidence from a number of settings, evidence for the psychosocial treatment of paraphilic disorders is mixed, with more success reported in outpatient settings with presumably less severe, more stable patients. But most results are uncontrolled observations from a small number of clinical research centers, and results may not be as good in other clinics and offices. In any case, as with treatment for sexual dysfunctions, psychosocial approaches to paraphilic disorders are not readily available outside of specialized treatment centers. In the meantime, the outlook for most individuals with these disorders is bleak because paraphilic disorders run a chronic course and recurrence is common.

Concept Check 10.3

Check your understanding of sexual paraphilic disorders by matching the scenarios with the correct label: (a) exhibitionistic disorder, (b) voyeuristic disorder, (c) fetishistic disorder, or (d) sexual masochism disorder.

1. Mae enjoys being slapped with leather whips during foreplay. Without such stimulation, she is unable to achieve orgasm during sex. _____
2. Kai has a collection of women's panties that arouse him. He loves to look at, collect, and wear them.

3. Sam finds arousal in walking up to strangers in the park and showing them his genitals.

4. Peeping Tom loves to look through Susie's bedroom window and watch her undress. He gets extremely excited as she disrobes. He is practicing _____.

5. What Peeping Tom does not realize is that Susie knows that he is watching. She is aroused by slowly undressing while others are watching, and she fantasizes about what they are thinking. Susie's behavior is called
_____.
6. What Peeping Tom will be shocked to find out is that "Susie" is actually Scott, a man who can become aroused only if he wears feminine clothing. Scott's behavior is _____.
_____.

Gender Dysphoria

What is it that makes you think you are a man? Or a woman? Clearly, it's more than your sexual arousal patterns or your anatomy. It's also more than the reactions and experiences of your family and society. The essence of your masculinity or femininity is a deep-seated personal sense called gender identity or the gender you actually experience. **Gender dysphoria** is present if a person's physical sex (male or female anatomy, also called "natal" sex) is not consistent with the person's sense of who he or she really is or with his or her experienced

gender. While gender dysphoria can occur on a continuum (American Psychological Association [APA] Task Force of Gender Identity and Gender Variance, 2008; Cohen-Kettenis & Pfäfflin, 2010), at the extreme end of the continuum are individuals who reject their natal sex altogether and wish to change it. People with this disorder often feel trapped in a body of the wrong sex. Consider the case of Joe.

Joe...

Trapped in the Wrong Body

Joe was a 17-year-old male and the last of five children. Although his mother had wanted a girl, he became her favorite child. His father worked long hours and had little contact with the boy. For as long as Joe could remember, he had thought of himself as a girl. He began dressing in girls' clothes of his own accord before he was 5 years old and continued cross-dressing into junior high school. He developed interests in cooking, knitting, crocheting, and embroidery, skills he acquired by reading an encyclopedia. His older brother often scorned him for his distaste of such "masculine" activities as hunting.

Joe associated mostly with girls during this period, although he remembered being strongly attached to a boy in the first grade. In his sexual fantasies, which developed around 12 years of age, he pictured himself as a female having intercourse with a male. His extremely effeminate behavior made him the object of scorn and ridicule when he entered high school at age 15. Usually passive and unassertive, he ran away from home and attempted suicide. Unable to continue in high school, he attended secretarial school, where he was the only boy in his class. During his first interview with a therapist, he reported, "I am a woman trapped in a man's body, and I would like to have surgery to become a woman." •

If the natal sex is female but the experienced gender (gender identity) is strongly male, the individual is typically referred to as a transsexual man or "transman," and a natal male would be a transwoman. If the individual has made the transition to full time living in their experienced gender (by interacting with people in their daily lives in a consistent manner in their desired gender) and they are preparing for, or have undergone sex reassignment surgery then they are referred to as "posttransition," and this is specified in the diagnostic criteria for gender dysphoria (see DSM Table 10.13). Some also prefer not to be referred to as a specific gender at all. For example, one person coming into our clinic recently preferred to be referred to as "hen" (a Swedish gender-neutral pronoun, used in place of "him" or "her").

Defining Gender Dysphoria

Gender dysphoria must be distinguished from transvestic fetishism, a paraphilic disorder (discussed earlier) in which individuals, usually males, are sexually aroused by wearing articles of clothing associated with the opposite sex. There is an occasional preference on the part of the male with transvestite patterns of sexual arousal

TABLE 10.13

Criteria for Gender Dysphoria

In Children:

- A.** A marked incongruence between one's experienced/expressed gender and assigned gender, of at least 6 months' duration, as manifested by at least six of the following (one of which must be Criterion A1)
1. A strong desire to be of the other gender or an insistence that one is the other gender (or some alternative gender different from one's assigned gender).
 2. In boys (assigned gender), a strong preference for cross-dressing or simulating female attire; or in girls (assigned gender), a strong preference for wearing only typical masculine clothing and a strong resistance to the wearing of typical feminine clothing.
 3. A strong preference for cross-gender roles in make-believe play or fantasy play.
 4. A strong preference for the toys, games, or activities stereotypically used or engaged in by the other gender.
 5. A strong preference for playmates of the other gender.
 6. In boys (assigned gender), a strong rejection of typically masculine toys, games, and activities and a strong avoidance of rough-and-tumble play or in girls (assigned gender), a strong rejection of typically feminine toys, games, and activities.
 7. A strong dislike of one's sexual anatomy.
 8. A strong desire for the primary and/or secondary sex characteristics that match one's experienced gender.

- B.** The condition is associated with clinically significant distress or impairment in social, school, or other important areas of functioning.

In Adolescents and Adults:

- A.** A marked incongruence between one's experienced/expressed gender and assigned gender, of at least 6 months' duration, as manifested by at least two of the following:
1. A marked incongruence between one's experienced/expressed gender and primary and/or secondary sex characteristics (or in young adolescents, the anticipated secondary sex characteristics).
 2. A strong desire to be rid of one's primary and/or secondary sex characteristics because of a marked incongruence with one's experienced/expressed gender (or in young adolescents, a desire to prevent the development of the anticipated secondary sex characteristics).
 3. A strong desire for the primary and/or secondary sex characteristics of the other gender.
 4. A strong desire to be of the other gender (or some alternative gender different from one's assigned gender).
 5. A strong desire to be treated as the other gender (or some alternative gender different from one's assigned gender).
 6. A strong conviction that one has the typical feelings and reactions of the other gender (or some alternative gender different from one's assigned gender).

- B.** The condition is associated with clinically significant distress or impairment in social, school, or other important areas of functioning.

for the female role, but the primary purpose of cross-dressing is sexual gratification. In the case of gender dysphoria, the primary goal is not sexual gratification but rather the desire to live life openly in a manner consistent with that of the other gender.

Gender dysphoria can also occur among individuals with disorders of sex development (DSD), formerly known as *intersexuality* or *hermaphroditism* who are born with ambiguous genitalia associated with documented hormonal or other physical abnormalities. Depending on their particular mix of characteristics, individuals with DSDs are usually "assigned" to a specific sex at birth, sometimes undergoing surgery, as well as hormonal treatments, to alter their sexual anatomy. If gender dysphoria occurs in the context of a DSD, this should be specified when making a diagnosis. But most individuals with gender dysphoria have no demonstrated physical abnormalities. (We return to the issue of DSD later.)

Finally, gender dysphoria must be distinguished from the same-sex arousal patterns of a male who sometimes behaves effeminately, or a woman with same-sex arousal patterns and masculine mannerisms. Such an individual does not feel like a

woman trapped in a man's body or have any desire to be a woman, or vice versa. Note also, as the *DSM-5* criteria do, that gender identity is independent of sexual arousal patterns (APA, 2013; Savin-Williams, 2006). For example, a transwoman (a biological [natal] male with a strongly experienced feminine gender identity) may be sexually attracted to females. Similarly, Eli Coleman and his associates (Coleman, Bockting, & Gooren, 1993) reported on nine transmen in which the individuals were sexually attracted to men. Thus, heterosexual women before surgery were gay men after surgery. Chivers and Bailey (2000) compared a group of transmen who were attracted to men (a rare occurrence) with a group of transmen who were attracted to women (the usual pattern) both before and after surgery. They found the groups did not differ in the strength of their gender identity (as males), although the latter group was more sexually assertive and, understandably, more interested in surgery to create an artificial penis.

Lawrence (2005) studied 232 transwomen both before and after surgery and found that the majority (54%) were mostly heterosexual (attracted to women) before the surgery. This changed after surgery slightly for some and dramatically for a few, such

that only 25% remained attracted to women after surgery, thus making them technically gay. This latter group may constitute a distinct subset of transwomen with a different pattern of development called *autogynephilia*, in which gender dysphoria begins with a strong and specific sexual attraction to a fantasy of oneself (*auto*) as a female (*gyne*). This fantasy then progresses to a more comprehensive all-encompassing experienced gender as a female. Individuals in this subgroup of biological males were not effeminate as boys but became sexually aroused while cross-dressing and to fantasies of themselves as women. Over time, these fantasies progress to *becoming* a woman (Bailey, 2003; Carroll, 2007; Lawrence, 2013). This distinction is controversial, but it is supported by research (Carroll, 2007; see p. 379).

Gender dysphoria resulting in a rejection of natal sex is relatively rare. The estimated prevalence in natal males is between 5 and 14 per 1,000 and for natal females between 2 and 3 per 1,000 (American Psychiatric Association, 2013; 2015), occurring approximately 3 times more frequently in natal males than in natal females (American Psychological Association, 2008; Judge, O'Donovan, Callaghan, Gaoatswe, & O'Shea, 2014; Sohn & Bosinski, 2007). Many countries now require a series of legal steps to change gender. In Germany, between 2.1 and 2.4 per 100,000 in the population took at least the first legal step of changing their first names in the 1990s; in that country, the male:female ratio of people with gender dysphoria is 2.3:1 (Weitze & Osburg, 1996). Since 2006 in New York City, people may choose to alter the natal sex listed on their birth certificates following surgery.

In some cultures, individuals with a different gender experience are often accorded the status of "shaman" or "seer" and treated as wisdom figures. A shaman is almost always a male adopting a female role (see, for example, Coleman, Colgan, & Gooren, 1992). Stoller (1976) reported on two contemporary feminized Native American men who were not only accepted but also esteemed by their tribes for their expertise in healing rituals. Contrary to the respect accorded these individuals in some cultures, social tolerance for them remains relatively low in Western

cultures, although that is changing particularly as individuals such as Kaitlyn Jenner and Chaz Bono forthrightly and openly discuss gender dysphoria. In recent years, actors such as Laverne Cox, books such as "Becoming Nicole", and movies such as *The Danish Girl*, have also begun to raise awareness about gender dysphoria and encourage more discussion on the topic.

Causes

Research has yet to uncover any specific biological contributions to gender dysphoria or alternative gender experience for that matter, although it seems likely that a biological predisposition will be discovered. Coolidge, Thede, and Young (2002) estimated that genetics contributed about 62% to creating a vulnerability to experience gender dysphoria in their twin sample. Thirty-eight percent of the vulnerability came from nonshared (unique) environmental events. A study from the Netherlands twin registry suggested that 70% of the vulnerability for cross-gender behavior (behaving in a manner consistent with the opposite natal sex) was genetic as opposed to environmental, but this behavior is not the same as gender identity, which was not measured (as explained later) (van Beijsterveldt, Hudziak, & Boomsma, 2006). Gomez-Gil and colleagues (2010) found a somewhat higher prevalence of gender dysphoria than would be expected by chance in nontwin siblings of a larger group (995) of individuals with gender dysphoria. Segal (2006), on the other hand, found two monozygotic (identical) female twin pairs in which one twin had gender dysphoria and the other did not; no unusual medical or life history factors were identified to account for this difference. Nevertheless, genetic contributions are clearly part of the picture (Heylens et al., 2012).

Early research suggested that, as with sexual orientation, slightly higher levels of testosterone or estrogen at certain critical periods of development might masculinize a female fetus or feminize a male fetus (see, for example, Keefe, 2002). Variations in hormonal levels could occur naturally or because of medication that a pregnant mother is taking. Scientists have studied girls

aged 5 to 12 with an intersex condition known as congenital adrenal hyperplasia (CAH). In CAH, the brains of these chromosomal females are flooded with male hormones (androgens), which, among other results, produce mostly masculine external genitalia, although internal organs (ovaries and so on) remain female. Meyer-Bahlburg and colleagues (2004) studied 15 girls with CAH who had been correctly identified as female at birth and raised as girls and looked at their development. Compared with groups of girls and boys without CAH, the CAH girls were masculine in their behavior, but there were no differences in gender identity. Thus, scientists have yet to establish a link between prenatal hormonal influence and later gender identity, although it is still possible that one exists. Structural differences in the area of the brain that controls male sex hormones have also been observed in individuals with male-to-female gender dysphoria (Zhou, Hofman,

Laverne Cox and Caitlin Jenner are both male-to-female transgender (trans women) who are strong and effective advocates for the transgender community.

Gooren, & Swaab, 1995; Hannema et al., 2014), with the result that the brains are comparatively more feminine. But it isn't clear whether this is a cause or an effect.

At least some evidence suggests that gender identity firms up between 18 months and 3 years of age (Ehrhardt & Meyer-Bahlburg, 1981; Money & Ehrhardt, 1972) and is relatively fixed after that. But newer studies suggest that possible preexisting biological factors have already had their impact. One interesting case illustrating this phenomenon was originally reported by Green and Money (1969), who described the sequence of events that occurred in the case of Bruce/Brenda. There do seem to be other case studies of children whose gender was reassigned at birth who adapted successfully (see, for example, Gearhart, 1989), but it certainly seems that biology expressed itself in Bruce's case.

Bruce/Brenda...

Gender and Biology

A set of male identical twins was born into a well-adjusted family. Several months later, an unfortunate accident occurred. Although circumcision went routinely for one of the boys, the physician's hand slipped so that the electric current in the device burned off the penis of the second baby. After working through their hostility toward the physician, the parents consulted specialists in children with intersexual problems and were faced with a choice. The specialists pointed out that the easiest solution would be to reassign their son Bruce as a girl, and the parents agreed. At the age of several months, Bruce became "Brenda." The parents purchased a new wardrobe and treated the child in every way possible as a girl. These twins were followed through childhood and, upon reaching puberty, the young girl was given hormonal replacement therapy. After 6 years, the doctors lost track of the case but assumed the child had adjusted well. However, Brenda endured almost intolerable inner turmoil. We know this because two clinical scientists found this individual and reported a long-term follow up (Diamond & Sigmundson, 1997). Brenda never adjusted to her assigned gender. As a child, she preferred rough-and-tumble play and resisted wearing girls' clothes. In public bathrooms, she often insisted on urinating while standing up, which usually made a mess. By early adolescence, Brenda was pretty sure she was a boy, but her doctors pressed her to act more feminine. When she was 14, she confronted her parents, telling them she was so miserable she was considering suicide. At that point, they told her the true story, and the muddy waters of her mind began to clear. Shortly thereafter, Brenda had additional surgery changing her back to Bruce, who married and became the father of three adopted children. But the turmoil of his early life never fully resolved. Perhaps because of this, perhaps because his twin brother had recently died and he had lost his job and was divorcing, or perhaps because of a combination of these factors, David Reimer (his real name) committed suicide at age 38 in 2004. •

Richard Green, a pioneering researcher in this area, has studied boys who behave in feminine ways and girls who behave in masculine ways, investigating what makes them that way and following what happens to them (Green, 1987). This set of behaviors and attitudes is referred to as **gender nonconformity** (see, for example, Skidmore, Linsenmeier, & Bailey, 2006). Green discovered that when most young boys spontaneously display "feminine" interests and behaviors, they are typically discouraged by most families, and these behaviors usually cease. Boys who consistently display these behaviors are not discouraged, however, and are sometimes encouraged.

Other factors, such as excessive attention and physical contact on the part of the mother, may also play some role, as may a lack of male playmates during the early years of socialization. These are just some factors identified by Green as characteristic of gender-nonconforming boys. Remember that as-yet-undiscovered biological factors may also contribute to the spontaneous display of cross-gender behaviors and interests. For example, one recent study found that exposure to higher levels of fetal testosterone was associated with more masculine play behavior in both boys and girls during childhood (Auyeng et al., 2009). In following up with these boys, however, Green discovered that few seem to develop the gender incongruence. The most likely outcome is the development of homosexual preferences, but even this particular sexual arousal pattern seems to occur exclusively in only approximately 40% of the gender-nonconforming boys. Another 32% show some degree of *bisexuality*, sexual attraction to both their own and the opposite sex. Looking at it from the other side, 60% were functioning heterosexually. These results were replicated in subsequent prospective studies of boys (Zucker, 2005). Girls with gender-nonconforming behavior are seldom studied, because their behavior attracts much less attention in Western societies. But one recent study followed 25 girls prospectively, beginning at approximately 9 years of age, whose behavior was extreme enough that they were referred to a gender identity clinic. Most of these girls met criteria for childhood gender dysphoria disorder or came very close to it. At a follow up, when these girls (now women) averaged 25 years of age, only three met criteria for gender dysphoria. Another six reported bisexual/homosexual behavior; eight more would have homosexual fantasies but not behavior. The remaining eight women were heterosexual (Drummond, Bradley, Peterson-Badali, & Zucker, 2008).

This finding of only a very loose relationship between gender-nonconforming behavior and later sexual development is not unique to American culture. For example, similar relationships between early gender-nonconforming behavior and later development exist among the Fa'afafine, a group of males with homosexual orientation in the Pacific Islands country of Samoa (Bartlett & Vasey, 2006). And even in strict Muslim societies where any hint of gender-nonconforming behavior is severely discouraged, gender-nonconforming behavior, gender dysphoria, or both may develop (Doğan & Doğan, 2006). We can safely say that the causes of the development of incongruent experienced gender is still something of a mystery.

Treatment

Treatment is available for gender dysphoria in specialty clinics around the world, although much controversy surrounds

treatment (Carroll, 2007; Meyer-Bahlburg, 2010). For adults requesting full sex transition treatment guidelines from both the American Psychiatric Association and the American Psychological Association have now been published (American Psychological Association, 2015; Byne et al., 2012). The treatment guidelines published by the American Psychological Association (2015) highlight the diversity of problems facing gender-nonconforming individuals and encourage therapists to take a holistic view of these patients (i.e., helping to build resilience, working within existing family structures, and collaborating with other care providers). Recommendations from the American Psychiatric Association guidelines, when addressing adult patients with gender dysphoria more specifically, begin with the least intrusive step of full psychological evaluation and education before proceeding to partially reversible steps such as administration of gonadal hormones to bring about desired secondary sex characteristics. The final nonreversible step is to alter anatomy physically to be consistent with gender identity through **sex reassignment surgery**.

Sex Reassignment Surgery

To qualify for surgery at a reputable clinic, individuals must live in the desired gender for 1 to 2 years so that they can be sure they want to change sex. They also must be stable psychologically, financially, and socially. In transwomen, hormones are administered to promote *gynecomastia* (the growth of breasts) and the development of other secondary sex characteristics. Facial hair is typically removed through electrolysis. If the individual is satisfied with the events of the trial period, the genitals are removed and a vagina is constructed.

For transmen, an artificial penis is typically constructed through plastic surgery, using sections of skin and muscle from elsewhere in the body, such as the thigh. Breasts are surgically removed. Genital surgery is more difficult and complex in natal females. Estimates of satisfaction with surgery indicate predominantly successful adjustment (between 75% and 100% generally satisfied) among those who could be reached for follow ups, with transmen generally adjusting better than transwomen (Blanchard & Steiner, 1992; Bodlund & Kullgren, 1996; Byne et al., 2012; Carroll, 2007; Costantino et al., 2013; Johansson, Sundbom, Höjerback, & Bodlund, 2010). Many people were not available for follow up, however. Approximately 1% to 7% of individuals who have sex reassignment surgery and were reached for follow-up later regret having the surgery to some extent (Bancroft, 1989; Byne et al., 2012; Dhejne, Öberg, Aryer, & Landén, 2014; Johansson et al., 2010; Lundstrom, Pauly, & Walinder, 1984). This is unfortunate, because the surgery is irreversible. Also, as many as 2% attempt suicide after surgery, a rate much higher than the rate for the general population. One problem may be incorrect diagnosis and assessment. For example, one study of 186 Dutch psychiatrists reporting on 584 patients presenting with gender dysphoria revealed little consensus on diagnostic features or the minimum age at which sex reassignment surgery is safe. Rather, the decision seemed to rest on personal preferences of the psychiatrist (Campo, Nijman, Merckelbach, & Evers, 2003). These assessments are complex and should always be done at highly specialized gender

clinics. Predictors of regret in addition to misdiagnosis include the presence of comorbid diagnoses such as alcohol use and psychosis, and poor family support (Byne et al., 2012). Nevertheless, surgery has made life worth living for many people who suffered the effects of existing in what they felt to be the wrong body with rates of satisfaction in recent years averaging about 90% (Johansson et al., 2010).

Treatment of Gender Nonconformity in Children

Even more controversial is the treatment of gender-nonconforming children. On the one hand, some segments of society, particularly in more traditionally tolerant areas of the country such as San Francisco and New York, are becoming more open to gender variations in both children and adults. In some schools, children are being allowed and even encouraged to dress and appear in gender-nonconforming ways on the assumption that this gives freer rein to who they “really are” (Brown, 2006). Indeed, one study suggests that gender non-conforming children, who presented themselves according to their gender identity in everyday life exhibit cognitions more consistent with their expressed gender than their natal sex (Olson, Key, & Eaton, 2015). On the other hand, Skidmore and colleagues (2006) examined whether gender nonconformity was related to psychological distress in a community-based sample of gay men and lesbians. Gender nonconformity was measured by self-reports of childhood gender nonconformity, as well as ratings of current behavior. The researchers found that gender nonconformity was related to psychological distress (depression, anxiety), but only for gay men and not for lesbians. More recent research has also found that gender nonconformity is associated with lower levels of psychological well-being, but it has not found the same interaction with sexual orientation (Rieger & Savin-Williams, 2012); thus more research is needed in this area.

Although only a minority of gay men report gender nonconformity as boys; research indicates that many of these

gender-nonconforming boys defeminize as they reach adulthood, perhaps because of persistent social pressure from their family and peers. Also, interventions exist to alter gender-nonconforming behavior in young children to avoid the ostracism and scorn these children encounter in most school settings (e.g., Rekers, Kilgus, & Rosen, 1990). Other interventions exist to build resilience in children who exhibit gender-nonconforming behavior by strengthening their relationships with peers and caregivers, increasing their sense of self-control, and increasing their sense of belonging within a community or culture (Allan & Ungar, 2014).

Thus, society is faced with a dilemma that requires more research. Should the free expression of gender nonconformity be encouraged knowing that, in most parts of world, gender nonconformity will make for difficult social adaptation leading to substantial psychological distress for decades to come, particularly since the gender nonconformity is unlikely to persist into adolescence or adulthood? Or will psychological adjustment be more positive if gender nonconformity is allowed and facilitated? If research confirms that adjustment is more positive if individuals find their own place on a gender continuum, then large-scale campaigns to alter social norms may well occur along the lines of the successful campaigns of the past several decades for gay rights, after a consensus developed in the 1970s that homosexuality was not a disorder. Research will continue on this important and interesting topic.

Treatment guidelines developed by the American Psychiatric Association and the American Psychological Association for gender nonconformity in youth simply outline the options available (American Psychological Association, 2015; Byne et al., 2012). One option would be to work with the child and caregivers to lessen gender dysphoria and decrease cross-gender behaviors and identification on the assumption that these behaviors are unlikely to persist anyway and the negative consequences of social rejection could be avoided and that avoiding later intrusive surgery would be desirable. A second approach could be described as “watchful waiting” by letting expressed gender unfold naturally. This goal requires strong support from caregivers and the community because of the potential social and interpersonal risks and lack of integration with peer groups. Yet a third approach advocates actively affirming and encouraging cross-gender identification, but critics point out that gender nonconformity usually does not persist and that taking this course would increase the likelihood of persistence. There is very little hard scientific information on which course would be the most beneficial for a given child.

More recently, new treatment approaches have been developed in some clinics for children who more clearly identify as transsexual. Given the irreversible nature of many treatments for gender dysphoria, treatment for these children needs to be administered with caution. One specialty clinic for these children at well-known Children’s Hospital in Boston, has attracted attention for their treatment approach. In pre-pubescent children, first-line treatments include psychoeducation and therapy

to help clarify gender identity and navigate the complex social issues associated with cross-gender identification. In individuals closer to puberty, psychotherapy is also recommended. However, a medical intervention that blocks puberty is also available (if, after detailed assessment, it is determined that such treatment would be in the best interest of the patient based on the severity of the discordance between gender identity and natal sex as well as family and social considerations). This medication allows the adolescent time to continue exploring gender identity issues without the added stress of beginning puberty in a gender that is inconsistent with their identity (Tishelman et al., 2014). While this treatment has received some positive press in recent years, it still remains controversial in many parts of the United States.

Treatment of Disorders of Sex Development (Intersexuality)

As we noted, surgery and hormonal replacement therapy has been standard treatment for many individuals with DSDs who may be born with physical characteristics of both sexes in order to make their sexual anatomy match as closely to their assigned gender as possible. These procedures usually take place soon after birth. But in later years, gender dysphoria may also develop in these individuals, and, if it does, a similar sequence of treatment steps beginning with the least intrusive would be initiated as described above (Byne et al., 2012). Of course, treatment for gender dysphoria in any form has always been controversial and particularly so when a DSD is present. For example, one alternative approach has been proposed by Anne Fausto-Sterling, who suggests that there are actually five sexes: males; females; “herms,” who are named after true hermaphrodites, or people born with both testes and ovaries; “merms,” who are anatomically more male than female but possess some aspect of female genitalia; and “ferms,” who have ovaries but possess some aspect of male genitalia (Fausto-Sterling, 2000a, 2000b; 2015). She estimates, based on the best evidence available, that for every 1,000 children born, 17, or 1.7%, may be present with a DSD in some form. What Fausto-Sterling (2000b) and others have noted is that individuals in this group are often dissatisfied with surgery, much as Bruce was in the case we described. There have been instances in which doctors, upon observing anatomical sexual ambiguity after birth, treat it as an emergency and immediately perform surgery.

Fausto-Sterling suggests that an increasing number of pediatric endocrinologists, urologists, and psychologists are examining the wisdom of early genital surgery that results in an irreversible gender assignment. Instead, health professionals may want to examine closely the precise nature of the DSD and consider surgery only as a last resort, and only when they are quite sure the particular condition will lead to a specific psychological gender identity. Otherwise, psychological treatments to help individuals adapt to their particular sexual anatomy, or their emerging gender experience, might be more appropriate.

Answer the following questions about normal sexuality and gender dysphoria.

1. Name some gender differences that exist in sexual attitudes and sexual behavior. _____
2. Which sexual preference or preferences are normal, and how are they developed? _____

3. Charlie always felt out of place with the boys. At a young age, he preferred to play with girls and insisted that his parents call him "Charlene." He later claimed that he felt like a woman trapped in a man's body. What disorder could Charlie have? _____

4. What could be the cause(s) of Charlie's disorder? _____

5. What treatments could be given to Charlie? _____

DSM Controversies: *Paraphilia or Paraphilic Disorder?*

In DSM-IV, a paraphilia was diagnosed based on the presence of intense and persistent sexual interest as determined by the presence of strong sexual fantasies, sexual urges, or behaviors generally involving nonhuman objects, the suffering or humiliation of oneself or one's partner, or children or other nonconsenting persons. It was also noted that these fantasies, urges, or behaviors cause clinically significant distress or impairment. In DSM-5, an explicit distinction is made between paraphilia, which denotes any intense and persistent sexual interest other than sexual interest and behaviors with phenotypically normal, physically mature, consenting human partners, and paraphilic disorder.

A paraphilic disorder is a paraphilia which either causes distress or impairment

to the individual or personal harm or risk of harm to others. Thus, one might have a strong and persistent sexual interest and arousal pattern in young children, but if it is not acted on and does not cause personal distress, it is not by definition a disorder; although abnormal, it is no different than being non-normally tall or short. This change was made to accommodate the high prevalence of "paraphilic" type fantasies that might occasionally occur among people without mental disorders (Ahlers et al., 2011). An example would be a harmless fetish for an article of clothing that is incorporated into sexual activity with a willing partner. Here, the individual would have a paraphilia but not a paraphilic disorder. But what if

the paraphilia focused on sex with small children or inflicting grievous harm on other individuals? Advocates of the change would point out that if these fantasies are not acted upon in any way, no harm is done and it is not a disorder, and that it does more harm to pathologize this very private behavior than to call it a mental disorder. Critics would point out that it is highly unlikely that anyone with such a strong and persistent pattern of sexual arousal would not at least watch an occasional video on the Internet if it were readily available, and in so doing, harm would occur. This example is yet another point of contention in the fundamental question of what defines a mental disorder, discussed in Chapter 1.

What Is Normal Sexuality?

- ▶ Patterns of sexual behavior, both heterosexual and homosexual, vary around the world in terms of both behavior and risks. Approximately 20% of individuals who have been surveyed engage in sex with numerous partners, which puts them at risk for sexually transmitted diseases such as AIDS. Recent surveys also suggest that as many as 60% of U.S. college females practice unsafe sex by not using condoms.
- ▶ Two types of disorders are associated with sexual functioning—sexual dysfunctions and paraphilic disorders. Gender dysphoria is not specifically a sexual disorder, but rather a marked incongruence between one's natal (biological) sex and the gender one experiences or identifies with.

An Overview of Sexual Dysfunctions

- ▶ Sexual dysfunction includes a variety of disorders in which people find it difficult to function adequately during sexual relations.
- ▶ Specific sexual dysfunctions include disorders of sexual desire (hypoactive sexual desire disorder in males and female sexual interest/arousal disorder) in which interest in sexual relations is extremely low or nonexistent; disorders of sexual arousal (erectile disorder and female sexual interest/arousal disorder) in which achieving or maintaining adequate penile erection or sexual excitement and vaginal lubrication is problematic; and orgasmic disorders (female orgasmic disorder and delayed or premature ejaculation in males) in which orgasm occurs too quickly or not at all. The most common disorder in this category is premature ejaculation, which occurs in males; inhibited orgasm is commonly seen in females.
- ▶ Sexual pain disorder, specifically genito-pelvic pain/penetration disorder in women, in which unbearable pain is associated with sexual relations, including vaginismus in which the pelvic muscles in the outer third of the vagina undergo involuntary spasms when intercourse is attempted.

Assessing Sexual Behavior

- ▶ The three components of assessment are interviews, a complete medical evaluation, and psychophysiological assessment.

Causes and Treatment of Sexual Dysfunction

- ▶ Sexual dysfunction is associated with socially transmitted negative attitudes about sex, current relationship difficulties, and anxiety focused on sexual activity.
- ▶ Psychosocial treatment of sexual dysfunctions is generally successful but not readily available. In recent years, various medical approaches have become available, including the drug Viagra and similar drugs. These treatments focus mostly on erectile dysfunction

and are effective and satisfying for about one third of patients who try them. Some preliminary evidence exists on a new drug, flibanserin, as a possible treatment for hypoactive sexual desire in women, but more research is needed.

Paraphilic Disorders: Clinical Descriptions

- ▶ Paraphilia is sexual attraction to inappropriate people, such as children, or to inappropriate objects, such as articles of clothing. Paraphilia becomes a paraphilic disorder when the sexual attraction causes significant distress or impairment to the individual or causes harm or the risk of harm to others.
- ▶ The paraphilic disorders include fetishistic disorder, in which sexual arousal occurs almost exclusively in the context of inappropriate objects or individuals; exhibitionistic disorder, in which sexual gratification is attained by exposing one's genitals to unsuspecting strangers; voyeuristic disorder, in which sexual arousal is derived from observing unsuspecting individuals undressing or naked; transvestic disorder, in which individuals are sexually aroused by wearing clothing of the opposite sex; sexual sadism disorder, in which sexual arousal is associated with inflicting pain or humiliation; sexual masochism disorder, in which sexual arousal is associated with experiencing pain or humiliation; and pedophilic disorder, in which there is a strong sexual attraction toward children. Incest is a type of pedophilia in which the victim is related, often a son or daughter.
- ▶ The development of paraphilic disorders is associated with deficiencies in consensual adult sexual arousal, deficiencies in consensual adult social skills, deviant sexual fantasies that may develop before or during puberty, and attempts by the individual to suppress thoughts associated with these arousal patterns.

Assessing and Treating Paraphilic Disorders

- ▶ Psychosocial treatments of these disorders are only modestly effective at best among individuals who are incarcerated, but somewhat more successful in less severe outpatients.

Gender Dysphoria

- ▶ Gender dysphoria is a dissatisfaction with one's natal (biological) sex and the sense that one is really the opposite gender (for example, a woman trapped in a man's body). A person develops a sense of gender or gender identity between 18 months and 3 years of age, and it seems that both congruent gender identity and incongruent gender identity have biological roots influenced by learning.
- ▶ Treatment for adults with marked gender incongruence (transsexualism) may include sex reassignment surgery integrated with psychological approaches.

Exploring Sexual Disorders and Gender Dysphoria

- Sexual behavior is considered normal in our culture unless it is associated with one of three kinds of impaired functioning—gender dysphoria, sexual dysfunction, or paraphilic disorders.
- Sexual orientation probably has a strong biological basis that is influenced by environmental and social factors.

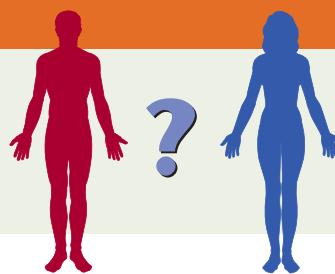

GENDER DYSPHORIA

Present when a person feels trapped in a body that is the “wrong” sex, that does not match his or her innate sense of personal identity. (Gender identity is independent of sexual arousal patterns.) Relatively rare.

Treatment

- Sex reassignment surgery: removal of breasts or penis; genital reconstruction
 - Requires rigorous psychological preparation and financial and social stability
- Psychosocial intervention to change gender identity
 - Usually unsuccessful except as temporary relief until surgery

PARAPHILIC DISORDERS

Sexual arousal occurs almost exclusively in the context of inappropriate objects or individuals.

Types

- **Fetishistic disorder:** Sexual attraction to nonliving objects
- **Voyeuristic disorder:** Sexual arousal achieved by viewing unsuspecting person undressing or naked
- **Exhibitionistic disorder:** Sexual gratification from exposing one's genitals to unsuspecting strangers
- **Transvestic disorder:** Sexual arousal from wearing opposite-sex clothing (cross-dressing)
- **Sexual sadism disorder:** Sexual arousal associated with inflicting pain or humiliation
- **Sexual masochism disorder:** Sexual arousal associated with experiencing pain or humiliation
- **Pedophilic disorder:** Strong sexual attraction to children
- **Incest:** Sexual attraction to family member

Causes

- Preexisting deficiencies
 - In levels of arousal with consensual adults
 - In consensual adult social skills
- Treatment received from adults during childhood
- Early sexual fantasies reinforced by masturbation
- Extremely strong sex drive combined with uncontrollable thought processes

Treatment

- **Covert sensitization:** Repeated mental reviewing of aversive consequences to establish negative associations with behavior
- **Relapse prevention:** Therapeutic preparation for coping with future situations
- **Orgasmic reconditioning:** Pairing appropriate stimuli with masturbation to create positive arousal patterns
- **Medical:** Drugs that reduce testosterone to suppress sexual desire; fantasies and arousal return when drugs are stopped

PhotoDisc/Getty Images

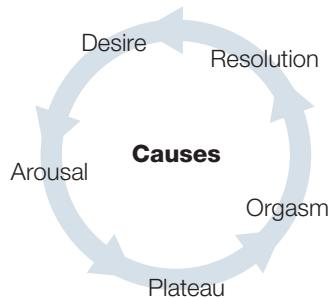

SEXUAL DYSFUNCTIONS

Sexual dysfunctions can be

- **Lifelong:** Present during entire sexual history
- **Acquired:** Interrupts normal sexual pattern
- **Generalized:** Present in every encounter
- **Situational:** Present only with certain partners or at certain times

The Human Sexual Response Cycle

A dysfunction is an impairment in one of the sexual response stages.

Types of Sexual Dysfunctions

Sexual Desire Disorders

- **Male hypoactive sexual desire disorder:** Apparent lack of interest in sexual activity or fantasy

Sexual Arousal Disorders

- **Erectile disorder:** Recurring inability to achieve or maintain adequate erection
- **Female sexual interest/arousal disorder:** Recurring inability to achieve or maintain adequate lubrication

Orgasm Disorders

- **Female orgasmic disorder:** Inability to achieve orgasm despite adequate desire and arousal
- **Premature ejaculation:** Ejaculation before it is desired, with minimal stimulation

Sexual Pain Disorders

- **Genito-pelvic pain/penetration disorder:** Marked pain, anxiety, and tension associated with intercourse for which there is no medical cause; vaginismus (i.e., involuntary muscle spasms in the front of the vagina that prevent or interfere with intercourse); occurs in females

Psychological and Physical Interactions

- A combination of influences is almost always present
 - Specific biological predisposition and psychological factors may produce a particular disorder

Psychological Contributions

- Distraction
- Underestimates of arousal
- Negative thought processes

Sociocultural Contributions

- Erotophobia, caused by formative experiences of sexual cues as alarming
- Negative experiences, such as rape
- Deterioration of relationship

Biological Contributions

- Neurological or other nervous system problems
- Vascular disease
- Chronic illness
- Prescription medication
- Drugs of abuse, including alcohol

Treatment

- **Psychosocial:** Therapeutic program to facilitate communication, improve sexual education, and eliminate anxiety. Both partners participate fully.
- **Medical:** Almost all interventions focus on male erectile disorder, including drugs, prostheses, and surgery. Medical treatment is combined with sexual education and therapy to achieve maximum benefit.

Would you be surprised if we told you that a group of psychological disorders costs U.S. citizens hundreds of billions of dollars each year, kills 500,000 Americans annually, and is implicated in street crime, homelessness, and gang violence? Would you be even more surprised to learn that most of us have behaved in ways characteristic of these disorders at some point in our lives? You shouldn't. Smoking cigarettes, drinking alcohol, and using illegal drugs are all related to these disorders, and they are responsible for astronomical financial costs and the tragic waste of hundreds of thousands of human lives each year. In this chapter, we explore **substance-related and addictive disorders**, which are associated with the abuse of drugs and other substances people take to alter the way they think, feel, and behave. In addition, the newly added disorder to this category in *DSM-5*—gambling disorder—will be discussed. These disorders have cursed us for centuries and continue to affect how we live, work, and play.

Equally disruptive to the people affected, **impulse-control disorders** represent a number of related problems that involve the inability to resist acting on a drive or temptation. Included in this group are those who cannot resist aggressive impulses or the impulse to steal, for example, or to set fires. Controversy surrounds substance-related, addictive, and impulse-control disorders because our society sometimes believes that these problems result simply from a lack of “will.” If you wanted to stop drinking, using cocaine, or gambling, well, you would just stop. We first examine those individuals who are being harmed by their use of a variety of chemical substances (substance-related disorders) or their addictive behaviors (gambling disorder) and then turn our attention to the puzzling array of disorders that are under the heading of impulse-control disorders.

Perspectives on Substance-Related and Addictive Disorders

The cost in lives, money, and emotional turmoil has made the issue of drug abuse a major concern worldwide. Currently, around

9.7% of the general population (12 years or older) are believed to use illegal drugs (Substance Abuse and Mental Health Services Administration [SAMHSA], 2013). Many U.S. presidential administrations have declared various “wars on drugs,” but the problem remains. The Roman Catholic Church issued a universal catechism in 1992 that officially declared drug abuse and drunk driving to be sins (Riding, 1992). Yet from the drug-related deaths of rock stars Jimi Hendrix and Janis Joplin in 1970 to contemporary celebrities such as Michael Jackson, Whitney Houston, and Amy Winehouse, drug use continues to negatively impact the lives of many. And stories such as these not only are about the rich and famous but are retold in every corner of our society.

As we have just seen, a significant number of people continue to use illicit drugs and abuse prescription drugs regularly. Consider the case of Danny, who has the disturbing but common habit of **alcohol use disorder**, and several substance use disorders.

Danny... Comorbid Substance Use Disorders

At the age of 43, Danny was in jail, awaiting trial on vehicular manslaughter charges stemming from a DUI accident that left one woman dead. Danny’s story illustrates the lifelong pattern that characterizes the behavior of many people who are affected by substance-related disorders.

Danny grew up in the suburbs in the United States, the youngest of three children. He was well liked in school and an average student. Like many of his friends, he smoked cigarettes in his early teens and drank beer with his friends at night behind his high school. Unlike most of his friends, however, Danny almost always drank until he was obviously drunk; he also experimented with many other drugs, including cocaine, heroin, “speed” (amphetamines), and “downers” (barbiturates).

(Continued next page)

After high school, Danny attended a local community college for one semester, but he dropped out after failing most of his courses. His dismal performance in school seemed to be related to his missing most classes rather than to an inability to learn and understand the material. He had difficulty getting up for classes after partying most of the night, which he did with increasing frequency. His moods were highly variable, and he was often unpleasant. Danny's family knew he occasionally drank too much, but they didn't know (or didn't want to know) about his other drug use. He had for years forbidden anyone to go into his room after his mother found little packets of white powder (probably cocaine) in his sock drawer. He said he was keeping them for a friend and that he would return them immediately. He was furious that his family might suspect him of using drugs. Money was sometimes missing from the house, and once some stereo equipment "disappeared," but if his family members suspected Danny they never admitted it.

Danny held a series of low-paying jobs, and when he was working his family reassured themselves that he was back on track and things would be fine. Unfortunately, he rarely held a job for more than a few months. The money he earned usually turned into drugs, and he was usually fired for poor job attendance and performance. Because he continued to live at home, Danny could survive despite frequent periods of unemployment. When he was in his late 20s, Danny seemed to have a personal revelation. He announced that he needed help and planned to check into an alcohol rehabilitation center; he still would not admit to using other drugs. His family's joy and relief were overwhelming, and no one questioned his request for several thousand dollars to help pay for the private program he said he wanted to attend. Danny disappeared for several weeks, presumably because he was in the rehabilitation program. However, a call from the local police station put an end to this fantasy: Danny had been found quite high, living in an abandoned building. As with many of these incidents, we never learned all the details, but it appears that Danny spent his family's money on drugs and had a 3-week binge with some friends. Danny's deceptiveness and financial irresponsibility greatly strained his relationship with his family. He was allowed to continue living at home, but his parents and siblings excluded him from their emotional lives. Following this, Danny seemed to straighten out, and he held a job at a gas station for almost 2 years. He became friendly with the station owner and his son, and he often went hunting with them during the season. Without any obvious warning, however, Danny resumed drinking and using drugs and was arrested for robbing the very place that had kept him employed for many months.

Although he received probation for that offense upon promising to attend drug treatment, his pattern continued. Years later while driving under the influence of multiple substances, he hit another car and the 28-year-old driver of that car was killed.

Why did Danny's drug use become so problematic when many of his friends' and siblings' use did not? Why did he steal from his family and friends? What ultimately became of him? We return to Danny's frustrating story later when we look at the causes and treatment of substance-related disorders. •

Levels of Involvement

Although each drug described in this chapter has unique effects, there are similarities in the ways they are used and how people who abuse them are treated. First, we present some concepts that apply to substance-related disorders in general, noting important terminology and addressing several diagnostic issues.

Can you use drugs without meeting criteria for a disorder? Can you use drugs and not become addicted to them? To answer these important questions, we first need to outline what we mean by *substance use*, *substance intoxication*, *substance use disorder*, and *substance dependence/addiction*. The term *substance* refers to chemical compounds that are ingested to alter mood or behavior. **Psychoactive substances** alter mood, behavior, or both. Although you might first think of drugs such as cocaine and heroin, this definition also includes more commonplace legal drugs such as alcohol, the nicotine found in tobacco, and the caffeine in coffee, soft drinks, and chocolate. As you will see, these so-called safe drugs also affect mood and behavior, they can be addictive, and they account for more health problems and a greater mortality rate than all illegal drugs combined. You could make a good argument for directing the war on drugs to cigarette smoking (nicotine use) because of its addictive properties and negative health consequences.

Substance use.

Substance Use

Substance use is the ingestion of psychoactive substances in moderate amounts that does not significantly interfere with social, educational, or occupational functioning. Most of you reading this chapter probably use some sort of psychoactive substance occasionally. Drinking a cup of coffee in the morning to wake up or smoking a cigarette and having a drink with a friend to relax are examples of substance use, as is the occasional ingestion of illegal drugs such as cannabis, cocaine, amphetamines, or barbiturates.

Intoxication

Our physiological reaction to ingested substances—drunkenness or getting high—is **substance intoxication**. For a person to become intoxicated, many variables interact, including the type of drug taken, the amount ingested, and the person's individual biological reaction. For many of the substances we discuss here, intoxication is experienced as impaired judgment, mood changes, and lowered motor ability (for example, problems walking or talking).

Substance Use Disorders

Defining **substance use disorders** by how much of a substance is ingested is problematic. For example, is drinking two glasses of wine in an hour abuse? Three glasses? Six? Is taking one injection of heroin considered abuse? The fifth edition of the *Diagnostic and Statistical Manual (DSM-5)* (American Psychiatric Association, 2013) defines substance use disorders in terms of how significantly the use interferes with the user's life. If substances disrupt your education,

job, or relationships with others, and put you in physically dangerous situations (for example, while driving) you would be considered to have a disorder. Some evidence suggests that drug use can predict later job outcomes. In one study, researchers controlled for factors such as educational interests and other problem behavior, and still found that repeated hard drug use (using one or more of the following: amphetamines, barbiturates, crack, cocaine, PCP, LSD, other psychedelics, crystal meth, inhalants, heroin, or other narcotics) predicted poor job outcomes after college (Arria et al., 2013).

Danny seems to fit this definition of a disorder. His inability to complete a semester of community college was a direct result of drug use. Danny often drove while drunk or under the influence of other drugs, and he had already been arrested twice. Danny's use of multiple substances was so relentless and pervasive that he would probably be diagnosed with severe forms of the disorders.

Substance use disorder is usually described as addiction. Although we use the term *addiction* routinely when we describe people who seem to be under the control of drugs, there is some disagreement about how to define addiction (Rehm et al., 2013; Edwards, 2012). In order to meet criteria for a disorder, a person must meet criteria for at least two symptoms in the past year that interfered with his/her life or bothered him/her a great deal. When a person has four or five symptoms, he or she is considered to fall in the moderate range. A severe substance use disorder would be someone like Danny that has six or more symptoms. Symptoms for substance use disorders can include a **physiological dependence** on the drug or drugs, meaning the use of increasingly greater amounts of the drug to experience the same effect (**tolerance**), and a negative physical response when the substance is no longer

Monkey Business Images/Shutterstock.com

Intoxication.

ingested (**withdrawal**) (Higgins, Sigmon, & Heil, 2014). Tolerance and withdrawal are physiological reactions to the chemicals being ingested. Have you ever experienced a headache when you didn't get your morning coffee? You were probably going through caffeine withdrawal. In a more extreme example, withdrawal from alcohol can cause alcohol withdrawal delirium, in which a person can experience frightening hallucinations and body tremors (a condition described later in this chapter). Withdrawal from many substances can bring on chills, fever, diarrhea, nausea and vomiting, and aches and pains. Not all substances are physiologically addicting, however. For example, you do not go through severe physical withdrawal when you stop taking LSD. Cocaine withdrawal has a pattern that includes anxiety, sleep changes, lack of motivation, and boredom (DSM-5; American Psychiatric Association, 2013), and withdrawal from cannabis includes such symptoms as irritability, nervousness, appetite change, and sleep disturbance (DSM-5). We return to the ways drugs act on our bodies when we examine the causes of abuse and addiction.

Other symptoms that make up a substance use disorder include "drug-seeking behaviors." The repeated use of a drug, a desperate need to ingest more of the substance (stealing money to buy drugs, standing outside in the cold to smoke), and the likelihood that use will resume after a period of abstinence are behaviors that define the extent of substance use disorders. Such behavioral reactions are different from the physiological responses to drugs we described before and are sometimes referred to in terms of psychological dependence. The previous version of the *DSM* considered substance abuse and **substance dependence** as separate diagnoses. The *DSM-5* combines the two into the general definition of substance-related disorders based on research that suggests the two co-occur (American Psychiatric Association, 2013; Dawson, Goldstein, & Grant, 2012; O'Brien, 2011).

Let's go back to the questions we started with: "Can you use drugs and not abuse them?" and "Can you abuse drugs and not become addicted to them?" The answer to the first question is yes. Some people drink wine or beer regularly without drinking to excess. And contrary to popular belief, some people use drugs such as heroin, cocaine, or crack (a form of cocaine) occasionally (for instance, several times a year) without abusing them (Ray, 2012). What is disturbing is that we do not know ahead of time who might be likely to lose control and abuse these drugs and who is likely to become dependent with even a passing use of a substance.

It may seem counterintuitive, but dependence can be present without abuse. For example, cancer patients who take morphine for pain may become dependent on the drug—build up a tolerance and go through withdrawal if it is stopped—without abusing it (Flemming, 2010; Portenoy & Mathur, 2009). Later in this chapter, we discuss biological and psychosocial theories of the causes of substance-related disorders and why we have individualized reactions to these substances.

Diagnostic Issues

In early editions of the *DSM*, alcoholism and drug abuse weren't treated as separate disorders. Instead, they were categorized as "sociopathic personality disturbances"—a forerunner of the current *antisocial personality disorder* we discuss in Chapter 12,

Ace Stock Limited/Alamy Stock Photo

Substance abuse.

because substance use was seen as a symptom of other problems. It was considered a sign of moral weakness, and the influence of genetics and biology was hardly acknowledged. A separate category was created for **substance abuse** disorders in *DSM-III*, in 1980, and since then we have acknowledged the complex biological and psychological nature of the problem.

The *DSM-5* term *substance-related disorders* include 11 symptoms that range from relatively mild (e.g., substance use results in a failure to fulfill major role obligations) to more severe (e.g., occupational or recreational activities are given up or reduced because of substance use). *DSM-5* removed the previous symptom that related to substance-related legal problems and added a symptom that indicates the presence of craving or a strong desire to use the substance (Dawson et al., 2012). These distinctions help clarify the problem and focus treatment on the appropriate aspect of the disorder. Danny would be considered to have a cocaine use disorder in the severe range because of the tolerance he showed for the drug, his use of larger amounts than he intended, his unsuccessful attempts to stop using it, and the activities he gave up to buy it. His pattern of use was more pervasive than simple abuse, and the diagnosis provided a clear picture of his need for help.

Symptoms of other disorders can complicate the substance use disorder picture significantly. For example, do some people take drugs to excess because they are depressed, or does drug use and its consequences (for example, loss of friends, job) create depression? Researchers estimate that almost three quarters of the people in addiction treatment centers have an additional psychiatric disorder, with mood disorders (such as major depression) observed in more than 40% and anxiety disorders and posttraumatic stress disorder seen in more than 25% of the cases (Dawson et al., 2012; Lieb, 2015).

Substance use might occur concurrently with other disorders for several reasons. Substance-related disorders and anxiety and mood disorders are highly prevalent in our society and may occur together so often just by chance. Drug intoxication and withdrawal can cause symptoms of anxiety, depression, and psychosis. Disorders such as schizophrenia and antisocial personality disorder are highly likely to include a secondary problem of substance use.

Because substance-related disorders can be so complicated, *DSM-5* tries to define when a symptom is a result of substance use and when it is not. Basically, if symptoms seen in schizophrenia or in extreme states of anxiety appear during intoxication or within 6 weeks after withdrawal from drugs, they are not considered signs of a separate psychiatric disorder. So, for example, individuals who show signs of severe depression just after they have stopped taking heavy doses of stimulants would not be diagnosed with a major mood disorder. However, individuals who were severely depressed before they used stimulants and those whose symptoms persist more than 6 weeks after they stop might have a separate disorder (Sheperis, Lionetti, & Snook, 2015).

We now turn to the individual substances themselves, their effects on our brains and bodies, and how they are used in our society. We have grouped the substances into six general categories.

- **Depressants:** These substances result in behavioral sedation and can induce relaxation. They include alcohol (ethyl alcohol) and the sedative and hypnotic drugs in the families of barbiturates (for example, Seconal) and benzodiazepines (for example, Valium, Xanax).
- **Stimulants:** These substances cause us to be more active and alert and can elevate mood. Included in this group are amphetamines, cocaine, nicotine, and caffeine.
- **Opiates:** The major effect of these substances is to produce analgesia temporarily (reduce pain) and euphoria. Heroin, opium, codeine, and morphine are included in this group.
- **Hallucinogens:** These substances alter sensory perception and can produce delusions, paranoia, and hallucinations. Cannabis and LSD are included in this category.
- **Other drugs of abuse:** Other substances that are abused but do not fit neatly into one of the categories here include inhalants (for example, airplane glue), anabolic steroids, and other over-the-counter and prescription medications (for example, nitrous oxide). These substances produce a variety of psychoactive effects that are characteristic of the substances described in the previous categories.
- **Gambling disorder:** As with the ingestion of the substances just described, individuals who display gambling disorder are unable to resist the urge to gamble which, in turn, results in negative personal consequences (e.g., divorce, loss of employment).

Depressants

Depressants primarily *decrease* central nervous system activity. Their principal effect is to reduce our levels of physiological arousal and help us relax. Included in this group are alcohol and the sedative, hypnotic, and anxiolytic drugs, such as those prescribed for insomnia (see Chapter 8). These substances are among those most likely to produce symptoms of physical dependence, tolerance, and withdrawal. We first look at the most commonly used of these substances—**alcohol**—and the **alcohol-related disorders** that can result.

Alcohol-Related Disorders

Danny's substance abuse began when he drank beer with friends, a rite of passage for many teenagers. Alcohol has been widely used throughout history. For example, scientists have found evidence of wine or beer in pottery jars at the site of a Sumerian trading post in western Iran and the country of Georgia that date back 7,000 years (McGovern, 2007). For hundreds of years, Europeans drank large amounts of beer, wine, and hard liquor. When they came to North America in the early 1600s, they brought their considerable thirst for alcohol with them. In the United States during the early 1800s, consumption of alcohol (mostly whiskey) was more than 7 gallons per year for every person older than 15. This is more than three times the current rate of U.S. alcohol use (Smith, 2008; Rorabaugh, 1991).

Alcohol is produced when certain yeasts react with sugar and water and *fermentation* takes place. Historically, we have been creative about fermenting alcohol from just about any fruit or vegetable, partly because many foods contain sugar. Alcoholic drinks have included mead from honey, sake from rice, wine from palm, mescal and pulque from agave and cactus, liquor from maple syrup, liquor from South American jungle fruits, wine from grapes, and beer from grains (Lazare, 1989).

Clinical Description

Apparent stimulation is the initial effect of alcohol, although it is a depressant. We generally experience a feeling of well-being, our inhibitions are reduced, and we become more outgoing. This is because the inhibitory centers in the brain are initially depressed—or slowed. With continued drinking, however, alcohol depresses more areas of the brain, which impedes the ability to function properly. Motor coordination is impaired (staggering, slurred speech), reaction time is slowed, we become confused, our ability to make judgments is reduced, and even vision and hearing can be negatively affected, all of which help explain why driving while intoxicated is clearly dangerous.

Effects

Alcohol affects many parts of the body (see ● Figure 11.1). After it is ingested, it passes through the esophagus (1 in Figure 11.1) and into the stomach (2), where small amounts are absorbed. From there, most of it travels to the small intestine (3), where it is easily absorbed into the bloodstream. The circulatory system distributes

Diagnostic Criteria for Alcohol Use Disorder

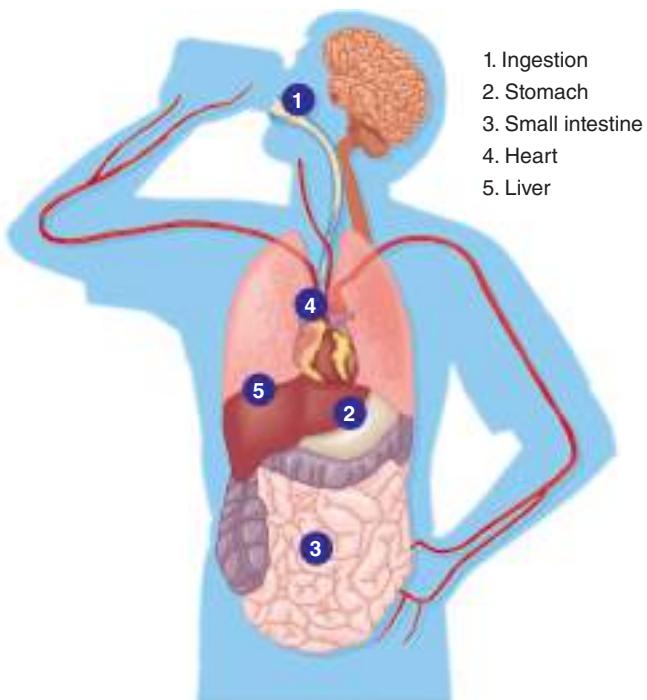

- A.** A problematic pattern of alcohol use leading to clinically significant impairment or distress, as manifested by at least two of the following, occurring within a 12-month period:
1. Alcohol is often taken in larger amounts or over a longer period than was intended.
 2. There is a persistent desire or unsuccessful efforts to cut down or control alcohol use.
 3. A great deal of time is spent in activities necessary to obtain alcohol, use alcohol, or recover from its effects.
 4. Craving, or a strong desire or urge to use alcohol.
 5. Recurrent alcohol use resulting in a failure to fulfill major role obligations at work, school, or home.
 6. Continued alcohol use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of alcohol.
 7. Important social, occupational, or recreational activities are given up or reduced because of alcohol use.
 8. Recurrent alcohol use in situations in which it is physically hazardous.
 9. Alcohol use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by alcohol.
- 10.** Tolerance, as defined by either or both of the following:
- a. A need for markedly increased amounts of alcohol to achieve intoxication or desired effect.
 - b. A markedly diminished effect with continued use of the same amount of alcohol.
- 11.** Withdrawal, as manifested by either of the following:
- a. The characteristic withdrawal syndrome for alcohol (refer to Criteria A and B of the criteria set for alcohol withdrawal).
 - b. Alcohol (or a closely related substance such as benzodiazepine) is taken to relieve or avoid withdrawal symptoms.

the alcohol throughout the body, where it contacts every major organ, including the heart (4). Some of the alcohol goes to the lungs, where it vaporizes and is exhaled, a phenomenon that is the basis for the *breathalyzer test* that measures levels of intoxication. As alcohol passes through the liver (5), it is broken down or metabolized into carbon dioxide and water by enzymes (Maher, 1997). ● Figure 11.2 shows how much time it takes to metabolize one to four drinks, with the dotted line showing when driving becomes impaired (National Institute on Alcohol Abuse and Alcoholism, 1997).

Most substances we describe in this chapter, including cannabis, opiates, and tranquilizers, interact with specific receptors in the brain cells. The effects of alcohol, however, are more complex. Alcohol influences a number of neurotransmitter systems, which makes it difficult to study (Ray, 2012). For example, the *gamma-aminobutyric acid (GABA)* system, which we discussed in Chapters 2 and 5, seems to be particularly sensitive to alcohol. GABA, as you will recall, is an inhibitory neurotransmitter. Its major role is to interfere with the firing of the neuron it attaches to. Because the GABA system seems to affect the emotion of anxiety, alcohol's antianxiety properties may result from its interaction with the GABA system. Also, when GABA attaches to its receptor, chloride ions enter the cell and make it less sensitive to the effects of other neurotransmitters. Alcohol seems to reinforce the movement of these chloride ions; as a result, the neurons have difficulty

firing. In other words, although alcohol seems to loosen our tongues and makes us more sociable, it makes it difficult for neurons to communicate with one another (Joslyn, Ravindranathan, Brush, Schuckit, & White, 2010). For example, there is some evidence from genetic research (further discussed below) that the genes responsible for communication between neurons may also be responsible for individual differences in response to alcohol.

The *glutamate system* is under study for its role in the effects of alcohol. In contrast to the GABA system, the glutamate system is excitatory, helping neurons fire. It is suspected to involve learning and memory, and it may be the avenue through which alcohol affects our cognitive abilities. Blackouts, the loss of memory for what happens during intoxication, may result from the interaction of alcohol with the glutamate system. The serotonin system also appears to be sensitive to alcohol. This neurotransmitter system affects mood, sleep, and eating behavior and is thought to be responsible for alcohol cravings (Sari, Johnson, & Weedman, 2011; Strain, 2009). Because alcohol affects so many neurotransmitter systems, we should not be surprised that it has such widespread and complex effects.

The long-term effects of heavy drinking are often severe. Withdrawal from chronic alcohol use typically includes hand tremors and, within several hours, nausea or vomiting, anxiety, transient hallucinations, agitation, insomnia, and, at its most extreme, **withdrawal delirium** (or **delirium tremens**—the DTs), a condition that can produce frightening hallucinations and body tremors. The devastating experience of delirium tremens can be reduced with adequate medical treatment (Schuckit, 2014b).

"When I drink, I don't care about anything, as long as I'm drinking. Nothing bothers me. The world doesn't bother me. So when I'm not drinking, the problems come back, so you drink again. The problems will always be there. You just don't realize it when you're drinking. That's why people tend to drink a lot."

Whether alcohol will cause organic damage depends on genetic vulnerability, the frequency of use, the length of drinking binges, the blood alcohol levels attained during the drinking periods, and whether the body is given time to recover between binges. Consequences of long-term excessive drinking include liver disease, pancreatitis, cardiovascular disorders, and brain damage.

Part of the folklore concerning alcohol is that it permanently kills brain cells (neurons). As you will see later, this may not be true. Some evidence for brain damage comes from the experiences of people who are alcohol dependent and experience blackouts, seizures, and hallucinations. Memory and the ability to perform certain tasks may also be impaired. More seriously, two types of organic brain syndromes may result from long-term heavy alcohol use: dementia and **Wernicke-Korsakoff syndrome**. **Dementia**, (or *neurocognitive disorder*), which we discuss

more fully in Chapter 15, involves the general loss of intellectual abilities and can be a direct result of neurotoxicity or “poisoning of the brain” by excessive amounts of alcohol (Ridley, Draper, & Withall, 2013). **Wernicke-Korsakoff syndrome** results in confusion, loss of muscle coordination, and unintelligible speech (Isenberg-Grzeda, Kutner, & Nicolson, 2012); it is believed to be caused by a deficiency of thiamine, a vitamin metabolized poorly by heavy drinkers. The dementia caused by this disease does not go away once the brain is damaged. It is important to note that mild to moderate intake of alcohol (especially wine) may actually serve a protective role in cognitive decline as we age (Panza et al., 2012).

The effects of alcohol abuse extend beyond the health and well-being of the drinker. **Fetal alcohol syndrome (FAS)** is now generally recognized as a combination of problems that can occur in a

child whose mother drank while she was pregnant. These problems include fetal growth retardation, cognitive deficits, behavior problems, and learning difficulties (Douzgou et al., 2012). In addition, children with FAS often have characteristic facial features.

We metabolize alcohol with the help of an enzyme called **alcohol dehydrogenase (ADH)** (Schuckit, 2009b, 2014a). Three different forms of this enzyme have been identified (beta-1, beta-2, and beta-3 ADH). Among children with FAS, beta-3 ADH may be prevalent according to new research. Beta-3 ADH is also found

most often in African Americans. What these two findings suggest is that, in addition to the drinking habits of the mother, the likelihood a child will have FAS may depend on whether there is a genetic tendency to have certain enzymes. Children from certain racial groups may thus be more susceptible to FAS than are others. If this research is confirmed, we may have a way of identifying parents who might put their unborn children at increased risk for FAS.

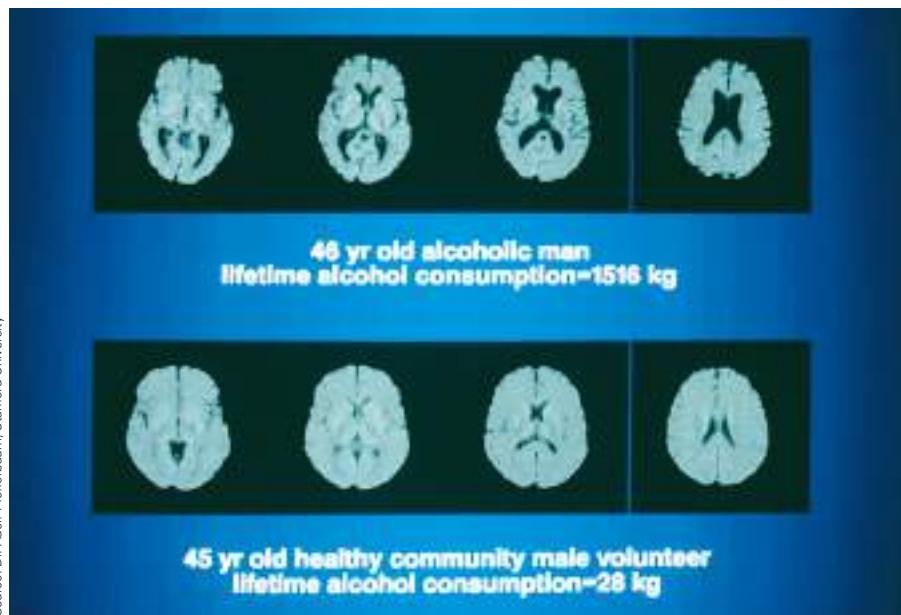

Statistics on Use and Abuse

Because alcohol consumption is legal in the United States, we know more about it than about most other psychoactive substances we discuss in this chapter (with the possible exception of nicotine and caffeine). Despite a national history of heavy alcohol use, most adults in the United States characterize themselves as light drinkers or abstainers. On the other hand, about half of all Americans over the age of 12 report being current drinkers of alcohol, and there are considerable differences among people from different racial and ethnic backgrounds (see ● Figure 11.3; SAMHSA, 2012). Caucasians report the highest frequency of drinking (56.8%); drinking is lowest among Asians (40.0%).

About 63 million Americans (24.6%) over the age of 18 report binge drinking (typically four or more drinks for women and five or more drinks for men over the span of 2 hours) in the past month—an alarming statistic (SAMHSA, 2013). Again, there are racial differences, with Asians reporting the lowest level of binge drinking (12.4%) and Caucasians (24.0%) and Hispanics or Latinos (24.1%) reporting the highest. Age seems to also be important given that peak lifetime alcohol use happens around late teens to early adolescence. In surveys across 100 four-year universities and colleges, about 36% of respondents said they had gone on a binge of heavy drinking once in the preceding 2 weeks (Johnston, O’Malley, Bachman, & Schulenberg, 2012). Unfortunately, this binge drinking trend seems to have increased in college students along with drunk driving

and alcohol-related deaths (Whiteside, Bittinger, Kilmer, Lostutter, & Larimer, 2015). Men, however, were more likely to report several binges in the 2-week period (White & Hingson, 2014; Presley & Meilman, 1992). The same survey found that students with a grade point average of A had no more than 3 drinks per week, whereas D and F students averaged 11 alcoholic drinks per week (Presley & Meilman, 1992). Overall, these data point to the popularity and pervasiveness of drinking in our society (Donath et al., 2012).

We know that not everyone who drinks develops an alcohol use disorder. Researchers estimate, however, that more than 16.6 million adults ages 18 and older meet criteria for an alcohol use disorder and the same is true of 697,000 adolescents ages 12 to 17 (SAMHSA, 2013). Lifetime prevalence rates for alcohol use disorders, meaning a person met criteria for an alcohol use disorder at some point in his or her life, are more than 29% (Grant et al., 2015). This means one in three people will meet criteria for an alcohol use disorder at some point in their lives.

The dark areas in the top brain images show the extensive loss of brain tissue caused by heavy alcohol use.

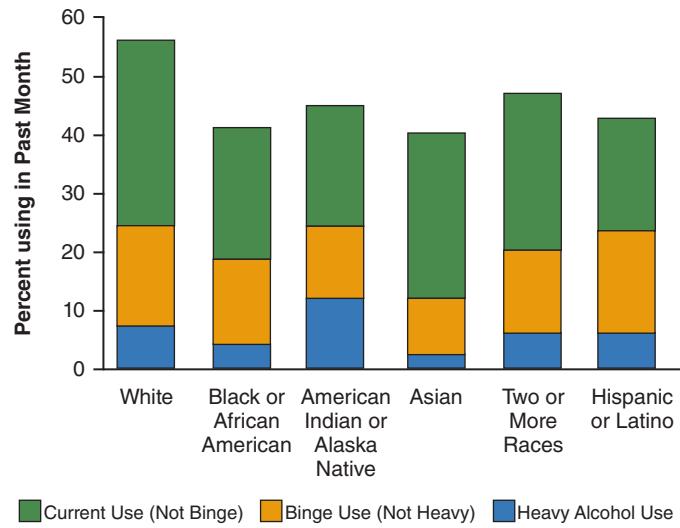

FIGURE 11.3

Alcohol use across racial groups. Binge drinking is defined as drinking five or more drinks on one occasion at least once per month, and heavy alcohol use is defined as binge drinking for five or more days in a month. (From Substance Abuse and Mental Health Services Administration, Office of Applied Studies. (2012). *Results from the 2011 National Survey on Drug Use and Health: National Findings*, NSDUH Series H-44, DHHS Publication No. (SMA) 12-4713. Rockville, MD: Author.)

Outside the United States, rates of alcohol use problems and dependence vary widely. The prevalence of alcohol use disorders in 2004 as measured by the World Health Organization was highest in eastern European countries (for example, in Russia it was close to 19% in 2004), followed by Colombia at 13%, South Korea at 13.5%, and Thailand at 11%. The prevalence for alcohol use disorders in 2004 was lowest in Northern Africa (e.g., in Libya at 0.05%) and the Middle East (e.g., in Afghanistan at 0.2%) (World Health Organization, 2004). Such cultural differences can be accounted for by different attitudes toward drinking, the availability of alcohol, physiological reactions, and family norms and patterns.

Progression

Remember that Danny went through periods of heavy alcohol and drug use but also had times when he was relatively “straight” and did not use drugs. Similarly, many people with an alcohol use disorder fluctuate between drinking heavily, drinking “socially” without negative effects, and being abstinent (not drinking) (McCrady, 2014). It seems that about 20% of people with severe alcohol dependence have a spontaneous remission (they are able to stop drinking on their own) and do not reexperience problems with drinking.

It used to be thought that once problems arose with drinking they would become steadily worse, following a predictable downward pattern as long as the person kept drinking (Sobell & Sobell, 1993). In other words, like a disease that isn’t treated properly, alcoholism will get progressively worse if left unchecked.

David H. Wells/Getty Images

Physical characteristics of fetal alcohol syndrome (FAS) include skin folds at the corners of the eyes, low nasal bridge, short nose, no groove between nose and upper lip, small head circumference, small eye opening, small midface, and thin upper lip.

First championed by Jellinek more than 50 years ago, this view continues to influence the way people view and treat the disorder (Jellinek, 1946, 1952, 1960). Unfortunately, Jellinek based his model of the progression of alcohol use on a now famous but faulty study (Jellinek, 1946), which we briefly review.

In 1945, the newly formed self-help organization Alcoholics Anonymous (AA) sent out some 1,600 surveys to its members asking them to describe symptoms related to drinking, such as feelings of guilt or remorse and rationalizations about their actions, and to note when these reactions first occurred. Only 98 of the almost 1,600 surveys were returned, however. As you know, such a small response could seriously affect data interpretation. A group of 98 may be different from the group as a whole, so they may not represent the typical person with alcohol problems. Also, because the responses were retrospective (participants were recalling past

events), their reports may be inaccurate. Despite these and other problems, Jellinek agreed to analyze the data, and he developed a four-stage model for the progression of alcoholism based on this limited information (Jellinek, 1952). According to his model, individuals go through a *prealcoholic stage* (drinking occasionally with few serious consequences), a *prodromal stage* (drinking heavily but with few outward signs of a problem), a *crucial stage* (loss of control, with occasional binges), and a *chronic stage* (the primary daily activities involve getting and drinking alcohol). Attempts by other researchers to confirm this progression of stages have not been successful (Schuckit, Smith, Anthenelli, & Irwin, 1993).

It appears instead that the course of a severe alcohol use disorder may be progressive for most people. For example, early use of alcohol may predict later abuse. A study of almost 6,000 lifetime drinkers found that drinking at an early age—from ages 11 to 14—was predictive of later alcohol-related disorders (DeWitt, Adlaf, Offord, & Ogborne, 2000). Similarly, a study tracking alcohol use onset and later use found that those who started drinking at age 11 or earlier were at higher risk for chronic and severe alcohol use disorders (Guttmannova et al., 2011). A third study followed 636 male inpatients in an alcohol rehabilitation center (Schuckit et al., 1993). Among these chronically alcohol-dependent men, a general progression of alcohol-related life problems did emerge, although not in the specific pattern proposed by Jellinek. Three quarters of the men reported moderate consequences of their drinking, such as demotions at work, in their 20s. During their 30s, the men had more serious problems, such as regular blackouts and signs of alcohol withdrawal. By their late 30s and early 40s, these men demonstrated long-term serious consequences of their drinking, which included hallucinations, withdrawal convulsions, and hepatitis or pancreatitis. This study suggests a common pattern among people with chronic alcohol abuse and dependence, one with increasingly severe consequences. This progressive pattern is not inevitable for everyone who abuses alcohol, although we do not as yet understand what distinguishes those who are and those who are not susceptible (Krenek & Maisto, 2013).

Research on the mechanism responsible for the differences in early alcohol use suggests that one's response to the sedative effects of the substance affects later use.

In other words, those individuals who tend not to develop the slurred speech, staggering, and other sedative effects of alcohol use are more likely to abuse it in the future (Chung & Martin, 2009; Schuckit, 2014a). This is of particular concern given the trend to mix highly caffeinated energy drinks with alcohol (McKetin, Coen, & Kaye, 2015). This combination of drinks can reduce the sedative effect of alcohol, which may increase the likelihood of later abuse.

Finally, statistics often link alcohol with violent behavior

(Boden, Fergusson, & Horwood, 2012; Bye, 2007). Numerous studies have found that many people who commit such violent acts as murder, rape, and assault are intoxicated at the time of the crime (Rossow & Bye, 2012). We hope you are skeptical of this type of correlation. Just because drunkenness and violence overlap does not mean that alcohol will necessarily make you violent. Laboratory studies show that alcohol may increase participants' aggression (Bushman, 1993). Whether a person behaves aggressively outside the laboratory, however, probably involves a number of interrelated factors, such as the quantity and timing of alcohol consumed, the person's history of violence, expectations about drinking, and what happens to the individual while intoxicated. Alcohol does not *cause* aggression, but it may increase a person's likelihood of engaging in impulsive acts and it may impair the ability to consider the consequences of acting impulsively (Bye, 2007). Given the right circumstances, such impaired rational thinking may increase a person's risk of behaving aggressively.

Sedative-, Hypnotic-, or Anxiolytic-Related Disorders

The general group of depressants also includes sedative (calming), hypnotic (sleep-inducing), and anxiolytic (anxiety-reducing) drugs (Bond & Lader, 2012). These drugs include barbiturates and benzodiazepines. **Barbiturates** (which include Amytal, Seconal, and Nembutal) are a family of sedative drugs first synthesized in Germany in 1882 (Cozanitis, 2004). They were prescribed to help people sleep and replaced such drugs as alcohol and opium. Barbiturates were widely prescribed by physicians during the 1930s and 1940s, before their addictive properties were fully understood. By the 1950s, they were among the drugs most abused by adults in the United States (Franklin & Frances, 1999).

Benzodiazepines (which today include Valium, Xanax, and Ativan) have been used since the 1960s, primarily to reduce anxiety. These drugs were originally touted as a miracle cure for the anxieties of living in our highly pressured technological society. Although in 1980 the U.S. Food and Drug Administration ruled that they are not appropriate for reducing the tension and anxiety resulting from everyday stresses and strains, an estimated 85 million prescriptions are written for benzodiazepines in the United States each year (Olfson, King, & Schoenbaum, 2015). In general, benzodiazepines are considered much safer than barbiturates, with less risk of abuse and dependence. Reports on the misuse of Rohypnol, however, show how dangerous even some benzodiazepine drugs can be. Rohypnol (otherwise known as "forget-me-pill," "roofenol," "roofies," "ruffies") gained a following among teenagers in the 1990s because it has the same effect as alcohol without the telltale odor. There have been numerous incidents of men giving the drug to women without their knowledge, however, making it easier for them to engage in date rape (Albright, Stevens, & Beussman, 2012).

Clinical Description

At low doses, barbiturates relax the muscles and can produce a mild feeling of well-being. Larger doses can have results similar to those of heavy drinking: slurred speech and problems walking,

Intoxication is often involved in cases of domestic violence.

concentrating, and working. At extremely high doses, the diaphragm muscles can relax so much that they cause death by suffocation. Overdosing on barbiturates is a common means of suicide.

Like the barbiturates, benzodiazepines are used to calm an individual and induce sleep. In addition, drugs in this class are prescribed as muscle relaxants and anticonvulsants (antiseizure medications) (Bond & Lader, 2012). People who use them for non-medical reasons report first feeling a pleasant high and a reduction of inhibition, similar to the effects of drinking alcohol. With continued use, however, tolerance and dependence can develop. Users who try to stop taking the drug experience symptoms like those of alcohol withdrawal (anxiety, insomnia, tremors, and delirium).

The *DSM-5* criteria for sedative-, hypnotic-, and anxiolytic-related disorders do not differ substantially from those for alcohol disorders. Both include maladaptive behavioral changes such as inappropriate sexual or aggressive behavior, variable moods, impaired judgment, impaired social or occupational functioning, slurred speech, motor coordination problems, and unsteady gait.

Sedative, hypnotic, and anxiolytic drugs affect the brain by influencing the GABA neurotransmitter system (Bond & Lader,

2012), although by mechanisms slightly different from those involving alcohol. As a result, when people use alcohol with any of these drugs or combine multiple types there can be synergistic effects. In other words, if you drink alcohol after taking a benzodiazepine or barbiturate or combine these drugs, the total effects can reach dangerous levels. One theory about actress Marilyn Monroe's death in 1962 is that she combined alcohol with too many barbiturates and unintentionally killed herself. Actor Heath Ledger's death in 2008 was attributed to the combined effects of oxycodone and a variety of barbiturates and benzodiazepines.

Statistics

Barbiturate use has declined and benzodiazepine use has increased since 1960 (SAMHSA, 2012). Of those seeking treatment for substance-related problems, less than 1% present problems with benzodiazepines compared with other drugs of abuse. Those who do seek help with abuse of these drugs tend to be female, Caucasian, and over the age of 35.

Diagnostic Criteria for Sedative-, Hypnotic-, or Anxiolytic-Related Disorders

- A.** A problematic pattern of sedative, hypnotic, or anxiolytic use leading to clinically significant impairment or distress, as manifested by at least two of the following, occurring within a 12-month period:
- 1.** Sedatives, hypnotics, or anxiolytics are often taken in larger amounts or over a longer period than was intended.
 - 2.** There is a persistent desire or unsuccessful efforts to cut down or control sedative, hypnotic, or anxiolytic use.
 - 3.** A great deal of time is spent in activities necessary to obtain the sedative, hypnotic, or anxiolytic; use the sedative, hypnotic, or anxiolytic; or recover from its effects.
 - 4.** Craving, or a strong desire to use the sedative, hypnotic, or anxiolytic.
 - 5.** Recurrent sedative, hypnotic, or anxiolytic use resulting in a failure to fulfill major role obligations at work, school, or home (e.g., repeated absences from work or poor work performance related to sedative, hypnotic, or anxiolytic use; sedative-, hypnotic-, or anxiolytic-related absences, suspensions, or expulsions from school; neglect of children or household).
 - 6.** Continued sedative, hypnotic or anxiolytic use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of sedatives, hypnotics or anxiolytics (e.g., arguments with a spouse about consequences of intoxication; physical fights).
 - 7.** Important social, occupational, or recreational activities are given up or reduced because of sedative, hypnotic or anxiolytic use.
 - 8.** Recurrent sedative, hypnotic or anxiolytic use in situations in which it is physically hazardous (e.g., driving in automobile or operating a machine when impaired by sedative, hypnotic, or anxiolytic use).
 - 9.** Sedative, hypnotic, or anxiolytic use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the sedative, hypnotic, or anxiolytic.
 - 10.** Tolerance, as defined by either of the following:
 - a.** A need for markedly increased amounts of sedative, hypnotic, or anxiolytic to achieve intoxication or desired effect.
 - b.** A markedly diminished effect with continued use of the same amount of sedative, hypnotic or anxiolytic.

Note: This criterion is not considered to be met for individuals taking sedatives, hypnotics, or anxiolytics under medical supervision.

- 11.** Withdrawal, as manifested by either of the following:

- a.** The characteristic withdrawal syndrome for sedatives, hypnotics, or anxiolytics (refer to Criteria A and B of the criteria set for sedative, hypnotic or anxiolytic withdrawal).
- b.** Sedatives, hypnotics, or anxiolytics (or closely related substance, such as alcohol) are taken to relieve or avoid withdrawal symptoms.

Concept Check 11.1

Part A

Check your understanding of substance use definitions by stating whether the following case summaries describe (a) use, (b) intoxication, or (c) use disorder.

1. Giya started a new job 5 weeks ago and is about to be fired. This is her third job this year. She has been absent from work at least once a week for the past 5 weeks. She was reprimanded in the past after being seen at a local pub in a drunken state during regular office hours although she called in sick. At her previous job, she was fired after she came to work unable to conduct herself appropriately and with alcohol on her breath. When confronted about her problems, Giya went to the nearest bar and drank some more to try to forget about the situation. _____
2. Brennan scored the winning goal for his high school soccer team and his friends take him out to celebrate. He doesn't smoke, but he doesn't mind drinking alcohol occasionally. Because Brennan had such a good game, he decides to have a few drinks. Despite his great performance in the game, he is easily irritated, laughing one minute and yelling the next. The more Brennan rambles on about his game-winning goal, the more difficult it is to understand him.
3. Marti is a 24-year-old college student who started drinking heavily when he was 15. Marti drinks a moderate amount every night, unlike his schoolmates who get drunk at weekend parties. In high school, he would become drunk after about four beers; now his tolerance has more than doubled. Marti claims alcohol relieves the pressures of college life. He once attempted to quit drinking, but he had chills, fever, diarrhea, nausea and vomiting, and body aches and pains.
4. Over the past year Henry picked up a habit of having a cigarette every day after lunch. Instead of sitting in the lounge with his friends he goes to his favorite spot in the courtyard and has his cigarette. If for some reason he is unable to have his cigarette after lunch, he is not dependent on it and can still function normally.

Part B

Match the following disorders with their corresponding effects:

(a) substance-related and addictive disorder, (b) dementia, (c) impulse-control disorder, (d) alcohol use disorder, and (e) Wernicke-Korsakoff syndrome.

5. Disorder that deprives a person of the ability to resist acting on a drive or temptation. _____
6. Disorder in which the effects of the drug impede the ability to function properly by affecting vision, motor control, reaction time, memory, and hearing. _____
7. The decline of intellectual abilities through, for example, excess consumption of alcohol. _____
8. A class of disorders that affects the way people think, feel, and behave. _____

Stimulants

Of all the **psychoactive** drugs used in the United States, the most commonly consumed are stimulants. Included in this group are caffeine (in coffee, chocolate, and many soft drinks), nicotine (in tobacco products such as cigarettes), amphetamines, and cocaine. You probably used caffeine when you got up this morning. In contrast to the depressant drugs, stimulants—as their name suggests—make you more alert and energetic. They have a long history of use. Chinese physicians, for example, prescribed an amphetamine compound called ma-huang (*Ephedra sinica*) for more than 5,000 years for illnesses such as headaches, asthma, and the common cold (Fushimi, Wang, Ebisui, Cai, & Mikage, 2008). We describe several stimulants and their effects on behavior, mood, and cognition.

Stimulant-Related Disorders

Amphetamines

At low doses, **amphetamines** can induce feelings of elation and vigor and can reduce fatigue. You feel “up.” After a period of elevation, however, you come back down and “crash,” feeling depressed or tired. Amphetamines are manufactured in laboratories; they were first synthesized in 1887 and later used as a treatment for asthma and as a nasal decongestant (Carvalho et al., 2012). Because amphetamines also reduce appetite, some people take them to lose weight. Adolph Hitler, partly because of his other physical maladies, became addicted to amphetamines (Judge & Rusyniak, 2009). Long-haul truck drivers, pilots, and some college students trying to “pull all-nighters” use amphetamines to get an extra energy “boost” and stay awake. Amphetamines are prescribed for people with narcolepsy, a sleep disorder characterized by excessive sleepiness (discussed in Chapter 8). Some of these drugs (Ritalin, Adderall) are even given to children with attention-deficit/hyperactivity disorder (ADHD) (discussed in Chapter 14). Amphetamines too are being misused for their psychostimulant effects. One large study found that almost two thirds of college students in their fourth year had been offered illegal prescription stimulants and 31% used them—usually to improve studying (Garnier-Dykstra, Caldeira, Vincent, O’Grady, & Arria, 2012).

DSM-5 diagnostic criteria for intoxication in amphetamine use disorders include significant behavioral symptoms, such as euphoria or affective blunting (a lack of emotional expression), changes in sociability, interpersonal sensitivity, anxiety, tension, anger, stereotyped behaviors, impaired judgment, and impaired social or occupational functioning. In addition, physiological symptoms occur during or shortly after amphetamine or related substances are ingested and can include heart rate or blood pressure changes, perspiration or chills, nausea or vomiting, weight loss, muscular weakness, respiratory depression, chest pain, seizures, or coma. Severe intoxication or overdose can cause hallucinations, panic, agitation, and paranoid delusions (Carvalho et al., 2012). Amphetamine tolerance builds quickly, making it doubly dangerous. Withdrawal often results in apathy, prolonged periods of sleep, irritability, and depression.

Periodically, certain “designer drugs” appear in local mini-epidemics. An amphetamine called methylene-dioxymethamphetamine (MDMA), first synthesized in 1912 in Germany, was used as an appetite suppressant (McCann & Ricaurte, 2009). Recreational use of this drug, now commonly called Ecstasy, rose sharply in the late 1980s. After cocaine and methamphetamine, MDMA is the club drug most often bringing people to emergency rooms, and it has passed LSD in frequency of use (SAMHSA,

2011). Its effects are described by users in a variety of ways: Ecstasy makes you “feel happy” and “love everyone and everything”; “music feels better” and “it’s more fun to dance”; “You can say what is on your mind without worrying what others will think” (Levy, O’Grady, Wish, & Arria, 2005, p. 1431). Recent years have also seen a rise in a variation of MDMA called “Molly” that has been marketed as a purified powder in capsules instead of the pressed pills of Ecstasy (National Institute of Drug Abuse, 2013).

A purified, crystallized form of amphetamine, called methamphetamine (commonly referred to as “crystal meth” or “ice”), is ingested through smoking. This drug causes marked aggressive tendencies and stays in the system longer than cocaine, making it particularly dangerous. This drug gained and dropped in popularity since it was invented in the 1930s, although its use has now spread wider than before (Maxwell & Brecht, 2011). However enjoyable these various amphetamines may be in the short term, the potential for users to become dependent on them is extremely high, with great risk for long-term difficulties. Some research also shows that repeated use of MDMA can cause lasting memory problems (Wagner, Becker, Koester, Gouzoulis-Mayfrank, & Daumann, 2013).

Amphetamines stimulate the central nervous system by enhancing the activity of norepinephrine and dopamine. Specifically, amphetamines help the release of these neurotransmitters and block

- A.** A pattern of amphetamine-type substance, cocaine, or other stimulant use leading to clinically significant impairment or distress, as manifested by at least two of the following, occurring within a 12-month period:
1. The stimulant is often taken in larger amounts or over a longer period than was intended.
 2. There is a persistent desire or unsuccessful efforts to cut down or control stimulant use.
 3. A great deal of time is spent in activities necessary to obtain the stimulant, use the stimulant, or recover from its effects.
 4. Craving, or a strong desire or urge to use the stimulant.
 5. Recurrent stimulant use resulting in a failure to fulfill major role obligations at work, school, or home.
 6. Continued stimulant use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of the stimulant.
 7. Important social, occupational, or recreational activities are given up or reduced because of stimulant use.
 8. Recurrent stimulant use in situations in which it is physically hazardous.
 9. Stimulant use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the stimulant.
 10. Tolerance, as defined by either of the following:
 - a. A need for markedly increased amounts of the stimulant to achieve intoxication or desired effect.
 - b. A markedly diminished effect with continued use of the same amount of the stimulant.

Note: This criterion is not considered to be met for those taking stimulant medications solely under appropriate medical supervision, such as medications for attention-deficit/hyperactivity disorder or narcolepsy

- 11.** Withdrawal, as manifested by either of the following:

- a. The characteristic withdrawal syndrome for the stimulant (refer to Criteria A and B of the criteria set for stimulant withdrawal).
- b. The stimulant (or a closely related substance) is taken to relieve or avoid withdrawal symptoms.

Note: This criterion is not considered to be met for those taking stimulant medications solely under appropriate medical supervision, such as medications for attention-deficit/hyperactivity disorder or narcolepsy.

their reuptake, thereby making more of them available throughout the system (Carvalho et al., 2012). Too much amphetamine—and therefore too much dopamine and norepinephrine—can lead to hallucinations and delusions. As we see in Chapter 13, this effect has stimulated theories on the causes of schizophrenia, which can also include hallucinations and delusions.

Cocaine

The use and misuse of drugs wax and wane according to societal fashion, moods, and sanctions. Cocaine replaced amphetamines as the stimulant of choice in the 1970s (Jaffe, Rawson, & Ling, 2005). Cocaine is derived from the leaves of the coca plant, a flowing bush indigenous to South America. In his essay “On Coca” (1885/1974, p. 60), a young Sigmund Freud wrote of cocaine’s magical properties: “I have tested [the] effect of coca, which wards off hunger, sleep, and fatigue and steals one to intellectual effort, some dozen times on myself.”

Latin Americans have chewed coca leaves for centuries to get relief from hunger and fatigue (Daamen, Penning, Brunt, & Verster, 2012). Cocaine was introduced into the United States in the late 19th century; it was widely used from then until the 1920s. In 1885, Parke, Davis & Co. manufactured coca and cocaine in 15 forms, including coca-leaf cigarettes and cigars, inhalants, and crystals. For people who couldn’t afford these products, a cheaper way to get cocaine was in Coca-Cola, which up until 1903 contained a small amount (60 mg of cocaine per 8-ounce serving) (Daamen et al., 2012).

Clinical Description

Like amphetamines, in small amounts cocaine increases alertness, produces euphoria, increases blood pressure and pulse, and causes insomnia and loss of appetite. Remember that Danny snorted (inhaled) cocaine when he partied through the night with his friends. He later said the drug made him feel powerful and invincible—the only way he really felt self-confident. The effects of cocaine are short lived; for Danny they lasted less than an hour,

and he had to snort repeatedly to keep himself up. During these binges, he often became paranoid, experiencing exaggerated fears that he would be caught or that someone would steal his cocaine. Such paranoia—referred to as *cocaine-induced paranoia*—is common among persons with **cocaine use disorders**, occurring in two thirds or more (Daamen et al., 2012). Cocaine also makes the heart beat more rapidly and irregularly, and it can have fatal consequences, depending on a person’s physical condition and the amount of the drug ingested.

We saw that alcohol can damage the developing fetus. It has also been suspected that the use of cocaine (especially crack) by pregnant women may adversely affect their babies. Crack babies appear at birth to be more irritable than normal babies and have long bouts of high-pitched crying. They were originally thought to have permanent brain damage, although recent research suggests that the effects are less dramatic than first feared (Buckingham-Howes, Berger, Scaletti, & Black, 2013; Schiller & Allen, 2005). Some work suggests that many children born to mothers who have used cocaine during pregnancy may have decreased birth weight and decreased head circumference, and are at increased risk for later behavior problems (Richardson, Goldschmidt, & Willford, 2009). Complicating the evaluation of children born to mothers who use cocaine is that their mothers almost always used other substances as well, including alcohol and nicotine. Many of these children are raised in disrupted home environments, which further complicates the picture (Barthelemy et al., 2016). Continuing research should help us better understand the negative effects of cocaine on children.

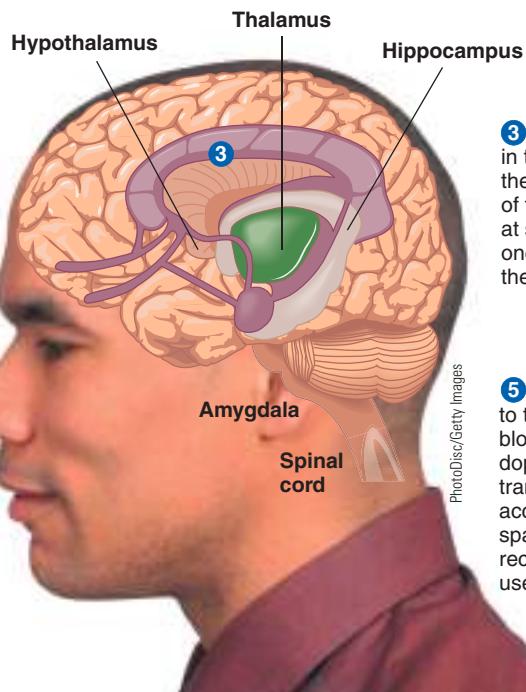

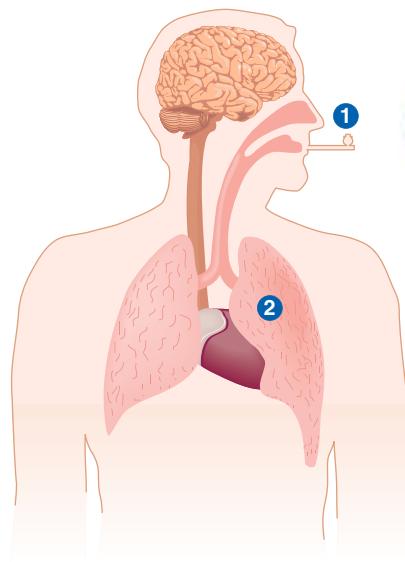

Statistics

Worldwide, almost 5% of adults report using cocaine at some point in their lives, and in the United States, more than 1.5 million people (0.6% of U.S. population) report using cocaine, including crack-cocaine, each year. Those aged 18 to 25 are about twice as likely to use cocaine compared with other age groups. Also, men are twice as likely to use cocaine as women (SAMHSA, 2014). Black individuals account for close to half of admissions to emergency rooms for cocaine-related problems (47%), followed by Caucasian individuals (37%) and Hispanic individuals (10%). Also, men were twice as likely as women to be in the emergency room (SAMHSA, 2011). Approximately 17% of cocaine users have also used crack cocaine (a crystallized form of cocaine that is smoked) (Closser, 1992). One estimate is that about 0.1% of people in the United States have tried crack and that an increasing proportion of the abusers seeking treatment are young, unemployed adults living in urban areas (SAMHSA, 2014).

Cocaine is in the same group of stimulants as amphetamines because it has similar effects on the brain. The “up” seems to come primarily from the effect of cocaine on the dopamine system. Look at ● Figure 11.4 to see how this action occurs. Cocaine enters the bloodstream and is carried to the brain. There the cocaine molecules block the reuptake of dopamine. As you know, neurotransmitters released at the synapse stimulate the next neuron and then are recycled back to the original neuron. Cocaine seems to bind to places where dopamine neurotransmitters reenter their home neuron, blocking their reuptake. The dopamine that cannot be

Researchers are beginning to understand how addictive drugs affect the brain. Some, including cocaine, intensify the transmission of signals among brain cells.

- 1 Drug user inhales cocaine molecules in smoke.
- 2 Cocaine enters bloodstream through lungs. Blood carries it throughout the body. Within seconds it reaches the brain.

- 3 Cocaine molecules act in the “pleasure pathway”—the limbic system in the middle of the brain. The effect occurs at synapses, where fibers from one nerve cell almost touch the surface of another.

- 5 Cocaine molecules bind to the dopamine transporter, blocking the route by which dopamine would reenter the transmitter cell. Dopamine accumulating in the synaptic space keeps stimulating the receiving cell, creating the user’s “high.”

- 4 Normally, a transmitting cell relays a signal by releasing dopamine molecules into the synaptic space. Dopamine drifts across the synapse and fits into receptors on the surface of the receiving cell, triggering an electrical signal that is relayed through the receiver. Then the dopamine molecules break away from the receptors and are recycled by the transmitter.

taken in by the neuron remains in the synapse, causing repeated stimulation of the next neuron. This stimulation of the dopamine neurons in the “pleasure pathway” (the site in the brain that seems to be involved in the experience of pleasure) causes the high associated with cocaine use.

As late as the 1980s, many felt cocaine was a wonder drug that produced feelings of euphoria without being addictive (Weiss & Iannucci, 2009). Such a conservative source as the *Comprehensive Textbook of Psychiatry* in 1980 indicated that “taken no more than two or three times per week, cocaine creates no serious problems” (Grinspoon & Bakalar, 1980). Just imagine—a drug that gives you extra energy, helps you think clearly and more creatively, and lets you accomplish more throughout the day, all without any negative side

effects! In our highly competitive and complex technological society, this would be a dream come true. But, as you probably realize, such temporary benefits have a high cost. Cocaine fooled us. Addiction does not resemble that of many other drugs early on; typically, people find only that they have a growing inability to resist taking more (Weiss & Iannucci, 2009). Few negative effects are noted at first; however, with continued use, sleep is disrupted, increased tolerance causes a need for higher doses, paranoia and other negative symptoms set in, and the cocaine user gradually becomes socially isolated. Chronic use may result in premature aging of the brain (Ersche, Jones, Williams, Robbins, & Bullmore, 2012).

Again, Danny’s case illustrates this pattern. He was a social user for a number of years, using cocaine only with friends and

only occasionally. Eventually, he had more frequent episodes of excessive use or binges, and he found himself increasingly craving the drug between binges. After the binges, Danny would crash and sleep. Cocaine withdrawal isn't like that of alcohol. Instead of rapid heartbeat, tremors, or nausea, withdrawal from cocaine produces pronounced feelings of apathy and boredom. Think for a minute how dangerous this type of withdrawal is. First, you're bored with everything and find little pleasure from the everyday activities of work or relationships. The one that can "bring you back to life" is cocaine. As you can imagine, a particularly vicious cycle develops: Cocaine is abused, withdrawal causes apathy, cocaine abuse resumes. The atypical withdrawal pattern misled people into believing that cocaine was not addictive. We now know that cocaine abusers go through patterns of tolerance and withdrawal comparable to those experienced by abusers of other psychoactive drugs (Daamen et al., 2012).

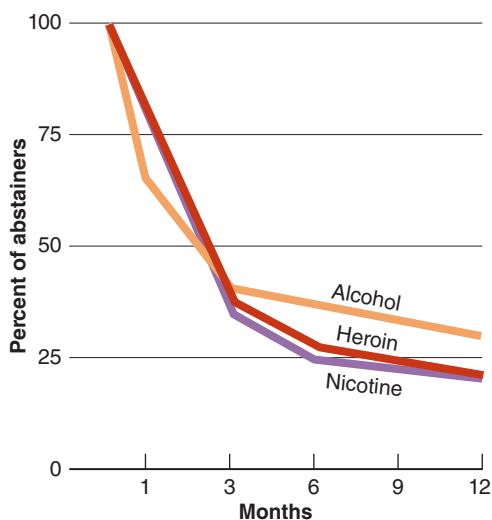

Tobacco-Related Disorders

When you think of addicts, what image comes to mind? Do you see dirty and disheveled people huddled on an old mattress in an abandoned building, waiting for the next fix? Do you picture businesspeople huddled outside a city building on a rainy afternoon furtively smoking cigarettes? Both these images are accurate, because the nicotine in tobacco is a psychoactive substance that produces patterns of dependence, tolerance, and withdrawal—**tobacco-related disorders**—comparable to those of the other drugs we have discussed so far (Litvin, Ditre, Heckman, & Brandon, 2012). In 1942, the Scottish physician Lennox Johnson "shot up" nicotine extract and found after 80 injections that he liked it more than cigarettes and felt deprived without it (Kanigel, 1988). This colorless, oily liquid—called nicotine after Jean Nicot, who introduced tobacco to the French court in the 16th century—is what gives smoking its pleasurable qualities.

The tobacco plant is indigenous to North America, and Native Americans cultivated and smoked the leaves centuries ago. Today, about 20% of all people in the United States smoke, which is down from the 42.4% who were smokers in 1965 (Litvin et al., 2012).

DSM-5 does not describe an intoxication pattern for tobacco-related disorders. Rather, it lists withdrawal symptoms, which include depressed mood, insomnia, irritability, anxiety, difficulty concentrating, restlessness, and increased appetite and weight gain. Nicotine in small doses stimulates the central nervous system; it can relieve stress and improve mood. But it can also cause high blood pressure and increase the risk of heart disease and cancer (Litvin et al., 2012). High doses can blur your vision, cause confusion, lead to convulsions, and sometimes even cause death. Once smokers are dependent on nicotine, going without it causes withdrawal symptoms. If you doubt the addictive power of nicotine, consider that the rate of relapse among people trying to give up drugs is equivalent among those using alcohol, heroin, and cigarettes (see ● Figure 11.5).

Nicotine is inhaled into the lungs, where it enters the bloodstream. Only 7 to 19 seconds after a person inhales the smoke, the nicotine reaches the brain. Nicotine appears to stimulate specific receptors—nicotinic acetylcholine receptors (*nAChRs*)—in the midbrain reticular formation and the limbic system, the site of the brain's pleasure pathway (the dopamine system responsible for feelings of euphoria) (Litvin et al., 2012). Smokers dose themselves

throughout the day in an effort to keep nicotine at a steady level in the bloodstream (see ● Figure 11.6; Dalack, Glassman, & Covey, 1993). Some evidence also points to how maternal smoking can predict later substance-related disorders in their children, but this appears to be an environmental (e.g., home environment) rather than biological influence (D'Onofrio et al., 2012).

Smoking has been linked with signs of negative affect, such as depression, anxiety, and anger (Rasmussen, Anderson, Krishnan-Sarin, Wu, & Paliwal, 2006). For example, many people who quit

smoking but later resume report that feelings of depression or anxiety were responsible for the relapse (Kahler, Litvin Bloom, Leventhal, & Brown, 2015). Due to this association between smoking and symptoms of depression and anxiety, relapse may be especially higher for women as compared to men, because women more than men tend to have these symptoms (Nakajima & al'Absi, 2012).

Severe depression is found to occur significantly more often among people with nicotine dependence. Does this mean that smoking causes depression or depression causes smoking? There is a complex and bi-directional relationship between cigarette smoking and

negative affect (Litvin et al., 2012). In other words, being depressed increases your risk of becoming dependent on nicotine, and at the same time, being dependent on nicotine will increase your risk of becoming depressed. Genetic studies suggest that a genetic vulnerability combined with certain life stresses may combine to make you vulnerable to both a nicotine use disorder and depression (e.g., Edwards & Kendler, 2012). (We discuss evidence for the genetics of smoking when we cover the causes of substance abuse later in this chapter.)

Caffeine-Related Disorders

Caffeine is the most common of the psychoactive substances; estimates indicate that upwards of 85% of the U.S. population has at least one caffeinated beverage per day. (Mitchell, Knight, Hockenberry, Teplansky, & Hartman, 2014). Called the “gentle stimulant” because it is thought to be the least harmful of all addictive drugs, caffeine can still lead to problems similar to that of other drugs (e.g., interfering with social and work obligations; Meredith, Juliano, Hughes & Griffiths, 2013). This drug is found in tea, coffee, many soda drinks, and cocoa products. High levels of caffeine are added to the “energy drinks” that are widely consumed in the United States today but are banned in some European countries (including France, Denmark, and Norway) due to health concerns (Price, Hilchey, Darredeau, Fulton, & Barrett, 2010; Thirlton, Colby & Devine, 2014).

As most of you have experienced firsthand, caffeine in small doses can elevate your mood and decrease fatigue. In larger doses,

DSM

- A. Recent consumption of caffeine (typically a high dose well in excess of 250 mg).
- B. Five (or more) of the following signs or symptoms developing during, or shortly after, caffeine use:
1. Restlessness.
 2. Nervousness.
 3. Excitement.
 4. Insomnia.
 5. Flushed face.
 6. Diuresis.
 7. Gastrointestinal disturbance.
 8. Muscle twitching.
 9. Rambling flow of thought and speech.
 10. Tachycardia or cardiac arrhythmia.
 11. Periods of inexpressibility.
 12. Psychomotor agitation.
- C. The signs or symptoms in Criterion B cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- D. The signs or symptoms are not attributable to another medical condition and are not better explained by another mental disorder, including intoxication with another substance.

it can make you feel jittery and can cause insomnia. Because caffeine takes a relatively long time to leave our bodies (about 6 hours), sleep can be disturbed if the caffeine is ingested in the hours close to bedtime. This effect is especially pronounced among those already suffering from insomnia (Byrne et al., 2012). As with the other psychoactive drugs, people react variously to caffeine; some are sensitive to it, and others can consume relatively large amounts with little effect. Research suggests that moderate use of caffeine (a cup of coffee per day) by pregnant women does not harm the developing fetus (Loomans et al., 2012).

DSM-5 includes caffeine use disorder—defined problematic caffeine use that causes significant impairment and distress—as a condition for further study (American Psychiatric Association, 2013). As with other stimulants, regular caffeine use can result in tolerance and dependence on the drug. Those of you who have experienced headaches, drowsiness, and a generally unpleasant mood when denied your morning coffee have had the withdrawal symptoms characteristic of this drug (Meredith et al., 2013). Caffeine's effect on the brain seems to involve the neuromodulator *adenosine* and, to a lesser extent, the neurotransmitter *dopamine* (Juliano, Ferré, & Griffiths, 2015). Caffeine seems to block adenosine reuptake. Adenosine plays an important role on the release of dopamine and glutamate in the striatum, which may explain the elation and increased energy that come with caffeine use (Juliano et al., 2015).

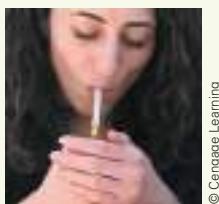

Opioid-Related Disorders

The word *opiate* refers to the natural chemicals in the opium poppy that have a narcotic effect (they relieve pain and induce sleep). In some circumstances, they can cause **opioid-related disorders**. The broader term *opioids* refers to the family of substances that includes natural opiates, synthetic variations (heroin, methadone, hydrocodone, oxycodone), and the comparable substances that occur naturally in the brain (enkephalins, beta-endorphins, and dynorphins) (Borg et al., 2015). References to the use of opium as a medicine date back more than 3,500 years (Strain, Lofwall, & Jaffe, 2009). In *The Wizard of Oz*, the Wicked Witch of the West puts Dorothy, Toto, and the Cowardly Lion to sleep by poisoning poppies in a field that is on the way to Oz, a literary allusion to the opium poppies used to produce morphine, codeine, and heroin.

Just as the poppies lull Dorothy, the Cowardly Lion, and Toto, opiates induce euphoria, drowsiness, and slowed breathing. High doses can lead to death if respiration is completely depressed. Opiates are also analgesics, substances that help relieve pain. People are sometimes given morphine before and after surgery to calm them and help block pain.

Withdrawal from opioids can be so unpleasant that people may continue to use these drugs despite a sincere desire to stop.

Nicotine Dependence

"You can't simply focus on nicotine itself. Many medications do that—they focus on replacing the nicotine, such as nicotine gum or the patch—and that's valuable, but you really have to focus on all the triggers, the cues, and the environment."

Barbiturate and alcohol withdrawal can be even more distressing, however. Even so, people who cease or reduce their opioid intake begin to experience symptoms within 6 to 12 hours; these include excessive yawning, nausea and vomiting, chills, muscle aches, diarrhea, and insomnia—temporarily disrupting work, school, and social relationships. The symptoms can persist for 1 to 3 days, and the withdrawal process is completed in about a week.

Addiction to heroin is reported in about almost a half million people in the United States, double the number estimated between 2002 and 2013. Illicit use of opioid-containing prescription medicines—the most commonly abused opiate class—has also risen in recent years with 4.13 million people over the age of 12 reporting non-medical use (SAMHSA, 2014). One survey found that 12.3% of high school seniors reported using opioids (e.g., hydrocodone,

oxycodone) for nonmedical reasons (McCabe, West, Teter, & Boyd, 2012). Illicit use of opioid-containing prescription was the second most common type of illicit drug use in 2014 after marijuana. This rise in opioid use over the past decade has been deemed an opioid epidemic and public health crisis in the United States. The rise is particularly problematic because 1.9 million met criteria for opioid use disorder in 2013 (SAMHSA, 2014). Additionally, the increase in number of deaths due to illicit opioid use was the leading cause of death for drug users in 2013, a 360% increase from 1999 (Centers for Disease Control, National Center for Health Statistics, 2014). Research also suggests that individuals who first became addicted to prescription pain medication transitioned to using heroin (Muhuri, Gfroerer & Davies, 2013). People who use opiates face risks beyond addiction and the threat of overdose. Because these drugs are usually injected intravenously, users are at increased risk for other chronic life-threatening illness such as Hepatitis C and HIV infection and therefore AIDS (Compton, Boyle & Wargo, 2015).

The life of an opiate addict can be bleak. Research suggests that mortality rates in this population range from 6 to 20 times higher than the general population's. And, those individuals who do live face much hardship recovering from addiction with stable abstinence rates as low as 30% with most individuals undergoing many relapses. Even those that discontinue opioids often use alcohol and other drugs in their place (Hser, Evans, Grella, Ling, & Anglin, 2015). Results from a 33-year follow-up study of more than 80 opioid users in an English town highlight this pessimistic view (Rathod, Addenbrooke, & Rosenbach, 2005). At the follow up, 22% of opioid users had died—about twice the national rate of about 12% for the general population. More than half the deaths were the result of drug overdose, and several took their own lives. The good news from this study was that of those who survived, 80% were no longer using opioids, and the remaining 20% were being treated with methadone. Persistence opioid use may be related to comorbid mental disorders and sexual or physical abuse. Long-term recovery has been shown to be associated with

family and social support, employment, and opioid abstinence of at least five years (Hser et al., 2015).

The high or “rush” experienced by users comes from activation of the body’s natural opioid system. In other words, the brain already has its own opioids—called enkephalins and endorphins—that provide narcotic effects (Ballantyne, 2012). Heroin, opium, morphine, and other opiates activate this system. The discovery of the natural opioid system was a major breakthrough in the field of psychopharmacology: Not only does it allow us to study the effects of addictive drugs on the brain, but it also has led to important discoveries that may help us treat people dependent on these drugs.

Cannabis-Related Disorders

Cannabis (marijuana) was the drug of choice in the 1960s and early 1970s. Although it has decreased in popularity, it is still the most routinely used illegal substance, with 5 to 15% of people in western countries reporting regular use (Jager, 2012). In the United States, 22.2 million individuals aged 12 or older used marijuana in the past 30 days (SAMHSA, 2014). Marijuana is the name given to the dried parts of the cannabis or hemp plant (its full scientific name is *Cannabis sativa*). Cannabis grows wild throughout the tropical and temperate regions of the world, which accounts for one of its nicknames, “weed.”

As demonstrated by the following parable, people who smoke marijuana often experience altered perceptions of the world.

Three men, so the story goes, arrived one night at the closed gates of a Persian city. One was intoxicated by alcohol, another was under the spell of opium, and the third was steeped in marijuana.

Kevin Mazur/Getty Images

The pop icon Prince died in 2016 at the age of 57 from an accidental overdose of the prescribed opioid, fentanyl.

The first blustered: “Let’s break the gates down.”

“Nay,” yawned the opium eater, “let us rest until morning, when we may enter through the wide-flung portals.”

“Do as you like,” was the announcement of the marijuana addict. “But I shall stroll in through the keyhole!” (Rowell & Rowell, 1939, p. 66)

Reactions to cannabis usually include mood swings. Otherwise-normal experiences seem extremely funny, or the person might enter a dreamlike state in which time seems to stand still. Users often report heightened sensory experiences, seeing vivid colors,

Diagnostic Criteria for Opioid Use Disorder

- A. A problematic pattern of opioid use leading to clinically significant impairment or distress, as manifested by at least two of the following, occurring within a 12-month period:
1. Opioids are often taken in larger amounts or over a longer period than was intended.
 2. There is a persistent desire or unsuccessful efforts to cut down or control opioid use.
 3. A great deal of time is spent in activities necessary to obtain the opioid, use the opioid, or recover from its effects.
 4. Craving, or a strong desire or urge to use opioids.
 5. Recurrent opioid use resulting in a failure to fulfill major role obligations at work, school, or home.
 6. Continued opioid use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of opioids.
 7. Important social, occupational, or recreational activities are given up or reduced because of opioid use.
 8. Recurrent opioid use in situations in which it is physically hazardous.
 9. Continued opioid use despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the substance.
 10. Tolerance, as defined by either of the following:
 - a. A need for markedly increased amounts of opioids to achieve intoxication or desired effect.
 - b. A markedly diminished effect with continued use of the same amount of an opioid.

Note: This criterion is not considered to be met for those taking opioids solely under appropriate medical supervision.

11. Withdrawal, as manifested by either of the following:

- a. The characteristic opioid withdrawal syndrome (refer to Criteria A and B of the criteria set for opioid withdrawal).
- b. Opioids (or a closely related substance) are taken to relieve or avoid withdrawal symptoms.

Note: This criterion is not considered to be met for those taking opioids solely under appropriate medical supervision.

or appreciating the subtleties of music. Perhaps more than any other drug, however, cannabis can produce different reactions in people. It is not uncommon for someone to report having no reaction to the first use of the drug; it also appears that people can “turn off” the high if they are sufficiently motivated (Jager, 2012). The feelings of well-being produced by small doses can change to paranoia, hallucinations, and dizziness when larger doses are taken. High school-age marijuana smokers get lower grades and are less likely to graduate, although it is not clear if this is the direct result of cannabis use or concurrent other drug use (Jager, 2012). Research on frequent cannabis users suggests that impairments of memory, concentration, relationships with others, and employment may be negative outcomes of long-term use (possibly leading to **cannabis use disorders**), although some researchers suggest that some psychological problems precede usage—increasing the likelihood that someone will use cannabis (Heron et al., 2013; Macleod et al., 2004). The introduction of synthetic marijuana (referred to with a number of different names such as “fake weed,” “K2” or “Spice” and marketed as “herbal incense”) has caused alarm because in many places it can be purchased legally and the reaction to its use can be extremely harmful (e.g., hallucinations,

seizures, heart rhythm problems, etc.) (Palamar & Barratt, 2016; Wells & Ott, 2011).

The evidence for cannabis tolerance is contradictory. Chronic and heavy users report tolerance, especially to the euphoric high (Mennes, Ben Abdallah, & Cottler, 2009); they are unable to reach the levels of pleasure they experienced earlier. However, evidence also indicates “reverse tolerance,” when regular users experience more pleasure from the drug after repeated use. Major signs of withdrawal do not usually occur with cannabis. Chronic users who stop taking the drug report a period of irritability, restlessness, appetite loss, nausea, and difficulty sleeping (Jager, 2012).

Controversy surrounds the use of cannabis for medicinal purposes. However, there appears to be an increasing database documenting the successful use of cannabis and its by-products for the symptoms of certain diseases. In Canada and 24 states including Washington, D.C., cannabis products are available for medical use, including an herbal cannabis extract (Sativex—delivered in a nasal spray), dronabinol (Marinol), nabilone (Cesamet), and the herbal form of cannabis that is typically smoked (Borgelt, Franson, Nussbaum, & Wang, 2013; Wang, Collet, Shapiro, & Ware, 2008). These cannabis-derived products are prescribed for chemotherapy-induced nausea and vomiting, HIV-associated anorexia, neuropathic pain in multiple sclerosis, and cancer pain. Unfortunately, marijuana smoke may contain as many carcinogens as tobacco smoke, although one long-term study that followed more than 5,000 men and women over 20 years suggested that occasional use does not appear to have a negative effect on lung functioning (Pletcher et al., 2012).

Most cannabis users inhale the drug by smoking the dried leaves in marijuana cigarettes; others use preparations such as hashish, which is the dried form of the resin in the leaves of the female plant. Marijuana contains more than 80 varieties of the chemicals called *cannabinoids*, which are believed to alter mood and behavior. The most common of these chemicals includes the *tetrahydrocannabinols*, otherwise known as *THC*. An exciting finding in the area of cannabis research was that the brain makes its own version of THC, a neurochemical called *anandamide* after the Sanskrit word *ananda*, which means “bliss” (Sedlak & Kaplin, 2009; Volkow, Baler, Compton, & Weiss, 2014). Subsequent research points to several other naturally-occurring brain chemicals including 2-AG (2-arachidonoylglycerol), noladin ether, virodhamine, and N-arachidonoyldopamine (Mechoulam & Parker, 2013; Piomelli, 2003). Scientists continue to explore how this neurochemical affects the brain and behavior (Piomelli, 2014).

Hallucinogen-Related Disorders

On a Monday afternoon in April 1943, Albert Hoffmann, a scientist at a large Swiss chemical company, prepared to test a newly synthesized compound. He had been studying derivatives of ergot, a fungus that grows on diseased kernels of grain, and sensed that he had missed something important in the 25th compound of the lysergic acid series. Ingesting what he thought was an infinitesimally small amount of this drug, which he referred to in his notes as LSD-25, he waited to see what subtle changes might come over him as a result. Thirty minutes later, he reported no change, but some 40 minutes after taking the drug, he began to feel dizzy and

had a noticeable desire to laugh. Riding his bicycle home, he hallucinated that the buildings he passed were moving and melting. By the time he arrived home, he was terrified he was losing his mind. Hoffmann was experiencing the first recorded “trip” on LSD (Jones, 2009).

LSD (*d-lysergic acid diethylamide*), sometimes referred to as “acid,” is the most common hallucinogenic drug. It is produced synthetically in laboratories, although naturally occurring derivatives of this grain fungus (ergot) have been found historically. In Europe during the Middle Ages, an outbreak of illnesses occurred as a result of people’s eating grain that was infected with the fungus. One version of this illness—later called *ergotism*—constricted the flow of blood to the arms or legs and eventually resulted in gangrene and the loss of limbs. Another type of illness resulted in convulsions, delirium, and hallucinations. Years later, scientists connected ergot with the illnesses and began studying versions of this fungus for possible benefits. This is the type of work Hoffmann was engaged in when he discovered LSD’s hallucinogenic properties.

LSD largely remained in the laboratory until the 1960s, when it was first produced illegally for recreational use. However, the Central Intelligence Agency (CIA) tested LSD as a “truth serum” during interrogations though the agency abandoned their efforts after several serious incidents and no evidence of truth (Lee & Shlain, 1992). The mind-altering effects of the drug suited the social effort to reject established culture and enhanced the search for enlightenment that characterized the mood and behavior of many

people during that decade (Parrott, 2012). The late Timothy Leary, at the time a Harvard University research professor, first used LSD in 1961 and immediately began a movement to have every child and adult try the drug and “turn on, tune in, and drop out.”

There are a number of other hallucinogens, some occurring naturally in a variety of plants: *psilocybin* (found in certain species of mushrooms), *lysergic acid amide* (found in the seeds of the morning glory plant), *dimethyltryptamine (DMT)* (found in the bark of the Virola tree, which grows in South and Central America); and *mescaline* (found in the peyote cactus plant). Phencyclidine (or PCP) is snorted, smoked, or injected intravenously, and it causes impulsivity and aggressiveness.

The DSM-5 diagnostic criteria for hallucinogen intoxication are similar to those for cannabis: perceptual changes such as the subjective intensification of perceptions, depersonalization, and hallucinations. Physical symptoms include pupillary dilation, rapid heartbeat, sweating, and blurred vision (American Psychiatric Association, 2013). Many users have written about hallucinogens, and they describe a variety of experiences. In one well-designed placebo-controlled study of hallucinogens, researchers at Johns Hopkins School of Medicine gave volunteers either the hallucinogen psilocybin or a control drug (the ADHD medication Ritalin) and assessed their reactions (Griffiths, Richards, McCann, & Jesse, 2006). Psilocybin ingestion resulted in individualized reactions including perceptual changes (for example, mild visual hallucinations) and mood changes (for example, joy or happiness, anxiety, or fearfulness). Interestingly, the drug increased reports

of mystical experiences (for example, deeply felt positive mood), and even 14 months later many rated the experience as having a spiritual significance (Griffiths, Richards, Johnson, McCann, & Jesse, 2008). More research is needed to explore how these types of drugs work with increased specificity, and this research may also tell us how our brains process experiences such as personal meaning and spirituality (Tylš, Páleníček, & Horáček, 2014).

Tolerance develops quickly to a number of hallucinogens, including LSD, psilocybin, and mescaline (**hallucinogen use disorders**) (Passie & Halpern, 2015). If taken repeatedly over a period of days, these drugs lose their effectiveness. Sensitivity returns after about a week of abstinence, however. For most hallucinogens, no withdrawal symptoms are reported. Even so, a number of concerns have been expressed about their use. One is the possibility of psychotic reactions. Stories in the popular press about people who jumped out of windows because they believed they could fly or who stepped into moving traffic with the mistaken idea that they couldn't be hurt have provided for sensational reading, but little evidence suggests that using hallucinogens produces a greater risk than being drunk or under the influence of any other drug. People do report having "bad trips"; these are the sort of frightening episodes in which clouds turn into threatening monsters or deep feelings of paranoia take over. Usually someone on a bad trip can be "talked down" by supportive people who provide constant reassurance that the experience

is the temporary effect of the drug and it will wear off in a few hours (Parrott, 2012).

Hallucinogens seem to affect the brain in diverse and non-specific ways, meaning by affecting multiple different receptors at one time in opposing ways. It is thought that this broad impact on brain receptors may lead to consciousness expanding experienced by some (Passie & Halpern, 2015). Most of these drugs bear some resemblance to neurotransmitters; LSD, psilocybin, lysergic acid amide, and DMT are chemically similar to serotonin; mescaline resembles norepinephrine; and a number of other hallucinogens we have not discussed are similar to acetylcholine. Psilocybin, for example, seems to increase serotonin as an agonist at 5HT2A/C and 5HT1A receptors to produce hallucinogenic effects but the remaining neural activity is less understood and it seems that psilocybin may also impact dopamine receptors. Recent fMRI studies show activation in "resting state networks" that are typically activated during a resting state or introspection, as well as networks that increase focused attention. Alternation and activation of these two networks typically happens during states like meditation or psychosis. Research in human and animal laboratory studies shows no short-term or long-toxicity, meaning one's body processes the substances without incurring any harm to organs including the brain. This may be in part why some researchers are exploring psilocybin as a "model" for psychosis as well as a substance with possible therapeutic potential (Tylš et al., 2014).

Other Drugs of Abuse

A number of other substances are used by individuals to alter sensory experiences. These drugs do not fit neatly into the classes of substances we just described but are nonetheless of great concern because they can be physically damaging to those who ingest them. We briefly describe inhalants, steroids, and a group of drugs commonly referred to as designer drugs.

Inhalants include a variety of substances found in volatile solvents—making them available to breathe into the lungs directly. Some common inhalants that are used abusively include spray paint, hair spray, paint thinner, gasoline, amyl nitrate, nitrous oxide (“laughing gas”), nail polish remover, felt-tipped markers, airplane glue, contact cement, dry-cleaning fluid, and spot remover (Ridenour & Howard, 2012). Inhalant use is highest during early adolescence, ages 13 to 14, especially in those in correctional or psychiatric institutions. Additionally, higher rates of inhalant use are found among Native Americans and Caucasians, as well as those who live in rural or small towns, come from disadvantaged backgrounds, have higher levels of anxiety and depression, and show more impulsive and fearless temperaments (Garland, Howard, Vaughn, & Perron, 2011; Halliburton & Bray, 2016). These drugs are rapidly absorbed into the bloodstream through the lungs when inhaled from containers or on a cloth held up to the mouth and nose. The high associated with the use of inhalants resembles

that of alcohol intoxication and usually includes dizziness, slurred speech, lack of coordination, euphoria, and lethargy (American Psychiatric Association, 2013). Users build up a tolerance to the drugs, and withdrawal—which involves sleep disturbance, tremors, irritability, and nausea—can last from 2 to 5 days. Unfortunately, use can also increase aggressive and antisocial behavior, and long-term use can damage bone marrow, kidneys, liver, lung, nervous system, and the brain (for example, leading to cognitive impairment for the user and for infants born to mothers who use while pregnant) (Ford, Sutter, Owen, & Albertson, 2014). If users are startled, this can cause a cardiac event that can lead to death (called “sudden sniffing death”) (Ridenour & Howard, 2012).

Anabolic-androgenic steroids (more commonly referred to as steroids or “roids” or “juice”) are derived from or are a synthesized form of the hormone testosterone (Pope & Kanayama, 2012). The legitimate medical uses of these drugs focus on people with asthma, anemia, breast cancer, and males with inadequate

sexual development. However, the anabolic action of these drugs (that can produce increased body mass) has resulted in their illicit use by those wishing to try to improve their physical abilities by increasing muscle bulk. Steroids can be taken orally or through injection, and some estimates suggest that approximately 2% to 6% of males will use the drug illegally at some point in their lives (Pope & Kanayama, 2012). Users sometimes administer the drug on a schedule of several weeks or months followed by a break from its use—called “cycling”—or combine several types of steroids—called “stacking.” Steroid use differs from other drug use because the substance does not produce a desirable high but instead is used to enhance performance and body size. Dependence on the substance therefore seems to involve the desire to maintain the performance gains obtained rather than a need to re-experience an altered emotional or physical state. Research on the long-term effects of steroid use seems to suggest that mood disturbances are common (for example, depression, anxiety, and panic attacks) (Pope & Kanayama, 2012), and there is a concern that more serious physical consequences may result from regular use.

Determine whether the following statements about stimulants are true (T) or false (F).

1. _____ Use of crack cocaine by a pregnant woman always adversely affects the developing fetus.
2. _____ Regular use of stimulants can result in tolerance and dependence on the drugs.
3. _____ Amphetamines have been used as appetite suppressants.
4. _____ Compared with all other drugs, caffeine can produce the most variable reactions in people.
5. _____ Amphetamines are naturally occurring drugs that induce feelings of elation and vigor and can reduce fatigue.
6. _____ An ingredient of the beverage Coca-Cola in the 1800s was cocaine.
7. _____ Stimulants are produced only in a laboratory.

Another class of drugs—dissociative anesthetics—causes drowsiness, pain relief, and the feeling of being out of one's body (Domino & Miller, 2015; Javitt & Zukin, 2009). Sometimes referred to as designer drugs, this growing group of drugs was originally developed by pharmaceutical companies to target specific diseases and disorders. It was only a matter of time before some began using the developing technology to design “recreational drugs.” We have already described one of the more common illicit designer drugs—MDMA, street names of Ecstasy or Molly—in the section on stimulants. This amphetamine is

one of a small but feared growing list of related substances that includes 3,4-methylenedioxymethamphetamine (MDEA, or Eve), and 2-(4-bromo-2,5-dimethoxy-phenyl)-ethylamine (BDMPEA, or Nexus) (Wu et al., 2009). Their ability to heighten a person's auditory and visual perception, as well as the senses of taste and touch, has been incorporated into the activities of those who attend nightclubs, all-night electronic dance music (EDM) parties (raves), or large social gatherings of primarily gay men (called “circuit parties”). A drug related to phencyclidine and associated with the “drug club” scene is ketamine (street names include K, Special K, and Cat Valium), a dissociative anesthetic that produces a sense of detachment, along with a reduced awareness of pain (Wolff, 2012). Gamma-hydroxybutyrate (GHB, or liquid Ecstasy) is a central nervous system depressant that was marketed in health food stores in the 1980s as a means of stimulating muscle growth. Users report that, at low doses, it can produce a state of relaxation and increased tendency to verbalize but that at higher doses or with alcohol or other drugs it can result in seizures, severe respiratory depression, and coma. These drugs taken at high doses may be especially dangerous for the developing teenager brain due to their high toxicity, which may cause irreversible memory loss and other cognitive problems (Domino & Miller, 2015).

Since 2010 there has been a rise in the use of synthetic cathinones (“bath salts”) 3,4-methylenedioxypyrovalerone (MDPV), synthetic form of a stimulant found in the khat plant from East Africa and Saudi Arabia known for its stimulant effects (Baumann, 2014). The effects of synthetic cathiones are much stronger and though similar to stimulants, they have an excitatory or agitating effect that can include paranoia, delirium, hallucinations and panic attacks (Baumann et al., 2013). Use of all these drugs can result in tolerance and dependence, and their increasing popularity among adolescents and young adults raises significant public health concerns.

Causes of Substance-Related Disorders

People continue to use psychoactive drugs for their effects on mood, perception, and behavior despite the obvious negative consequences of abuse and dependence. We saw that despite his clear potential as an individual, Danny continued to use drugs to his detriment. Various factors help explain why people like Danny persist in using drugs. Drug abuse and dependence, once thought to be the result of moral weakness, are now understood to be influenced by a combination of biological and psychosocial factors.

Why do some people use psychoactive drugs without abusing or becoming dependent on them? Why do some people stop using these drugs or use them in moderate amounts after being dependent on them and others continue a lifelong pattern of dependence despite their efforts to stop? These questions continue to occupy the time and attention of numerous researchers throughout the world.

Biological Dimensions

In 2007, when American model and television personality Anna Nicole Smith died from an apparently accidental overdose of at least nine prescription medications—including methadone, Valium, and the sedative chloral hydrate—the unfortunate news created a media sensation. The tragedy was compounded by the

fact that, just months before, her only son Daniel had died, also from an apparent drug overdose. Did the son inherit a vulnerability to addiction from his mother? Did he pick up Anna Nicole's habits from living with her over the years? Is it just a coincidence that both mother and son were so involved with drugs?

Familial and Genetic Influences

As you already have seen throughout this book, many psychological disorders are influenced in important ways by genetics. Mounting evidence indicates that drug abuse follows this pattern. Researchers conducting twin, family, and adoption and other genetic studies have found that certain people are genetically vulnerable to drug abuse (Strain, 2009; Volkow & Warren, 2015). Twin studies of smoking, for example, indicate a moderate genetic influence (e.g., Hardie, Moss, & Lynch, 2006; Seglem, Waaktaar, Ask, & Torgersen, 2015). Most genetic data on substance abuse come from research on alcoholism, which is widely studied because alcohol use is legal and many people are dependent on it. Research in general suggests that genetic risk factors cut across all mood-altering drugs (Kendler et al., 2012).

In a major twin study, the role of the environment, as well as the role of genetics, was examined in substance use problems. Researchers studied more than 1,000 pairs of male twins and questioned them about their use of cannabis, cocaine, hallucinogens, sedatives, stimulants, and opiates (Kendler, Jacobson, Prescott, & Neale, 2003). The findings—which may have major implications for how we approach treatment and prevention—suggest that there are common genetic influences on the use of all of these drugs. Although it is clear that genetics plays an important role in substance-related disorders, specific genes and their influence on these disorders are still being explored (Ray, 2012; Volkow & Warren, 2015). As the search for the genes influencing substance

use disorders, the next obvious question is how these genes function when it comes to addiction—a field of research called *functional genomics* (Demers, Bogdan, & Agrawal, 2014; Khokhar, Ferguson, Zhu, & Tyndale, 2010).

Genetic factors may affect how people experience and metabolize certain drugs, which in turn may partly determine who will or will not become regular users (Volkow & Warren, 2015). Just to illustrate how complex these relationships can be, research has found that certain genes are associated with a greater likelihood of heroin addiction in Hispanic and African American populations (Nielsen et al., 2008). Other research points out that a pharmacological treatment for alcohol use disorder—naltrexone (an opioid antagonist)—may be most effective with individuals who have a particular genetic variant in their opioid receptors (the OPRM1 gene) (Ray, 2012). In other words, your genetics may not only influence whether you develop a substance-related disorder but also help predict which treatments may be effective in reducing these problems.

Neurobiological Influences

In general, the pleasurable experiences reported by people who use psychoactive substances partly explain why people continue to use them. In behavioral terms, people are positively reinforced for using drugs. But what mechanism is responsible for such experiences? Studies indicate the brain appears to have a natural “pleasure pathway” that mediates our experience of reward. All abused substances seem to affect this internal reward center in the same way as you experience pleasure from certain foods or from sex (Ray, 2012). In other words, what psychoactive drugs may have in common is their ability to activate this reward center and provide the user with a pleasurable experience, at least for a time.

The pleasure center was discovered more than 50 years ago by James Olds, who studied the effects of electrical stimulation on rat brains (Olds, 1956; Olds & Milner, 1954). If certain areas were stimulated with small amounts of electricity, the rats behaved as if they had received something pleasant, such as food. The exact location of the area in the human brain is still subject to debate. It is believed that the *dopaminergic system* and its *opioid-releasing neurons* known as MOP-r receptors are involved. Opioids have an agonist effect at MOP-r receptors, which are spread throughout the central nervous system and are encoded by mu opioid receptor gene of OPRM1. This means opioids encourage more production of the brains’ own opioids. The pleasure center of reward that keeps opioid users using is made up of MOP-r receptors mostly found in ventral and dorsal striatal areas and is highly influenced by the downstream activation of the dopaminergic mesocortico-limbic and nigrostriatal systems (Berridge & Kringelbach, 2015; Borg et al., 2015).

How do different drugs that affect different neurotransmitter systems all converge to activate the pleasure pathway, which is primarily made up of dopamine-sensitive neurons? Researchers are only beginning to sort out the answers to this question, but some surprising findings have emerged in recent years. For example, we know that amphetamines and cocaine act directly on the dopamine system. Other drugs, however, appear to increase the availability of dopamine in more roundabout and intricate ways.

For example, the neurons in the brain's ventral tegmental area are kept from continuous firing by GABA neurons. (Remember that the GABA system is an inhibitory neurotransmitter system that blocks other neurons from sending information.) One thing that keeps us from being on an unending high is the presence of these GABA neurons, which act as the "brain police," or super-egos of the reward neurotransmitter system. Opiates (opium, morphine, heroin) inhibit GABA, which in turn stops the GABA neurons from inhibiting dopamine, which makes more dopamine available in the brain's pleasure pathway. Drugs that stimulate the reward center directly or indirectly include not only amphetamine, cocaine, and opiates but also nicotine and alcohol (Strain, 2009; Volkow & Warren, 2015).

This complicated picture is far from complete. We now understand that other neurotransmitters in addition to dopamine—including serotonin and norepinephrine—are also involved in the brain's reward system (Khokhar et al., 2010; Volkow & Warren, 2015). The coming years should yield interesting insights into the interaction of drugs and the brain. One aspect that awaits explanation is how drugs not only provide pleasurable experiences (positive reinforcement) but also help remove unpleasant experiences such as pain, feelings of illness, or anxiety (negative reinforcement). Aspirin is a negative reinforcer: We take it not because it makes us feel good but because it stops us from feeling bad. In much the same way, one property of the psychoactive drugs is that they stop people from feeling bad, an effect as powerful as making them feel good.

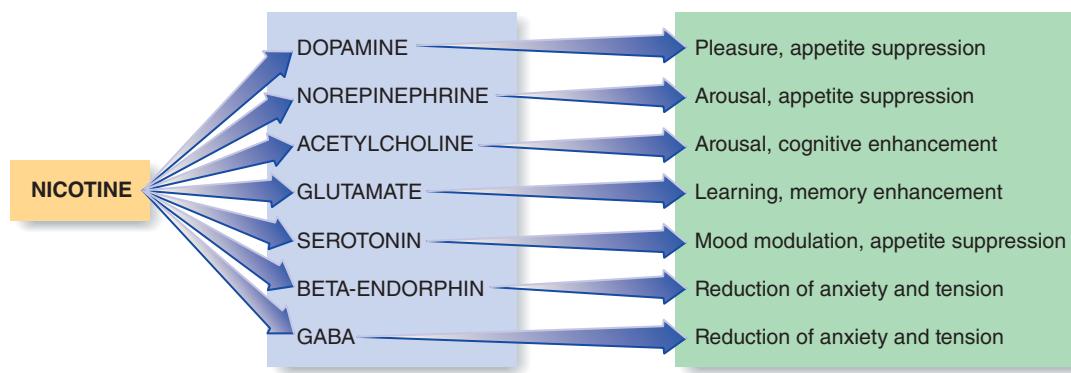

With several drugs, negative reinforcement is related to the anxiolytic effect, the ability to reduce anxiety (discussed briefly in the section on the sedative, hypnotic, and anxiolytic drugs). Alcohol has an anxiolytic effect. The neurobiology of how these drugs reduce anxiety seems to involve the septal–hippocampal system (Ray, 2012), which includes a large number of GABA-sensitive neurons. Certain drugs may reduce anxiety by enhancing the activity of GABA in this region, thereby inhibiting the brain's normal reaction (anxiety or fear) to anxiety-producing situations.

- Figure 11.7 illustrates how a drug such as nicotine has a multifaceted impact on a variety of neurotransmitter systems and in turn their effects on the experience of smoking.

Researchers have identified individual differences in the way people respond to alcohol. Understanding these response differences is important because they may help explain why some people continue to use drugs until they acquire a dependence on them, whereas others stop before this happens. A number of studies compare individuals with and without a family history of alcoholism (Gordis, 2000). They concluded that, compared with the sons of nonalcoholics, the sons of alcoholics may be more sensitive to alcohol when it is first ingested and then become less sensitive to its effects as the hours pass after drinking. This finding is significant because the euphoric effects of alcohol occur just after drinking but the experience after several hours is often sadness and depression. People who are at risk for developing alcoholism (in this case, the sons of alcoholics) may be better able to appreciate the initial highs of drinking and be less sensitive to the lows that come later, making them ideal candidates for continued drinking. In support of this observation, follow-up research over a 10-year period found that those men who tended to be less sensitive to alcohol also tended to drink more heavily and more often (Schuckit, 1994, 1998).

One current line of research involves analyzing the brain wave patterns of people at risk for developing alcoholism. This research is studying the sons of people with alcohol problems because of their own increased likelihood of having alcohol problems. Participants are asked to sit quietly and listen for a particular tone. When they hear the tone, they are to signal the researcher. During this time, their brain waves are monitored and a particular pattern emerges called the *P300 amplitude*. Approximately 300 milliseconds (the origin of the "P300" designation) after the tone is presented, a characteristic spike in brain waves occurs that indicates the brain is processing this information. In general, researchers find this spike is lower among those with a family history of alcoholism (Tapert & Jacobus, 2012).

Is this brain wave difference somehow connected to the reasons people later develop a dependence on alcohol, or is it just a marker or sign that these individuals have in common but is not related to their drinking? One piece of evidence that argues against the P300 differences as a marker for alcoholism is that individuals with a variety of other substance use problems (for

example, opioid users) and psychological disorders (for example, schizophrenia and depression) also show lower P300 amplitude than control participants (Singh, Basu, Kohli, & Prabhakar, 2009). Researchers are continuing to try to understand this interesting but puzzling phenomenon.

Psychological Dimensions

We have shown that the substances people use to alter mood and behavior have unique effects. The high from heroin differs substantially from the experience of smoking a cigarette, which in turn differs from the effects of amphetamines or LSD. Nevertheless, it is important to point out the similarities in the way people mentally react to most of these substances.

Positive Reinforcement

The feelings that result from using psychoactive substances are pleasurable in some way, and people will continue to take the drugs to recapture the pleasure. Research shows quite clearly that many drugs used and abused by humans also seem to be pleasurable to animals (Young & Herling, 1986). Laboratory animals will work to have their bodies injected with drugs such as cocaine, amphetamines, opiates, sedatives, and alcohol, which demonstrates that even without social and cultural influences these drugs are pleasurable.

Human research also indicates that to some extent all psychoactive drugs provide a pleasurable experience (Ray, 2012). In addition, the social contexts for drug taking may encourage its use, even when the use alone is not the desired outcome. One study found that among volunteers who preferred not to take Valium, pairing money with pill taking caused participants to switch from a placebo to Valium (Alessi, Roll, Reilly, & Johanson, 2002). Positive reinforcement in the use and the situations surrounding the use of drugs contributes to whether or not people decide to try to continue using drugs.

Negative Reinforcement

Most researchers have looked at how drugs help reduce unpleasant feelings through negative reinforcement. Many people are likely to initiate and continue drug use to escape from unpleasantness in their lives. In addition to the initial euphoria, many drugs provide escape from physical pain (opiates), from stress (alcohol), or from panic and anxiety (benzodiazepines). This phenomenon has been explored under a number of different names, including *tension reduction*, *negative affect*, and *self-medication*, each of which has a somewhat different focus (Ray, 2012).

One premise is that substance use becomes a way for users to cope with the unpleasant feelings that go along with life circumstances. For example, one study of 1,252 U.S. Army soldiers returning home from Operation Iraqi Freedom found that those exposed to violent combat, human trauma, and having direct responsibility for taking the life of another person were at increased risk for risk-taking and for more frequent and greater alcohol use (Killgore et al., 2008; Stappenbeck, Hellmuth, Simpson, & Jakupcak, 2014). People who experience other types of trauma such as sexual abuse

are also more likely to abuse alcohol (Breckenridge, Salter, & Shaw, 2012). These observations emphasize the important role played by each aspect of abuse and dependence—biological, psychological, social, and cultural—in determining who will and who will not have difficulties with these substances.

In a study that examined substance use among adolescents as a way to reduce stress (Chassin, Pillow, Curran, Molina, & Barrera, 1993), researchers compared a group of adolescents who had alcoholic parents with a group whose parents did not have drinking problems. The average age of the adolescents was 12.7 years. The researchers found that just having a parent with alcohol dependence was a major factor in predicting who would use alcohol and other drugs. However, they also found that adolescents who reported negative affect, such as feeling lonely, crying a lot, or being tense, were more likely than others to use drugs. The researchers further determined that the adolescents from both groups tended to use drugs as a way to cope with unpleasant feelings. This study and others (see, for example, Pardini, Lochman, & Wells, 2004) suggest that one contributing factor to adolescent drug use is the desire to escape from unpleasantness. It also suggests that to prevent people from using drugs we may need to address influences such as stress and anxiety, a strategy we discuss in our section on treatment.

Many people who use psychoactive substances experience a crash after being high. If people reliably crash, why don't they just stop taking drugs? One explanation is given by Solomon and Corbit in an interesting integration of both the positive and the negative reinforcement processes (Solomon, 1980; Solomon & Corbit, 1974). The *opponent-process theory* holds that an increase in positive feelings will be followed shortly by an increase in negative feelings. Similarly, an increase in negative feelings will be followed by a period of positive feelings (Ray, 2012). Athletes often report feeling depressed after finally attaining a long-sought goal. The opponent-process theory claims that this mechanism is strengthened with use and weakened by disuse. So a person who has been using a drug for some time will need more of it to achieve the same results (tolerance). At the same time, the negative feelings that follow drug use tend to intensify. For many people, this is the point at which the motivation for drug taking shifts from desiring the euphoric high to alleviating the increasingly unpleasant crash. Unfortunately, they come to believe that the best remedy is more of the same drug. People who are hung over after drinking too much alcohol are often advised to have “the hair of the dog that bit you” (that is, have another drink). The sad irony here is that the very drug that can make you feel so bad is also the one thing that can take away your pain. You can see why people can become enslaved by this insidious cycle.

Researchers have also looked at substance abuse as a way of self-medicating for other problems (Bailey & Baillie, 2012). If people have difficulties with anxiety, for example, they may be attracted to barbiturates or alcohol because of their anxiety-reducing qualities. In one study, researchers were successful in treating a group of cocaine addicts who had ADHD with methylphenidate (Ritalin) (Dursteler et al., 2015; Levin, Evans, Brooks, & Garawi, 2007). They had hypothesized that these individuals used cocaine to help focus their attention. Once their ability to concentrate improved with the methylphenidate, the users reduced their use of cocaine.

Research is just beginning to outline the complex interplay among stressors, negative feelings, other psychological disorders, and negative reactions to the drugs themselves as causative factors in psychoactive drug use.

Cognitive Dimensions

What people expect to experience when they use drugs influences how they react to them. A person who expects to be less inhibited when she drinks alcohol will act less inhibited whether she actually drinks alcohol or a placebo she thinks is alcohol (Bailey & Baillie, 2012). This observation about the influence of how we think about drug use has been labeled an *expectancy effect* and has received considerable research attention.

Expectancies develop before people actually use drugs, perhaps as a result of parents' and peers' drug use, advertising, and media figures who model drug use (Campbell & Oei, 2013). In an important study, students in Canada in grades 7 to 11 were questioned each year for three years about their thoughts about alcohol and marijuana use (Fulton, Krank, & Stewart, 2012; Young, 2013). Included were instructions for them to list 3 or 4 things they expected would happen if they used a particular substance. Positive expectancies about the effects of alcohol or marijuana use predicted who was more likely to use and increase their use of these drugs three years later. These results suggest that adolescents may begin drinking or using other drugs partly because they believe these substances will have positive effects.

Expectations appear to change as people have more experience with drugs, although their expectations are similar for alcohol, nicotine, cannabis, and cocaine (Simons, Dvorak, & Lau-Barraco, 2009; Young, 2013). Some evidence points to positive expectancies—believing you will feel good if you take a drug—as an indirect influence on drug problems. In other words, what these beliefs may do is increase the likelihood you will take certain drugs, which in turn will increase the likelihood that problems will arise.

Once people stop taking drugs after prolonged or repeated use, powerful urges called "cravings" can interfere with efforts to remain off these drugs (Hollander & Kenny, 2012; Young, 2013). *DSM-5* includes cravings as one of the criteria for diagnosing a substance-related disorder. If you've ever tried to give up ice cream and then found yourself compelled to have some, you have a limited idea of what it might be like to crave a drug. These urges seem to be triggered by factors such as the availability of the drug, contact with things associated with drug taking (for example, sitting in a bar), specific moods (for example, being depressed), or having a small dose of the drug. For example, one study used a virtual reality apparatus to simulate visual, auditory, and olfactory (an alcohol-dipped tissue) cues (Lee et al., 2009) for alcohol-dependent adults. The participants could choose among kinds of alcoholic beverages (e.g., beer, whiskey, or wine), snacks, and drinking environments (beer garden,

restaurant, and pub). The researchers found significant increases in cravings for alcohol under these conditions (Lee et al., 2009). This type of technology may make it easier for clinicians to assess potential problem areas for clients, which can then be targeted to help keep them from relapsing. Research is under way to determine how cravings may work in the brain and if certain medications can be used to reduce these urges and help supplement treatment (Hollander & Kenny, 2012).

Social Dimensions

Exposure to psychoactive substances is a necessary prerequisite to their use and possible abuse, as previously discussed. You could probably list a number of ways people are exposed to these substances—through friends, through the media, and so on. Research on the consequences of cigarette advertising, for example, suggests the effects of media exposure may be more influential than peer pressure in determining whether teens smoke (Jackson, Brown, & L'Engle, 2007). In one large study, 820 adolescents (ages 14–17) were studied to assess what factors influenced the age at which they would have their first drink of alcohol (Kuperman et al., 2013). This study found several factors predicted early alcohol use including when their best friends started drinking, whether their family was at high risk for alcohol dependence, and the presence of behavior problems in these children.

Research suggests that drug-addicted parents spend less time monitoring their children than parents without drug problems (Dishion, Patterson, & Reid, 1988) and that this is an important contribution to early adolescent substance use (Kerr, Stattin, & Burk, 2010). When parents do not provide appropriate supervision, their children tend to develop friendships with peers who supported drug use (Van Ryzin, Fosco, & Dishion, 2012). Children influenced by drug use at home may be exposed to peers who use drugs as well. A self-perpetuating pattern seems to be associated with drug use that extends beyond the genetic influences we discussed previously.

Many young children are exposed to drug use.

How does our society view people who are dependent on drugs? This issue is of tremendous importance because it affects efforts to legislate the sale, manufacture, possession, and use of these substances. It also dictates how drug-dependent individuals are treated. Two views of substance-related disorders characterize contemporary thought: the moral weakness and the disease models of dependence. According to the *moral weakness model of chemical dependence*, drug use is seen as a failure of self-control in the face of temptation; this is a psychosocial perspective. Propponents of this model see drug users as lacking the character or moral fiber to resist the lure of drugs. We saw earlier, for example, that the Catholic Church made drug use an official sin—an indication of its disdain. The *disease model of physiological dependence*, in contrast, assumes that drug use disorders are caused by an underlying physiological cause; this is a biological perspective. Those who ascribe to this model think that just as diabetes or asthma can't be blamed on the afflicted individuals, neither should drug use disorders. AA and similar organizations see drug use disorders as an incurable disease over which the addict has no control (Kelly, Stout, Magill, Tonigan, & Pagano, 2010).

Neither perspective does justice to the complex interrelationship between the psychosocial and biological influences that affect substance disorders. Viewing drug use as moral weakness leads to punishing those afflicted with the disorder, whereas a disease model includes seeking treatment for a medical problem. Messages that the disorder is out of their control can at times be counterproductive. A comprehensive view of substance-related disorders that includes both psychosocial and biological influences is needed for this important societal concern to be addressed adequately.

Cultural Dimensions

Culture is a pervasive factor in the influence of drug use and treatment. For example, the extent to which and how well people

adapt to new cultures (*acculturation*) can be either a source of strength or a stress that can impact drug use. Cultural factors such as *machismo* (male dominance in Latin cultures), *marianismo* (female Latin role of motherly nurturance and identifying with the Virgin Mary), spirituality, and *tiu lien* ("loss of face" among Asians, that can lead to shame for not living up to cultural expectations) are just a few cultural viewpoints that can affect drug use and treatment in either a positive or negative way (Castro & Nieri, 2010). In addition, when we examine a behavior as it appears in different cultures, it is necessary to reexamine what is considered abnormal (Kohn, Wintrob, & Alarcón, 2009). Each culture has its own preferences for acceptable psychoactive drugs, as well as its own prohibitions for substances it finds unacceptable. Keep in mind that in addition to defining what is or is not acceptable, cultural norms affect the rates of substance use in important ways. For example, research suggests that alcohol may be more available in poorer Mexican towns (i.e., more stores or individuals selling alcohol), leading to higher rates of alcoholism in these areas (Parker, McCaffree, & Alaniz, 2013).

On the other hand, in certain cultures, including Korea, people are expected to drink alcohol heavily on certain social occasions (C. K. Lee, 1992). As we have seen before, exposure to these substances, in addition to social pressure for heavy and frequent use, may facilitate their abuse, and this may explain the high alcohol abuse rates in countries like Korea. This cultural influence provides an interesting natural experiment when exploring gene-environment interactions. People of Asian descent are more likely to have the ALDH2 gene, which produces a severe "flushing" effect (reddening and burning of the face) after drinking alcohol. This flushing effect was thought to be responsible for a relatively low rate of drinking in the population (de Wit & Phillips, 2012). However, between 1979 and 1992—when increased drinking became socially expected—there was an increase in alcohol abuse (Higuchi et al., 1994). The protective value of having the ALDH2 gene was diminished by the change in cultural norms (Rutter, Moffit, & Caspi, 2006).

Cultural factors not only influence the rates of substance abuse but also determine how it is manifested. Research indicates that alcohol consumption in Poland and Finland is relatively low, yet conflicts related to drinking and arrests for drunkenness in those countries are high compared with those in the Netherlands, which has about the same rate of alcohol consumption (Osterberg, 1986). Our discussion of expectancies may provide some insight into how the same amount of drinking can have different behavioral outcomes. Expectancies about the effects of alcohol use differ across cultures (for example, "Drinking makes me more aggressive" versus "Drinking makes me more withdrawn"); these differing expectancies may partially account for the variations in the consequences of drinking in Poland, Finland, and the Netherlands. Whether substance use is considered a

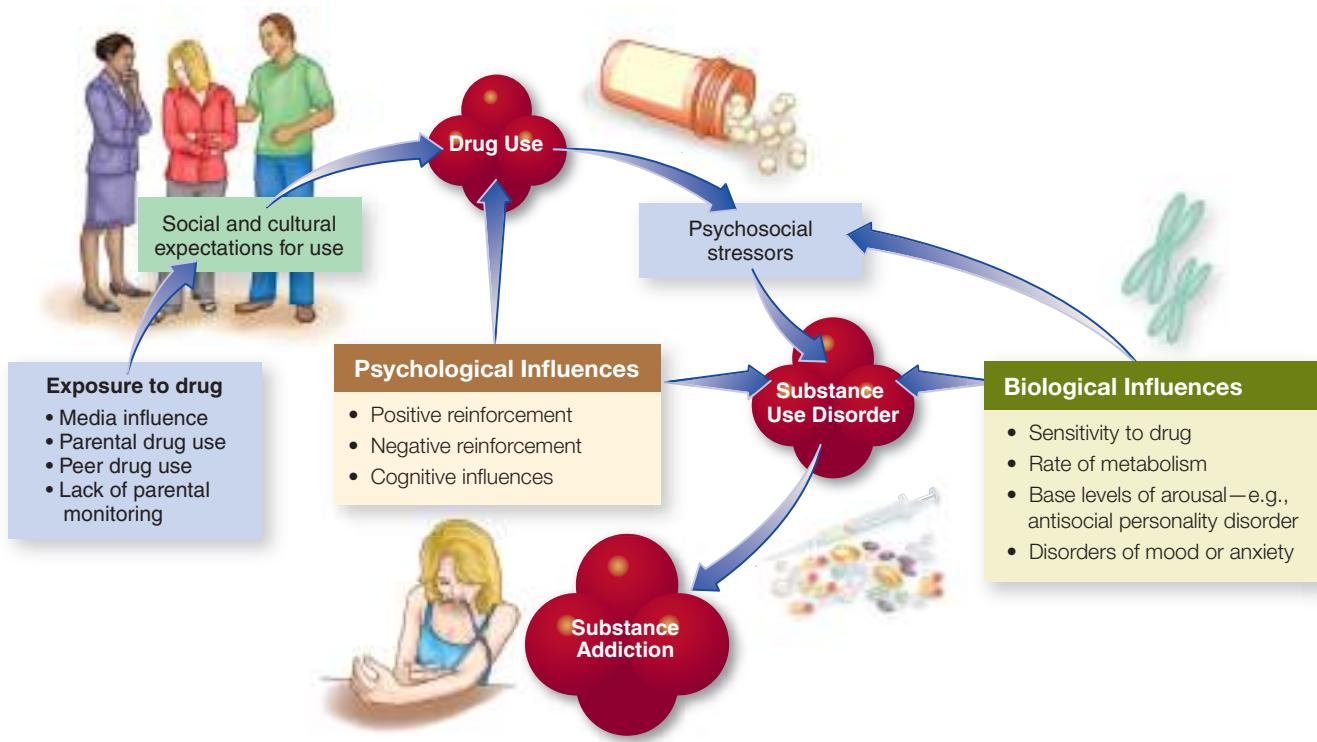

FIGURE 11.8

harmful dysfunction often depends on the assumptions of the cultural group.

An Integrative Model

Any explanation of substance use disorders must account for the basic issue raised earlier in this chapter: Why do some people use drugs but not abuse them or become dependent? ● Figure 11.8 illustrates how the multiple influences we have discussed may interact to account for this process. Access to a drug is a necessary but not a sufficient condition for abuse or dependence. Exposure has many sources, including the media, parents, peers, and, indirectly, lack of supervision. Whether people use a drug depends also on social and cultural expectations, some encouraging and some discouraging, such as laws against possession or sale of the drug.

The path from drug use to abuse and dependence is more complicated (see Figure 11.8). As major stressors aggravate many disorders we have discussed, so do they increase the risk of abuse and dependence on psychoactive substances. Genetic influences may be of several types. Some individuals may inherit a greater sensitivity to the effects of certain drugs; others may inherit an ability to metabolize substances more quickly and are thereby able to tolerate higher (and more dangerous) levels (Young-Wolff, Enoch, & Prescott, 2011). Other psychiatric conditions may indirectly put someone at risk for substance abuse. Antisocial personality disorder, characterized by the frequent violation of social norms (see Chapter 12), is thought to include a lowered rate of arousal; this may account for the increased prevalence of substance abuse in

this group. People with mood disorders or anxiety disorders may self-medicate by using drugs to relieve the negative symptoms of their disorder, and this may account for the high rates of substance abuse in this group.

We know also that continued use of certain substances changes the way our brains work through a process called *neuroplasticity*. We tend to think of neuroplasticity—the brain's tendency to reorganize itself by forming new neural connections—when we hear stories of people recovering abilities after some brain damage. This ability to adapt to change is something we hope for when injury occurs to the brain. The other side of this ability shows itself in drug addiction. With the continued use of substances such as alcohol, cocaine, or the other drugs we explore in this chapter, the brain reorganizes itself to adapt. Unfortunately, this change in the brain increases the drive to obtain the drug and decreases the desire for other nondrug experiences—both of which contribute to continued use and relapse (Russo et al., 2010).

It is clear that abuse and dependence cannot be predicted from one factor, be it genetic, neurobiological, psychological, or cultural. For example, *some* people with the genes common to many with substance abuse problems do not become abusers. Many people who experience the most crushing stressors, such as abject poverty or bigotry and violence, cope without resorting to drug use. There are different pathways to abuse, and we are only now beginning to identify their basic outlines.

Once a drug has been used repeatedly, biology and cognition conspire to create dependence. Continual use of most drugs causes tolerance, which requires the user to ingest more of the drug to produce the same effect. Conditioning is also a factor. If

pleasurable drug experiences are associated with certain settings, a return to such a setting will later cause urges to develop, even if the drugs themselves are not available.

This complex picture still does not convey the intricate lives of people who develop substance-related disorders. Each person has a story and path to abuse and dependence. We have only begun to discover the commonalities of substance disorders; we need to understand a great deal more about how all the factors interact to produce them.

Concept Check 11.3

Part A

Match the following descriptions with their corresponding substance: (a) opioids, (b) amphetamines, (c) cocaine, (d) hallucinogens, (e) nicotine, and (f) caffeine.

1. This is the most common psychoactive substance because it is legal, elevates mood, and decreases fatigue. It's readily available in many beverages. _____
2. This substance causes euphoria, appetite loss, and increased alertness. Dependence appears after years of use. Mothers addicted to this have the potential to give birth to irritable babies. _____
3. These drugs, including LSD, influence perception, distorting feelings, sights, sounds, and smells. _____
4. These lead to euphoria, drowsiness, and slowed breathing. These substances are analgesics, relieving pain. Users tend to be secretive, preventing a great deal of research in this area. _____
5. This substance stimulates the nervous system and relieves stress. *DSM-5* describes withdrawal symptoms instead of an intoxication pattern. _____
6. These create feelings of elation and vigor and reduce fatigue. They are prescribed to people with narcolepsy and ADHD. _____

Part B

Indicate whether these statements about the causes of substance-related disorders are true (T) or false (F).

7. _____ Negative reinforcement is involved in the continuance of drug use, because drugs often provide escape from pain, stress, panic, and so on.
8. _____ Research with both animals and humans indicates that substance abuse in general is affected by our genes, although not one particular gene.

9. _____ The media and parental influences have no effect on adolescent drug use; it is solely a peer pressure factor.

10. _____ The expectancy effect is illustrated when a person who expects to be less inhibited when drinking alcohol is given a placebo and acts or feels normally.

11. _____ To some extent, all psychoactive drugs provide a pleasurable experience, creating positive reinforcement.

Treatment of Substance-Related Disorders

When we left Danny, he was in jail, awaiting the legal outcome of being arrested for vehicular manslaughter. At this point in his life, Danny needs more than legal help; he needs to free himself from his addiction to alcohol and cocaine. And the first step in his recovery has to come from him. Danny must admit he needs help, that he does indeed have a problem with drugs, and that he needs others to help him overcome his chronic dependence. The personal motivation to work on a drug problem appears to be important but not necessarily essential in the treatment of substance abuse (National Institute on Drug Abuse [NIDA], 2009). Unfortunately, although Danny's arrest seemed to shock him into realizing how serious his problems had become, he was not ready to confront them head-on. He spent many hours researching how the antidepressant medication he was also taking could have caused the deadly accident and did not own up to his drug use as the cause.

Treating people who have substance-related disorders is a difficult task. Perhaps because of the combination of influences that often work together to keep people hooked, the outlook for those who are dependent on drugs is often not positive. You will see in the case of heroin dependence, for example, that a best-case scenario is often just trading one addiction (heroin) for another (methadone). And even people who successfully cease taking drugs may feel the urge to resume drug use all their lives.

Treatment for substance-related disorders focuses on multiple areas (Higgins et al., 2014). The National Institute on Drug Abuse recommends 13 principles of effective treatment for illicit drug abuse based on more than 35 years of research (NIDA, 2009) (see Table 11.1). Sometimes the first step is to help someone through the withdrawal process; typically, the ultimate goal is abstinence. In other situations, the goal is to get a person to maintain a certain level of drug use without escalating its intake, and sometimes it is geared toward preventing exposure to drugs. Because substance abuse arises from so many influences, it should not be surprising that treating people with substance-related disorders is not a simple matter of finding just the right drug or the best way to change thoughts or behavior.

Importantly, it is estimated that fewer than 25% of the people who have significant problems with substance use seek treatment

TABLE 11.1 Principles of Effective Treatment

1. No single treatment is appropriate for all individuals.
2. Treatment needs to be readily available.
3. Effective treatment attends to multiple needs of the individual, not just his or her drug use.
4. An individual's treatment and services plan must be assessed continually and modified as necessary to ensure that the plan meets the person's changing needs.
5. Remaining in treatment for an adequate period of time is critical for treatment effectiveness (i.e., 3 months or longer).
6. Counseling (individual and/or group) and other behavioral therapies are critical components of effective treatment for addiction.
7. Medications are an important element of treatment for many patients, especially when combined with counseling and other behavioral therapies.
8. Addicted or drug-abusing individuals with coexisting mental disorders should have both disorders treated in an integrated way.
9. Medical detoxification is only the first stage of addiction treatment and by itself does little to change long-term drug use.
10. Treatment does not need to be voluntary to be effective.
11. Possible drug use during treatment must be monitored continuously.
12. Treatment programs should provide assessment for HIV/AIDS, hepatitis B and C, tuberculosis and other infectious diseases, and counseling to help patients modify or change behaviors that place themselves or others at risk of infection.
13. Recovery from drug addiction can be a long-term process and frequently requires multiple episodes of treatment.

for their problems (Dawson et al., 2005). In order to reach out to these individuals, efforts are under way to put in place routine screenings for substance use problems in settings such as doctor's offices, hospital emergency rooms, and even in college and university health clinics. This community-wide approach is an important part of identifying difficulties and bringing treatment to those in need (Tucker, Murphy, & Kertesz, 2011).

We discuss the treatment of substance-related disorders as a group because treatments have so much in common. For example, many programs that treat people for dependence on a variety of substances also teach skills for coping with life stressors. Some biological treatments focus on how to cancel out the effects of the ingested substances. We discuss the obvious differences among substances as they arise.

Biological Treatments

There have been a variety of biologically based approaches designed primarily to change the way substances are experienced. In other words, scientists are trying to find ways to prevent people from experiencing the pleasant highs associated with drug use or to find alternative substances that have some of the positive effects (for example, reducing anxiety) without their addictive properties. Table 11.2 lists the current recommended medical treatments for many of the more intractable substance dependence problems.

TABLE 11.2 Medical Treatments

	Substance Treatment Goal	Treatment Approach
Nicotine	Reduce withdrawal symptoms and cravings	Nicotine replacement therapy (patch, gum, spray, lozenge, and inhaler)
	Reduce withdrawal symptoms and cravings	Bupropion (Zyban)
Alcohol	Reduce reinforcing effects of alcohol	Naltrexone
	Reduce alcohol craving in abstinent individuals	Acamprosate (Campral)
	Maintenance of abstinence	Disulfiram (Antabuse)
Cannabis		No specific medical interventions recommended
Cocaine		No specific medical interventions recommended
Opioids	Maintenance of abstinence	Methadone

Agonist Substitution

Increased knowledge about how psychoactive drugs work on the brain has led researchers to explore ways of changing how they are experienced by people who are dependent on them. One method, **agonist substitution**, involves providing the person with a safe drug that has a chemical makeup similar to the addictive drug (therefore the name *agonist*). *Methadone* is an opiate agonist that is often given as a heroin substitute (Schwartz, Brooner, Montoya, Currens, & Hayes, 2010). Methadone is a synthetic narcotic developed in Germany during World War II when morphine was not available for pain control; it was originally called *adolphine* after Adolph Hitler (Martínez-Fernández, 2002). Although it does not give the quick high of heroin, methadone initially provides the same analgesic (pain reducing) and sedative effects. When users develop a tolerance for methadone, however, it loses its analgesic and sedative qualities. Because heroin and methadone have *cross-tolerance*, meaning they act on the same neurotransmitter receptors, a heroin addict who takes methadone may become addicted to the methadone instead, but this is not always the case (Maremmanni et al., 2009). Research suggests that when addicts combine methadone with counseling, many reduce their use of heroin and engage in less criminal activity (Schwartz et al., 2009). A newer agonist—buprenorphine—blocks the effects of opiates and seems to encourage better compliance than would a nonopiate or opiate antagonist (Strain et al., 2009).

Addiction to cigarette smoking is also treated by a substitution process. The drug—**nicotine**—is provided to smokers in the form of gum, patch, inhaler, or nasal spray, which lack the carcinogens included in cigarette smoke; the dose is later tapered off to lessen withdrawal from the drug. In general, these replacement strategies successfully help people stop smoking, although they work best with psychological therapy (Carpenter et al., 2013; Hughes, 2009). People must be taught how to use the gum properly, and a portion

of the people who successfully quit smoking become dependent on the gum itself (Etter, 2009). The **nicotine patch** requires less effort and provides a steadier nicotine replacement (Hughes, 2009). Another medical treatment for smoking—bupropion (Zyban)—is also commonly prescribed, under the trade name Wellbutrin, as an antidepressant. This drug curbs the cravings without being an agonist for nicotine (rather than helping smokers trying to quit by making them less depressed). All of these medical treatments have roughly the same effectiveness in helping people quit smoking, with a 6-month abstinence rate of approximately 20 to 25% (Litvin et al., 2012).

Antagonist Treatments

We described how many psychoactive drugs produce euphoric effects through their interaction with the neurotransmitter systems in the brain. What would happen if the effects of these drugs were blocked so that the drugs no longer produced the pleasant results? Would people stop using the drugs? **Antagonist drugs** block or counteract the effects of psychoactive drugs, and a variety of drugs that seem to cancel out the effects of opiates have been used with people dependent on a variety of substances. The most often prescribed opiate-antagonist drug, naltrexone, has had only limited success with individuals who are not simultaneously participating in a structured treatment program (Krupitsky & Blokhina, 2010). When it is given to a person who is dependent on opiates, it produces immediate withdrawal symptoms, an extremely unpleasant effect. A person must be free from these withdrawal symptoms completely before starting naltrexone, and because it removes the euphoric effects of opiates, the user must be highly motivated to continue treatment. Acamprosate also seems to decrease cravings in people dependent on alcohol, and it works best with highly motivated people who are also participating in psychosocial interventions (Kennedy et al., 2010). The brain mechanisms for the effects of this drug are not well understood (Oslin & Klaus, 2009).

Overall, naltrexone or the other drugs being explored are not the magic bullets that would shut off the addict's response to psychoactive drugs and put an end to dependence. They do appear to help some drug abusers handle withdrawal symptoms and the cravings that accompany attempts to abstain from drug use; antagonists may therefore be a useful addition to other therapeutic efforts.

Aversive Treatment

In addition to looking for ways to block the euphoric effects of psychoactive drugs, clinicians in this area may prescribe drugs that make ingesting the abused substances extremely unpleasant. The expectation is that a person who associates the drug with feelings of illness will avoid using the drug. The most commonly known aversive treatment uses disulfiram (Antabuse) with people who have an alcohol use disorder (Ivanov, 2009). Antabuse prevents the breakdown of acetaldehyde, a by-product of alcohol, and the resulting buildup of acetaldehyde causes feelings of illness. People who drink alcohol after taking Antabuse experience nausea, vomiting, and elevated heart rate and respiration. Ideally, Antabuse is taken each morning, before the desire to drink arises. Unfortunately, noncompliance is a major concern, and a person

who skips the Antabuse for a few days is able to resume drinking (Ellis & Dronsfield, 2013).

Efforts to make smoking aversive have included the use of silver nitrate in lozenges or gum. This chemical combines with the saliva of a smoker to produce a bad taste in the mouth. Research has not shown it to be particularly effective (Jensen, Schmidt, Pedersen, & Dahl, 1991). Both Antabuse for alcohol abuse and silver nitrate for cigarette smoking have generally been less than successful as treatment strategies on their own, primarily because they require that people be extremely motivated to continue taking them outside the supervision of a mental health professional.

Other Biological Approaches

Medication is often prescribed to help people deal with the often-disturbing symptoms of withdrawal. Clonidine, developed to treat hypertension, has been given to people withdrawing from opiates. Because withdrawal from certain prescribed medications such as sedative drugs can cause cardiac arrest or seizures, these drugs are gradually tapered off to minimize dangerous reactions. In addition, sedative drugs (benzodiazepines) are often prescribed to help minimize discomfort for people withdrawing from other drugs, such as alcohol (Sher, Martinez, & Littlefield, 2011).

Psychosocial Treatments

Most biological treatments for substance abuse show some promise with people who are trying to eliminate their drug habit. Not one of these treatments alone is successful for most people, however (Schuckit, 2009b). Most research indicates a need for social support or therapeutic intervention. Because so many people need help to overcome their substance disorder, a number of models and programs have been developed. Unfortunately, in no other area of psychology have unvalidated and untested methods of treatment been so widely accepted. A reminder: A program that has not been subject to the scrutiny of research *may* work, but the sheer number of people receiving services of unknown value is still cause for concern. We next review several therapeutic approaches that *have* been evaluated.

Inpatient Facilities

The first specialized facility for people with substance abuse problems was established in 1935, when the first federal narcotic "farm" was built in Lexington, Kentucky. Now mostly privately run, such facilities are designed to help people get through the initial withdrawal period and to provide supportive therapy so that they can go back to their communities (Morgan, 1981). Inpatient care can be extremely expensive (Bender, 2004). The question arises, then, as to how effective this type of care is compared with outpatient therapy that can cost 90% less. Research suggests there may be no difference between intensive residential setting programs and quality outpatient care in the outcomes for alcoholic patients (Miller & Hester, 1986) or for drug treatment in general (NIDA, 2009). Although some people do improve as inpatients, they may do equally well in outpatient care that is significantly less expensive.

Alcoholics Anonymous and Its Variations

Without question, the most popular model for the treatment of substance abuse is a variation of the Twelve Steps program first developed by Alcoholics Anonymous (AA). Established in 1935 by two alcoholic professionals, William “Bill W.” Wilson and Robert “Dr. Bob” Holbrook Smith, the foundation of AA is the notion that alcoholism is a disease and alcoholics must acknowledge their addiction to alcohol and its destructive power over them. The addiction is seen as more powerful than any individual; therefore, they must look to a higher power to help them overcome their shortcomings. Central to the design of AA is its independence from the established medical community and the freedom it offers from the stigmatization of alcoholism (Denzin, 1987; Robertson, 1988). An important component is the social support it provides through group meetings.

Since 1935, AA has steadily expanded to include almost 106,000 groups in more than 100 countries (White & Kurtz, 2008). In one survey, 9% of the adult population in the United States reported they had at one time attended an AA meeting (Room & Greenfield, 2006). The Twelve Steps of AA are the basis of its philosophy (see Table 11.3). In them, you can see the reliance on prayer and a belief in God.

Many people credit AA and similar organizations, such as Cocaine Anonymous and Narcotics Anonymous, with saving their lives. Despite challenges conducting systematic research on

AA because participants attend meetings anonymously and only when they feel the need to, there have been numerous attempts to evaluate the program’s effect on alcoholism (McCrady & Tonigan, 2015). Research finds that those people who regularly participate in AA activities—or other similar supportive approaches—and follow its guidelines carefully are more likely to have positive outcomes, such as reduced drinking and improved psychological health (Kelly, 2013; Zemore, Subbaraman, & Tonigan, 2013). Studies suggest that those who are more likely to engage with AA tend to have more severe alcohol use problem and seem to be more committed to abstinence (McCrady & Tonigan, 2015). Thus, AA can be an effective treatment for highly motivated people with alcohol dependence. Research to date has not shown how AA compares to other treatments. However, preliminary evidence shows that AA can be helpful for individuals seeking to achieve total abstinence and may be more cost effective than other treatments. Researchers are still trying to understand exactly why AA and the 12-step program work, but it seems that social support plays an important role (McCrady & Tonigan, 2015).

Some individuals have a more mixed experience with AA and this includes agnostics and atheists, women, and minority groups (McCrady & Tonigan, 2015). Other groups now exist (e.g., Rational Recovery, Moderation Management, Women for Sobriety, SMART Recovery) for individuals who benefit from the social support of others but who may not want the abstinence-oriented 12-step program offered by groups modeled after AA (Tucker et al., 2011).

TABLE 11.3 Twelve Suggested Steps of Alcoholics Anonymous

1. We admitted we were powerless over alcohol—that our lives had become unmanageable.
2. Came to believe that a power greater than ourselves could restore us to sanity.
3. Made a decision to turn our will and our lives over to the care of God as we understood Him.
4. Made a searching and fearless moral inventory of ourselves.
5. Admitted to God, to ourselves, and to another human being the exact nature of our wrongs.
6. Were entirely ready to have God remove all these defects of character.
7. Humbly asked Him to remove our shortcomings.
8. Made a list of all persons we had harmed, and became willing to make amends to them all.
9. Made direct amends to such people wherever possible, except when to do so would injure them or others.
10. Continued to take personal inventory and, when we were wrong, promptly admitted it.
11. Sought through prayer and meditation to improve our conscious contact with God as we understood Him, praying only for knowledge of His will for us and the power to carry that out.
12. Having had a spiritual awakening as the result of these steps, we tried to carry this message to alcoholics and to practice these principles in all our affairs.

Permission to reprint the Twelve Steps does not mean that AAWS has reviewed or approved the contents of the publication or that AAWS necessarily agrees with the views expressed herein. AA is a program of recovery from alcoholism only—use of the Twelve Steps in connection with programs and activities which are patterned after AA, but which address other problems, or in any other non-AA context, does not imply otherwise.

Controlled Use

One of the tenets of AA is total abstinence; recovering alcoholics who have just one sip of alcohol are believed to have “slipped” until they again achieve abstinence. Some researchers question this assumption, however, and believe at least a portion of abusers of several substances (notably alcohol and nicotine) may be capable of becoming social users without resuming their abuse of these drugs.

In the alcoholism treatment field, the notion of teaching people **controlled drinking** is extremely controversial, partly because of a classic study showing partial success in teaching severe abusers to drink in a limited way (Sobell & Sobell, 1978). The participants were 40 male alcoholics in an alcoholism treatment program at a state hospital who were thought to have a good prognosis. The men were assigned either to a program that taught them how to drink in moderation (experimental group) or to a group that was abstinence oriented (control group). The researchers, Mark and Linda Sobell, followed the men for more than 2 years, maintaining contact with 98% of them. During the second year after treatment, those who participated in the controlled drinking group were functioning well 85% of the time, whereas the men in the abstinence group were reported to be doing well only 42% of the time. Although results in the two groups differed significantly, some men in both groups suffered serious relapses and required rehospitalization and some were incarcerated. The results of this study suggest that controlled drinking may be a viable alternative to abstinence for some alcohol abusers, although it clearly isn’t a cure.

The controversy over this study began with a paper published in the prestigious journal *Science* (Pendery, Maltzman, & West, 1982). The authors reported they had contacted the men in the Sobell study after 10 years and found that only 1 of the 20 men in the experimental group maintained a pattern of controlled drinking. Although this reevaluation made headlines and was the subject of a segment on the *60 Minutes* television show, it had a number of flaws (Marlatt, Larimer, Baer, & Quigley, 1993). Most serious was the lack of data on the abstinence group over the same 10-year follow-up period. Because no treatment study on substance abuse pretends to help everyone who participates, control groups are added to compare progress. In this case, we need to know how well the controlled drinking group fared compared with the abstinence group.

The controversy over the Sobell study still has a chilling effect on controlled drinking as a treatment of alcohol abuse in the United States. In contrast, controlled drinking is widely accepted as a treatment for alcoholism in the United Kingdom. Despite opposition, research on this approach has been conducted in the ensuing years (e.g., Orford & Keddie, 2006; van Amsterdam & van den Brink, 2013), and the results seem to show that controlled drinking is at least as effective as abstinence but that neither treatment is successful for 70% to 80% of patients over the long term—a rather bleak outlook for people with alcohol dependence problems.

Component Treatment

Most comprehensive treatment programs aimed at helping people with substance use disorder have a number of components thought to boost the effectiveness of the “treatment package” (NIDA, 2009). We saw in our review of biological treatments that their effectiveness is increased when psychologically based therapy is added. In aversion therapy, which uses a conditioning model, substance use is paired with something extremely unpleasant, such as a brief electric shock or feelings of nausea. For example, a person might be offered a drink of alcohol and receive a painful shock when the glass reaches his lips. The goal is to counteract the positive associations with substance use with negative associations. The negative associations can also be made by imagining unpleasant scenes in a technique called *covert sensitization* (Cautela, 1966); the person might picture herself beginning to snort cocaine and be interrupted with visions of herself becoming violently ill (Kearney, 2006).

One component that seems to be a valuable part of therapy for substance use is *contingency management* (Higgins et al., 2014). Here, the clinician and the client together select the behaviors that the client needs to change and decide on the reinforcers that will reward reaching certain goals, perhaps money or small retail items like CDs. In a study of cocaine abusers, clients received cash vouchers (up to almost \$2,000) for having cocaine-negative urine specimens (Higgins et al., 2006). This study found greater abstinence rates among cocaine-dependent users with the contingency management approach and other skills training than among users in a more traditional counseling program that included a 12-step approach to treatment.

Another package of treatments is the *community reinforcement approach* (e.g., Campbell, Miele, Nunes, McCrimmon, & Ghitza, 2012). In keeping with the multiple influences that affect substance use, several facets of the drug problem are addressed to help identify

and correct aspects of the person’s life that might contribute to substance use or interfere with efforts to abstain. First, a spouse, friend, or relative who is not a substance user is recruited to participate in relationship therapy to help the abuser improve relationships with other important people. Second, clients are taught how to identify the antecedents and consequences that influence their drug taking. For example, if they are likely to use cocaine with certain friends, clients are taught to recognize the relationships and encouraged to avoid the associations. Third, clients are given assistance with employment, education, finances, or other social service areas that may help reduce their stress. Fourth, new recreational options help the person replace substance use with new activities. There is now strong empirical support for the effectiveness of this approach with alcohol and cocaine abusers (Higgins et al., 2014).

Obstacles to successful treatment for substance use and dependence include a lack of personal awareness that one has a problem and an unwillingness to change. An increasingly common intervention approach that directly addresses these needs is referred to as *Motivational Enhancement Therapy (MET)* (NIDA, 2009). MET is based on the work of Miller and Rollnick (2012), who proposed that behavior change in adults is more likely with empathetic and optimistic counseling (the therapist understands the client’s perspective and believes that he or she can change) and a focus on a personal connection with the client’s core values (for example, drinking and its consequences interferes with spending more time with family). By reminding the client about what he or she cherishes most, MET intends to improve the individual’s belief that any changes made (e.g., drinking less) will have positive outcomes (e.g., more family time) and the individual is therefore more likely to make the recommended changes. MET has been used to assist individuals with a variety of substance use problems, and it appears to be a useful component to add to psychological treatment (e.g., Manuel, Houck, & Moyers, 2012).

Cognitive-behavioral therapy (CBT) is an effective treatment approach for many psychological disorders (see Chapter 5, for example) and it is also one of the most well designed and studied approaches for treating substance dependence (Granillo, Perron, Jarman, & Gutowski, 2013). This treatment addresses multiple aspects of the disorder, including a person’s reactions to cues that lead to substance use (for example, being among certain friends) and thoughts and behaviors to resist use. Another target of CBT addresses the problem of relapse. Marlatt and Gordon’s (1985) **relapse prevention** treatment model looks at the learned aspects of dependence and sees relapse as a failure of cognitive and behavioral coping skills (Witkiewitz & Marlatt, 2004). Therapy involves helping people remove any ambivalence about stopping their drug use by examining their beliefs about the positive aspects of the drug (“There’s nothing like a cocaine high”) and confronting the negative consequences of its use (“I fight with my wife when I’m high”). High-risk situations are identified (“having extra money in my pocket”), and strategies are developed to deal with potentially problematic situations, as well as with the craving that arises from abstinence. Incidents of relapse are dealt with as occurrences from which the person can recover; instead of looking on these episodes as inevitably leading to more drug use, people in treatment are encouraged to see them as episodes brought on by temporary stress or a situation that can be changed. Research on this

technique suggests that it may be particularly effective for alcohol problems (McCrady, 2014), as well as in treating a variety of other substance-related disorders (Marlatt & Donovan, 2005).

Prevention

Adolescents are at high risk for drug addiction due to their higher rates of experimentation with drugs. When done right, education about drugs' risks can lead to decreases in drugs of abuse (e.g., ecstasy and tobacco) (Volkow & Warren, 2015). However, over the past few years, the strategies for preventing substance abuse and dependence have shifted from education-based approaches (for example, teaching schoolchildren that drugs can be harmful) to more wide-ranging approaches, including changes in the laws regarding drug possession and use and community-based interventions (Sher et al., 2011). Many states, for example, have implemented education-based programs in schools to try to deter students from using drugs. The widely used Drug Abuse Resistance Education (DARE) program encourages a "no drug use" message

through fear of consequences, rewards for commitments not to use drugs, and strategies for refusing offers of drugs. Unfortunately, several extensive evaluations suggest that this type of program may not have its intended effects (Pentz, 1999). Fortunately, more comprehensive programs that involve skills training to avoid or resist social pressures (such as peers) and environmental pressures (such as media portrayals of drug use) can be effective in preventing drug abuse among some. For example, one large-scale longitudinal study used a community-based intervention strategy to reduce binge drinking and alcohol-related injuries (for example, car crashes and assaults) (Holder et al., 2000). Three communities were mobilized to encourage responsible beverage service (that is, not serving too much alcohol to bar patrons), limit alcohol access to underage drinkers, and increase local enforcement of drinking and driving laws to limit access to alcohol. People's self-reports of drinking too much and drinking and driving were fewer after the intervention, as were alcohol-related car accidents and assaults. These types of comprehensive programs may need to be replicated across communities and extended to more pervasive

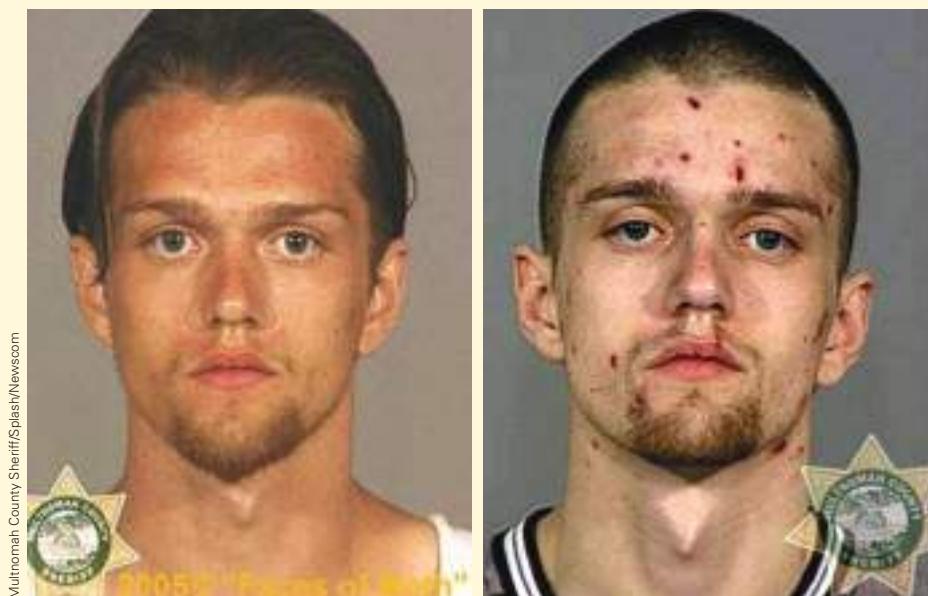

TWO NEW PATHS TO PREVENTION

We see that the problem with drug abuse is not just use of the drug. A complicating factor in drug abuse includes the brain's desire to continue to use the drug, especially when in the presence of stimuli and situations usually associated with the drug. This "drug seeking" and relapse continue to interfere with successful treatment. Groundbreaking research is now exploring where in the brain these processes occur, which in turn may lead to new approaches to help people remain drug-free (Kalivas, 2005).

Taking this one step further, new research with animals suggests the possibility of creating "vaccines" that would use the immune system to fight drugs such as heroin, just as your body attacks infectious bacteria (Anton & Leff, 2006). A vaccine that would take away the pleasurable aspects of smoking is now being tested with humans (Moreno, et al., 2010). What this means is that—theoretically—children could be vaccinated early in their lives and that if they tried a drug it would not have the pleasurable effects that would encourage repeated use. These "vice vaccines" could hold the answer to one of our most pressing social issues.

On the other end of the intervention spectrum, new and more comprehensive prevention approaches may help many individuals avoid initially trying dangerous drugs. One such approach is being used in Montana—called the Montana Meth Project (Generations United, 2006). Initially funded by software billionaire Timothy Siegel, this initiative supports advertising and community action programs

to inform youth across the state about the devastating effects of methamphetamine use. The project uses dramatic and sometimes shocking pictures and video ads, and its surveys suggest that the methods were successful in changing attitudes about meth use in many 12- to 17-year-olds. Although no controlled research yet exists, this may be an additional powerful tool for reducing drug dependence.

The Montana Meth Project used photos like these from Faces of Meth, a project of the Multnomah County Sheriff's Office in Portland, Oregon.

influences (for example, how drug use is portrayed in the media) to effect significant prevention results (Newton, Conrod, Teesson, & Faggiano, 2012).

It may be that our most powerful preventive strategy involves cultural change. Over the past 45 years or so, we have gone from a “turn on, tune in, drop out,” “if it feels good, do it,” and “I get high with a little help from my friends” society to one that champions statements like “Just say no to drugs.” The social unacceptability of excessive drinking, smoking, and other drug use is probably responsible for this change. The sociocultural disapproval of cigarette smoking, for example, is readily apparent in the following description by a former smoker:

I began smoking (in Boy Scouts!) at age 11. By the time I was a college freshman, freed from the restrictions of school and home, my smoking had increased to a pack a day. The seminal Surgeon General’s Report *Smoking and Health* was issued that year (1964), but I didn’t notice. The warnings that began appearing on cigarette packs a couple of years later were also easy to ignore, since I had grown up knowing that smoking was unhealthy. As a graduate student and young professor I often smoked while leading class discussions, as had some of my favorite teachers. That ended in 1980, when an undergraduate student, no doubt empowered by the antismoking movement, asked me to stop because smoke bothered him. A few years later there were hardly any social situations left in which it was acceptable to smoke. Even my home was no longer a refuge, since my children were pestering me to quit. And so I did. Now my status as former smoker puts me in company with fully half of all those who have ever smoked regularly and are alive today. For many of us, the deteriorating social environment for smoking made it easier to quit (Cook, 1993, p. 1750).

Implementing this sort of intervention is beyond the scope of one research investigator or even a consortium of researchers collaborating across many sites. It requires the cooperation of governmental, educational, and even religious institutions. We may need to rethink our approach to preventing drug use and abuse (Newton et al., 2012).

Concept Check 11.4

Determine whether you understand how treatments for substance-related disorders work by matching the examples with the following terms: (a) dependent, (b) cross-tolerant, (c) agonist substitution, (d) antagonist, (e) relapse prevention, (f) controlled drinking, (g) aversion therapy, (h) covert sensitization, (i) contingency management, and (j) anonymous.

1. _____ is a controversial treatment for alcohol abuse because of a negative but flawed experimental finding, but also because it conflicts with the belief in total abstinence.

2. Methadone is used to help heroin addicts kick their habit in a method called _____.
3. _____ drugs block or counteract the effects of psychoactive drugs and are sometimes effective in treating addicts.
4. In _____ the clinician and the client work together to decide which behaviors the client needs to change and which reinforcers will be used as rewards for reaching set goals.
5. It has been difficult to evaluate rigorously the effectiveness of Alcoholics Anonymous, because the participants are _____.
6. In _____, substance use is paired with something extremely unpleasant (like alcohol and vomiting with Antabuse).
7. Heroin and methadone are _____, which means they affect the same neurotransmitter receptors.
8. The _____ model involves therapy that helps individuals remove ambivalence about stopping their drug use by examining their beliefs about the positive and negative aspects of drug use.
9. By imagining unpleasant scenes, the _____ technique helps the person associate the negative effects of the drug with drug use.
10. Unfortunately, the heroin addict may become permanently _____ on methadone.

Gambling Disorder

Gambling has a long history—for example, dice have been found in Egyptian tombs (Greenberg, 2005). It is growing in popularity in this country, and in many places it is a legal and acceptable form of entertainment. Perhaps as a result, **gambling disorder** affects an increasing number of people, with a lifetime estimate of approximately 1.9% of adult Americans (Ashley & Boehlke, 2012). Research suggests that among pathological gamblers, 14% have lost at least one job, 19% have declared bankruptcy, 32% have been arrested, and 21% have been incarcerated (Gerstein et al., 1999). The *DSM-5* criteria for gambling disorder set forth the associated behaviors that characterize people who have this addictive disorder. These include the same pattern of urges we observe in the other substance-related disorders. Note too the parallels with substance dependence, with the need to gamble increasing amounts of money over time and the “withdrawal symptoms” such as restlessness and irritability when attempting to stop. These parallels to substance-related disorders led to the recategorization of gambling disorder as an “Addictive Disorder” in *DSM-5* (Denis, Fatséas, & Auriacombe, 2012).

There is a growing body of research on the nature and treatment of gambling disorder. For example, work is under way to explore the biological origins of the urge to gamble among pathological gamblers. Research in this area and others (e.g., genetic

research) show strong similarities in the biological origins of gambling disorders and substance use disorders. In one study, brain-imaging technology (echoplanar functional magnetic resonance imaging) was used to observe brain function while gamblers observed videotapes of other people gambling (Potenza et al., 2003). A decreased level of activity was observed in those regions of the brain that are involved in impulse regulation when compared with controls, suggesting an interaction between the environmental cues to gamble and the brain's response (which may be to decrease the ability to resist these cues). Studies have found that the ventromedial prefrontal cortex and orbitofrontal cortex ("the executive parts" of the brain) do not function as normal in those with gambling disorder. Poor impulse control and risky decisions are both processes that involve ventromedial prefrontal cortex and those individuals with higher problems in these areas also show poorer response to treatment and higher relapse rates (Yau, Yip, & Potenza, 2015).

Treatment of gambling problems is difficult. Those with gambling disorder exhibit a combination of characteristics—including denial of the problem, impulsivity, and continuing optimism ("One big win will cover my losses!")—that interfere

with effective treatment. Pathological gamblers often experience cravings similar to people who are substance dependent (Grant, Odlaug, & Schreiber, 2015). Treatment is often similar to substance dependence treatment, and there is a parallel Gambler's Anonymous that incorporates the same 12-step program we discussed previously. However, the evidence of effectiveness for Gambler's Anonymous suggests that 70% to 90% drop out of these programs and that the desire to quit must be present before intervention (Ashley & Boehlke, 2012). Cognitive-behavioral interventions help reduce the symptoms of gambling disorder. Brief and full course treatments have both been found to help and both are recommended. Given the higher rates of impulsivity of those with these disorder and thus their high dropout rates from treatment, more research is starting to compare the brief versions to the full course ones (Grant et al., 2015).

In addition to gambling disorder being included under the heading of "Addictive Disorders," *DSM-5* includes another potentially addictive behavior "Internet Gaming Disorder" as a condition for further study (American Psychiatric Association, 2013). There are indications that some individuals are so preoccupied with online games (sometimes in a social context with other players) that a similar pattern of tolerance and withdrawal develops (Petry & O'Brien, 2013). The goal of including this potentially new category of addictive behavior is to encourage additional research on its nature and treatment.

DSM 5

TABLE 11.10
Diagnostic Criteria for Gambling Disorder

- A.** Persistent and recurrent problematic gambling behavior leading to clinically significant impairment or distress, as indicated by the individual exhibiting four (or more) of the following in a 12-month period:
1. Needs to gamble with increasing amounts of money in order to achieve the desired excitement.
 2. Is restless or irritable when attempting to cut down or stop gambling.
 3. Has made repeated unsuccessful efforts to control, cut back, or stop gambling.
 4. Is often preoccupied with gambling (e.g., having persistent thoughts of reliving past gambling experiences, handicapping or planning the next venture, or thinking of ways to get money with which to gamble).
 5. Often gambles when feeling distressed (e.g., helpless, guilty, anxious, depressed).
 6. After losing money gambling, often returns another day to get even ("chasing" one's losses).
 7. Lies to conceal the extent of involvement with gambling.
 8. Has jeopardized or lost a significant relationship, job, or educational or career opportunity because of gambling.
 9. Relies on others to provide money to relieve desperate financial situations caused by gambling.
- B.** The gambling behavior is not better explained by a manic episode.

Impulse-Control Disorders

A number of the disorders we describe in this book start with an irresistible impulse—usually one that will ultimately be harmful to the person affected. Typically, the person experiences increasing tension leading up to the act and, sometimes, pleasurable anticipation of acting on the impulse. For example, paraphilic such as pedophilia (sexual attraction to children), eating disorders, and the substance-related disorders in this chapter often commence with temptations or desires that are destructive but difficult to resist. *DSM-5* includes three additional impulse-control disorders: intermittent explosive disorder, kleptomania, and pyromania (Muresanu, Stan, & Buzoianu, 2012). In *DSM-IV-TR*, gambling disorder was included as an impulse-control disorder, but as we have seen, it is listed as an addictive disorder in *DSM-5*. Finally, trichotillomania (hair pulling disorder) was also moved out of this category and is now included under the obsessive-compulsive-related disorders (see Chapter 5).

Intermittent Explosive Disorder

People with **intermittent explosive disorder** have episodes in which they act on aggressive impulses that result in serious assaults or destruction of property (Coccaro & McCloskey, 2010). Although it is unfortunately common among the general population to observe aggressive outbursts, when you rule out the influence of other disorders (for example, antisocial personality disorder, borderline personality disorder, a psychotic disorder, and Alzheimer's disease) or substance use, this disorder is not often diagnosed. In a rare but important large study of more than 9,000 people, researchers found that the lifetime prevalence of this disorder was 7.3% (Kessler et al., 2006).

This diagnosis is controversial and has been debated throughout the development of the *DSM*. One concern, among others, is that by validating a general category that covers aggressive behavior it may be used as a legal defense—insanity—for all violent crimes (Coccaro & McCloskey, 2010).

Research is at the beginning stages for intermittent explosive disorder and focuses on the brain regions involved as well as the influence of neurotransmitters such as serotonin and norepinephrine and testosterone levels, along with their interaction with psychosocial influences (stress, disrupted family life, and parenting styles). Recent studies have proposed that there is a disruption of the orbital frontal cortex's role (“the executive parts” of the brain) in inhibiting amygdala activation (the “emotional part” of the brain) combined with changes in the serotonin system in those with this disorder (Yau et al., 2015). These and other influences are being examined to explain the origins of this disorder (Coccaro, 2012). Cognitive-behavioral interventions (for example, helping the person identify and avoid “triggers” for aggressive outbursts) and approaches modeled after drug treatments appear the most effective for these individuals, although few controlled studies yet exist (McCloskey, Noblett, Deffenbacher, Gollan, & Coccaro, 2008).

Kleptomania

The story of wealthy actress Winona Ryder stealing \$5,500 worth of merchandise from Saks Fifth Avenue in Beverly Hills, California, in December 2001, was as puzzling as it was titillating. Why risk a multimillion-dollar career over some clothes that she could easily afford? Was hers a case of **kleptomania**—a recurrent failure to resist urges to steal things that are not needed for personal use or their monetary value? This disorder appears to be rare, but it is not well studied, partly because of the stigma associated with identifying oneself as acting out this illegal behavior. Some studies suggest that that disorder may be more common in women than in men and that it typically starts in adolescence (Yau et al., 2015). One study has reported a lifetime prevalence rate of close to 1% in the United States (Grant, 2003). The patterns described by those with this disorder are strikingly similar—the person begins to feel a sense of tension just before stealing, which is followed by feelings of pleasure or relief while the theft is committed (Grant, Odlaug, & Kim, 2010). People with kleptomania score high on assessments of impulsivity, reflecting their inability to judge the immediate gratification of stealing compared with the long-term negative consequences (for example, arrest, embarrassment) (Grant & Kim, 2002). Patients with kleptomania often report having no memory (amnesia) about the act of shoplifting (Hollander, Berlin, & Stein, 2009). Brain-imaging research supports these observations, with one study finding damage in areas of the brain associated with poor decision making (inferior frontal regions) (Grant, Correia, & Brennan-Krohn, 2006).

There appears to be high comorbidity between kleptomania and mood disorders, and to a lesser extent with substance abuse and dependence (Grant et al., 2010). Some refer to kleptomania as an “antidepressant” behavior, or a reaction on the part of some to relieve unpleasant feelings through stealing (Fishbain, 1987). To date, few reports of treatment exist, and these involve either behavioral interventions or use of antidepressant medication.

In 2002, actress Winona Ryder was found guilty of shoplifting items worth several thousand dollars from a Beverly Hills department store.

In one exception, naltrexone—the opioid antagonist used in the treatment of alcoholism—was somewhat effective in reducing the urge to steal in persons diagnosed with kleptomania (Grant, Kim, & Odlaug, 2009).

Pyromania

Just as we know that someone who steals does not necessarily have kleptomania, it is also true that not everyone who sets fires is considered to have **pyromania**—an impulse-control disorder that involves having an irresistible urge to set fires. Again, the pattern parallels that of kleptomania, where the person feels a tension or arousal before setting a fire and a sense of gratification or relief while the fire burns. These individuals will also be preoccupied with fires and the associated equipment involved in setting and putting out these fires (Dickens & Sugarman, 2012). Also rare, pyromania is diagnosed in only about 3% of arsonists (Lindberg, Holi, Tani, & Virkkunen, 2005), because arsonists can include people who set fires for monetary gain or revenge rather than to satisfy a physical or psychological urge. Because so few people are diagnosed with this disorder, research on etiology and treatment is limited (Dickens & Sugarman, 2012). Research that has been conducted follows the general group of arsonists (of which only a small percentage have pyromania) and examines the role of a family history of fire setting along with comorbid impulse disorders (antisocial personality disorder and alcoholism). Treatment is generally cognitive-behavioral and involves helping the person identify the signals that initiate the urges and teaching coping strategies to resist the temptation to start fires (Bumpass, Fagelman, & Brix, 1983; McGrath, Marshall, & Prior, 1979).

Match the following disorders with their corresponding symptoms: (a) gambling disorder, (b) intermittent explosive disorder, (c) kleptomania, and (d) pyromania.

1. This rarely diagnosed disorder is characterized by episodes of aggressive impulses and can sometimes be treated with cognitive-behavioral interventions, drug treatments, or both. _____

2. This disorder begins with the person feeling a sense of tension that is released and followed with pleasure after he has committed a robbery. _____
3. This disorder affects somewhere between 3% and 5% of the adult American population and is characterized by the need to gamble. _____
4. Individuals with this disorder are preoccupied with fires and the equipment involved in setting and putting out fires. _____

DSM Controversies: Are Substance Dependency and Substance Abuse the Same?

One of the changes to *DSM-5* that caused concern among some in the field of substance-related disorders was dropping the distinction between dependence on a substance and abuse of that substance (G. Edwards, 2012; Hasin, 2012; Schuckit, 2012). Although there is general agreement that abusing a substance (e.g., binge drinking) and being dependent on that substance (e.g., increasing tolerance to alcohol and going through withdrawal symptoms if drinking is stopped) are different processes, research shows that, practically speaking, they tend to go together. In other words, if someone is routinely abusing a drug that person will likely become dependent on it (O'Brien, 2011). From a scientific point of view, therefore, there is an obvious difference between abuse

and dependence, but from a clinical perspective (which is the main function of the *DSM*) the argument was made that having these as separate diagnoses was more complicated than was necessary.

In addition, a second major change was the addition of "Addictive Disorder"—in specific, gambling disorder—to the substance-related disorders section. Here again the science suggests that the phenomena are quite similar with both substance-related disorders and gambling disorder showing patterns of dependence, cravings, and working on similar brain pathways (Ashley & Boehlke, 2012). However, this potentially opens up the category for the inclusion of many different kinds of "addictions." Other

problems that cause real dysfunction among some people include the new *DSM-5* disorder under further study ("Internet gaming disorder") (Block, 2008; Van Rooij, Schoenmakers, Vermulst, Van Den Eijnden, & Van De Mheen, 2011) and even "tanning addiction" (Poorsattar & Hornung, 2010), and they are being taken seriously as similar types of problems. It is likely that many activities have the potential for causing dependence because they activate the reward systems in our brains in much the same way as the substances described. The difference in whether or not they constitute a "disorder" may come back to whether or not they cause the harmful distress that is part of most psychological diagnoses.

Summary

Perspectives on Substance-Related Disorders

- In *DSM-5*, substance-related and addictive disorders include problems with the use of depressants (alcohol, barbiturates, and benzodiazepines), stimulants (amphetamines, cocaine, nicotine, and caffeine), opiates (heroin, codeine, and morphine), and hallucinogens (cannabis and LSD) as well as gambling.
- Specific diagnoses are further categorized as substance intoxication and substance withdrawal.
- Nonmedical drug use in the United States has declined in recent times, although it continues to cost billions of dollars and seriously impairs the lives of millions of people each year.

Depressants, Stimulants, Opioids, and Hallucinogens

- Depressants are a group of drugs that decrease central nervous system activity. The primary effect is to reduce our levels of physiological arousal and help us relax. Included in this group are alcohol and sedative, hypnotic, and anxiolytic drugs, such as those prescribed for insomnia.
- Stimulants, the most commonly consumed psychoactive drugs, include caffeine (in coffee, chocolate, and many soft drinks), nicotine (in tobacco products such as cigarettes), amphetamines, and cocaine. In contrast to the depressant drugs, stimulants make us more alert and energetic.

- ▶ Opiates include opium, morphine, codeine, and heroin; they have a narcotic effect—relieving pain and inducing sleep. The broader term *opioids* is used to refer to the family of substances that includes these opiates and synthetic variations created by chemists (e.g., methadone) and the similarly acting substances that occur naturally in our brains (enkephalins, beta-endorphins, and dynorphins).
- ▶ Hallucinogens essentially change the way the user perceives the world. Sight, sound, feelings, and even smell are distorted, sometimes in dramatic ways, in a person under the influence of drugs such as cannabis and LSD.

Causes and Treatment of Substance-Related Disorders

- ▶ Most psychotropic drugs seem to produce positive effects by acting directly or indirectly on the dopaminergic mesolimbic system (the pleasure pathway). In addition, psychosocial factors such as expectations, stress, and cultural practices interact with the biological factors to influence drug use.

- ▶ Substance dependence is treated successfully only in a minority of those affected, and the best results reflect the motivation of the drug user and a combination of biological and psychosocial treatments.
- ▶ Programs aimed at preventing drug use may have the greatest chance of significantly affecting the drug problem.

Gambling Disorder

- ▶ Problem gamblers display the same types of cravings and dependence as persons who have substance-related disorders.
- ▶ Similar brain systems appear to be involved with those addicted to gambling as seen in persons with substance-related disorders.

Impulse-Control Disorders

- ▶ In *DSM-5*, impulse-control disorders include three separate disorders: intermittent explosive disorder, kleptomania, and pyromania.

Exploring Substance Use Disorders

- Many kinds of problems can develop when people use and abuse substances that alter the way they think, feel, and behave.
- Once seen as due to personal weakness, drug abuse and dependence are now thought influenced by both biological and psychosocial factors.

TREATMENT: BEST TO USE MULTIPLE APPROACHES

Psychosocial Treatments

- Aversion therapy—to create negative associations with drug use (shocks with drinking, imagining nausea with cocaine use)
- Contingency management to change behaviors by rewarding chosen behaviors
- Alcoholics Anonymous and its variations
- Inpatient hospital treatment (can be expensive)
- Controlled use
- Community reinforcement
- Relapse prevention

Biological Treatments

- Agonist substitution
 - Replacing one drug with a similar one (methadone for heroin, nicotine gum and patches for cigarettes)
- Antagonist substitution
 - Blocking one drug's effect with another drug (naltrexone for opiates and alcohol)
- Aversive treatments
 - Making taking drug very unpleasant (using Antabuse, which causes nausea and vomiting when mixed with alcohol, to treat alcoholism)
- Drugs to help recovering person deal with withdrawal symptoms (clonidine for opiate withdrawal, sedatives for alcohol, etc.)

TYPES OF DRUGS

An Overview of Personality Disorders

We all think we know what a personality is. It's all the characteristic ways a person behaves and thinks: "Michael tends to be shy"; "Mindy likes to be dramatic"; "Juan is always suspicious of others"; "Anna is outgoing"; "Bruce seems to be sensitive and gets upset easily over minor things"; "Sean has the personality of an eggplant!" We tend to type people as behaving in one way in many situations. For example, like Michael, many of us are shy with people we don't know, but we won't be shy around our friends. A truly shy person is shy even among people he has known for some time. The shyness is part of the way the person behaves in most situations. We also have all probably behaved in all the other ways noted here (dramatic, suspicious, outgoing, easily upset). However, when personality characteristics interfere with relationships with others, cause the person distress, or in general disrupt activities of daily living, we consider these to be "personality disorders" (Skodol, 2012). In this chapter, we look at characteristic ways of behaving in relation to a number of specific personality disorders. First, we examine how we conceptualize personality disorders and the issues related to them; then we describe the disorders themselves.

Aspects of Personality Disorders

What if a person's characteristic ways of thinking and behaving cause significant distress to the self or others? What if the person can't change this way of relating to the world and is unhappy? We might consider this person to have a personality disorder. Unlike many of the disorders we have already discussed, personality disorders are chronic; they do not come and go but originate in childhood and continue throughout adulthood (Widiger, 2012). Because these chronic problems affect personality, they pervade every aspect of a person's life. For example, if a woman is overly suspicious (a sign of a possible paranoid personality disorder), this trait will affect almost everything she does, including her employment (she

may change jobs often if she believes coworkers conspire against her), her relationships (she may not be able to sustain a lasting relationship if she can't trust anyone), and even where she lives (she may move often if she suspects her landlords are out to get her).

A **personality disorder** is a persistent pattern of emotions, cognitions, and behavior that results in enduring emotional distress for the person affected and/or for others and may cause difficulties with work and relationships (American Psychiatric Association, 2013). *DSM-5* notes that having a personality disorder may distress the affected person. Individuals with personality disorders may not feel any subjective distress, however; indeed, it may in fact be others who acutely feel distress because of the actions of the person with the disorder. This is particularly common with antisocial personality disorder, because the individual may show a blatant disregard for the rights of others yet exhibit no remorse (Hare, Neumann, & Widiger, 2012). In certain cases, someone other than the person with the personality disorder must decide whether the disorder is causing significant functional impairment, because the affected person often cannot make such a judgment.

DSM-5 lists 10 specific personality disorders. Although the prospects for treatment success for people who have personality disorders may be more optimistic than previously thought (Nelson, Beutler, & Castonguay, 2012), unfortunately, as you will see later, many people who have personality disorders in addition to other psychological problems (for example, major depression) tend to do poorly in treatment. One factor important to the success (or lack of success) of treatment is how the therapist feels about the client. The emotions of therapists brought out by clients (called "countertransference" by Sigmund Freud) tend to be negative for those diagnosed with personality disorders, especially those (as you will see next) in Cluster A (the odd or eccentric cluster) and Cluster B (the dramatic, emotional, or erratic cluster) (Lieberman & Burnette, 2013). Therapists especially need to guard against letting their personal feelings interfere with treatment when working with people who have personality disorders.

Prior to *DSM-5*, most disorders we discuss in this book were in Axis I of the *DSM-IV-TR*, which included the traditional disorders. The personality disorders were included in a separate axis, Axis II, because as a group they were seen as distinct. It was thought that the characteristic traits were more ingrained and inflexible in people who have personality disorders, and the disorders themselves were less likely to be successfully modified. With the changes made with *DSM-5*, these separate axes were eliminated, and now the personality disorders are listed with the rest of the *DSM-5* disorders (American Psychiatric Association, 2013).

You may be surprised to learn that the category of personality disorders is controversial, because it involves a number of unresolved issues. Examining these issues can help you understand all the disorders described in this book.

Categorical and Dimensional Models

Most of us are sometimes suspicious of others and a little paranoid, overly dramatic, too self-involved, or reclusive. Fortunately, these characteristics do not last long or are not overly intense; they haven't significantly impaired how we live and work. People with personality disorders, however, display problem characteristics over extended periods and in many situations, which can cause great emotional pain for themselves, others, or both (Widiger, 2012). Their difficulty, then, can be seen as one of *degree* rather than *kind*; in other words, the problems of people with personality disorders may just be extreme versions of the problems many of us experience temporarily, such as being shy or suspicious (South, Oltmanns, & Krueger, 2011).

The distinction between problems of degree and problems of kind is usually described in terms of *dimensions* instead of *categories*. The issue that continues to be debated in the field is whether personality disorders are extreme versions of otherwise typical personality variations (dimensions) or ways of relating that are different from psychologically healthy behavior (categories) (Skodol, 2012). You can see the difference between dimensions and categories in everyday life. For example, we tend to look at gender categorically. Society generally views us as being in one category—"female"—or the other—"male." Yet many believe it is more accurate to look at gender in terms of dimensions. For example, we know that "male" and "female" may describe a range of choices in gender expression (e.g., personal grooming, attire, use of makeup and other body modifications). We could just as easily place people along a continuum of maleness and femaleness rather than in the absolute categories of male or female. We also often label people's size categorically, as tall, average, or short. But height, too, can be viewed dimensionally, in inches or centimeters.

Many researchers and clinicians in this field see personality disorders as extremes on one or more personality dimensions. Yet because of the way people are diagnosed with the *DSM*, the personality disorders—like most other disorders—end up being viewed in categories. You have two choices—either you do ("yes") or you do not ("no") have a disorder. For example, either you have antisocial personality disorder or you don't. *DSM* diagnoses don't rate how dependent you are; if you meet the criteria, you are labeled as having dependent personality disorder. There is no "somewhat" when it comes to personality disorders.

There are advantages to using categorical models of behavior, the most important being their convenience. With simplification,

however, come problems. One is that the mere act of using categories leads clinicians to reify them; that is, to view disorders as real "things," comparable to the realness of an infection or a broken arm. Some argue that personality disorders are not things that exist but points at which society decides a particular way of relating to the world has become a problem. There is the important unresolved issue again: Are personality disorders just an extreme variant of normal personality, or are they distinctly different disorders?

Some had proposed that the *DSM-5* personality disorders section be replaced or at least supplemented by a dimensional model (South et al., 2011; Widiger, 2012) in which individuals would not only be given categorical diagnoses but also would be rated on a series of personality dimensions. Widiger and colleagues (Widiger & Simonsen, 2005; Widiger & Trull, 2007; Widiger, 2011) have argued for decades that such a system would have at least three advantages over a purely categorical system: (1) It would retain more information about each individual, (2) it would be more flexible because it would permit both categorical and dimensional differentiations among individuals, and (3) it would avoid the often arbitrary decisions involved in assigning a person to a diagnostic category. Currently, there is an alternative model of personality disorders included in the section on "emerging measures and models" in *DSM-5* that is included for further study (American Psychiatric Association, 2013). This model focuses on a continuum of disturbances of "self" (i.e., how you view yourself and your ability to be self-directed) and interpersonal (i.e., your ability to empathize and be intimate with others) functioning. It remains to be seen how this alternative model will be used in the future.

Although no general consensus exists about what the basic personality dimensions might be, there are several contenders (South et al., 2011). One of the more widely accepted is called the *five-factor model*, or the "Big Five," and is taken from work on normal personality (Hopwood & Thomas, 2012; McCrae & Costa Jr., 2008). In this model, people can be rated on a series of personality dimensions, and the combination of five components describes why people are so different. The five factors or dimensions are *extroversion* (talkative, assertive, and active versus silent, passive, and reserved); *agreeableness* (kind, trusting, and warm versus hostile, selfish, and mistrustful); *conscientiousness* (organized, thorough, and reliable versus careless, negligent, and unreliable); *neuroticism* (even-tempered versus nervous, moody, and temperamental); and *openness to experience* (imaginative, curious, and creative versus shallow and imperceptive) (McCrae & Costa Jr., 2008). On each dimension, people are rated high, low, or somewhere between.

Cross-cultural research establishes the relatively universal nature of the five dimensions—although there are individual differences across cultures (Valchev et al., 2013; Carlo, Knight, Roesch, Opal, & Davis, 2014). One study examined Big Five traits in high school students across six different cultures and found, for example, that young adults in Turkey reported higher levels of conscientiousness and extraversion than those in China, whereas students in Taiwan reported about as much openness as those in Slovenia (Vazsonyi, Ksinan, Mikuška, & Jiskrova, 2015). A number of researchers are trying to determine whether people with personality disorders can also be rated in a meaningful way along the Big Five dimensions and whether the system will help us better understand these disorders (Costa & McCrae, 2013).

Personality Disorder Clusters

DSM-5 divides the personality disorders into three groups, or clusters; this will probably continue until a strong scientific basis is established for viewing them differently (American Psychiatric Association, 2013) (see Table 12.1). The cluster division is based on resemblance. Cluster A is called the odd or eccentric cluster; it includes paranoid, schizoid, and schizotypal personality disorders. Cluster B is the dramatic, emotional, or erratic cluster; it consists of antisocial, borderline, histrionic, and narcissistic personality disorders. Cluster C is the anxious or fearful cluster; it includes avoidant, dependent, and obsessive-compulsive personality disorders. We follow this order in our review.

Statistics and Development

Because many people with these problems do not seek help on their own as do those with many of the other *DSM-5* disorders, gathering information about the prevalence of personality disorders is difficult and therefore varies a great deal. An important population survey suggests that as many as 1 in 10 adults in the United States may have a diagnosable personality disorder (Lenzenweger, Lane, Loranger, & Kessler, 2007), which makes them relatively common (see Table 12.2). Numbers vary somewhat across countries, but worldwide about 6% of adults may have at least one personality disorder (Huang et al., 2009). Differences in prevalence estimates may be the result of different survey methods: surveying people

in clinical settings versus surveying the general population—even those not seeking assistance (Torgersen, 2012). Similarly, gender differences in the disorders—for example, more women were diagnosed with borderline personality disorder and more men identified with antisocial personality disorder—are highly variable when surveying the general population. There may be several reasons for these differences in diagnoses, including bias in diagnoses and differences in help-seeking behavior and tolerance of behavior in a culture. We discuss several of these concerns later in the chapter.

Personality disorders were thought to originate in childhood and continue into the adult years (Cloninger & Svakic, 2009). More sophisticated analyses suggest that personality disorders can remit over time (Zanarini, Frankenburg, Hennen & Silk, 2006, 2014); however, they may be replaced by other personality disorders (Torgersen, 2012). In other words, a person could receive a diagnosis of one personality disorder at one point in time and then years later no longer meet the criteria for his original problem but now have characteristics of a second (or third) personality disorder. Our relative lack of information about such important features of personality disorders as their developmental course is a repeating theme. The gaps in our knowledge of the course of about half these disorders are visible in Table 12.2. One reason for this dearth of research is that many individuals do not seek treatment in the early developmental phases of their disorder but only after years of distress. This makes it difficult to study people with personality disorders from the beginning, although a few research studies

TABLE 12.1 Personality Disorders

Personality Disorder	Description
Cluster A—Odd or Eccentric Disorders	
Paranoid personality disorder	A pervasive distrust and suspiciousness of others such that their motives are interpreted as malevolent.
Schizoid personality disorder	A pervasive pattern of detachment from social relationships and a restricted range of expression of emotions in interpersonal settings.
Schizotypal personality disorder	A pervasive pattern of social and interpersonal deficits marked by acute discomfort with reduced capacity for close relationships, as well as by cognitive or perceptual distortions and eccentricities of behavior.
Cluster B—Dramatic, Emotional, or Erratic Disorders	
Antisocial personality disorder	A pervasive pattern of disregard for and violation of the rights of others.
Borderline personality disorder	A pervasive pattern of instability of interpersonal relationships, self-image, affects, and control over impulses.
Histrionic personality disorder	A pervasive pattern of excessive emotion and attention seeking.
Narcissistic personality disorder	A pervasive pattern of grandiosity (in fantasy or behavior), need for admiration, and lack of empathy.
Cluster C—Anxious or Fearful Disorders	
Avoidant personality disorder	A pervasive pattern of social inhibition, feelings of inadequacy, and hypersensitivity to negative evaluation.
Dependent personality disorder	A pervasive and excessive need to be taken care of, which leads to submissive and clinging behavior and fears of separation.
Obsessive-compulsive personality disorder	A pervasive pattern of preoccupation with orderliness, perfectionism, and mental and interpersonal control, at the expense of flexibility, openness, and efficiency.

have helped us understand the development of several disorders (Hecht, Cicchetti, Rogosch, & Crick, 2014).

People with borderline personality disorder are characterized by their volatile and unstable relationships; they tend to have persistent problems in early adulthood, with frequent hospitalizations, unstable personal relationships, severe depression, and suicidal gestures. Individuals with borderline personality disorder die by suicide at a rate about 50 times higher than the general population, with most research suggesting that 8% to 10% of patients with this illness complete suicide (Gunderson, 2011; Björkenstam, Björkenstam, Holm, Gerdin, & Ekselius, 2015). On the bright side, their symptoms gradually improve if they survive into their 30s (Zanarini et al., 2006, 2014), although elderly individuals may still experience higher than average interpersonal difficulties (Powers, Gleason, & Oltmanns, 2013). People with antisocial personality

disorder display a characteristic disregard for the rights and feelings of others; they tend to continue their destructive behaviors of lying and manipulation through adulthood. Fortunately, some tend to “burn out” in middle adulthood, reflected in a decline in the prevalence of antisocial personality disorder across the lifespan (Vachon et al., 2013). As a group, however, the problems of people with personality disorders continue, as shown when researchers follow their progress over the years (Torgersen, 2012).

Gender Differences

Men diagnosed with a personality disorder tend to display traits characterized as more aggressive, structured, self-assertive, and detached, and women tend to present with characteristics that are more submissive, emotional, and insecure (Torgersen, 2012). It is

not surprising, then, that antisocial personality disorder is present more often in males and dependent personality disorder more often in females. Historically, histrionic and borderline personality disorders were identified by clinicians more often in women (Dulit, Marin, & Frances, 1993; Stone, 1993), but according to more recent studies of their prevalence in the general population, equal numbers of males and females may have histrionic and borderline personality disorders (see Table 12.2). If this observation holds up in future studies, why have these disorders been predominantly diagnosed among females in general clinical practice and in other studies?

Do the disparities indicate differences between men and women in certain basic experiences that are genetic, sociocultural, or both, or do they represent biases on the part of the clinicians who make the diagnoses? Take, for example, a classic study by Maureen Ford and Thomas Widiger (1989), who sent fictitious case histories to clinical psychologists for diagnosis. One case described a person with *antisocial personality disorder*, which is characterized by irresponsible and reckless behavior and usually diagnosed in males; the other case described a person with *histrionic personality disorder*, which is characterized by excessive emotionality and attention seeking and more often diagnosed in females. The subject was identified as male in some versions of each case and as female in others, although everything else was identical. As the graph in Figure 12.1 shows, when the antisocial personality disorder case was labeled male, most psychologists gave the correct diagnosis. When the same case of antisocial personality disorder was labeled female, however, most psychologists diagnosed it as histrionic personality disorder rather than antisocial personality disorder. In the case of histrionic personality disorder, being labeled a woman increased the likelihood of that diagnosis. Ford and Widiger (1989) concluded that the psychologists incorrectly diagnosed more women as having histrionic personality disorder.

This gender difference in diagnosis has also been criticized by other authors (see, for example, Kaplan, 1983) on the grounds that histrionic personality disorder, like several of the other personality disorders, is biased against females. As Kaplan (1983) points out, many of the features of histrionic personality disorder, such as overdramatization, vanity, seductiveness, and overconcern with physical appearance, are characteristic of the Western “stereotypical female.” This disorder may simply be the embodiment of extremely “feminine” traits (Chodoff, 1982); branding such an individual mentally ill, according to Kaplan, reflects society’s inherent bias against females. (See Table 12.3 for a humorous take on a male version of a personality disorder.) Interestingly, the “macho” personality (Mosher & Sirkin, 1984), in which the individual possesses stereotypically masculine traits, is nowhere to be found in the DSM.

The issue of gender bias in diagnosing personality disorder remains highly controversial (Liebman & Burnette, 2013). Remember, however, that just because certain disorders are observed more in men or women doesn’t necessarily indicate bias (Lilienfeld, VanValkenburg, Larntz, & Akiskal, 1986). When it is present, bias can occur

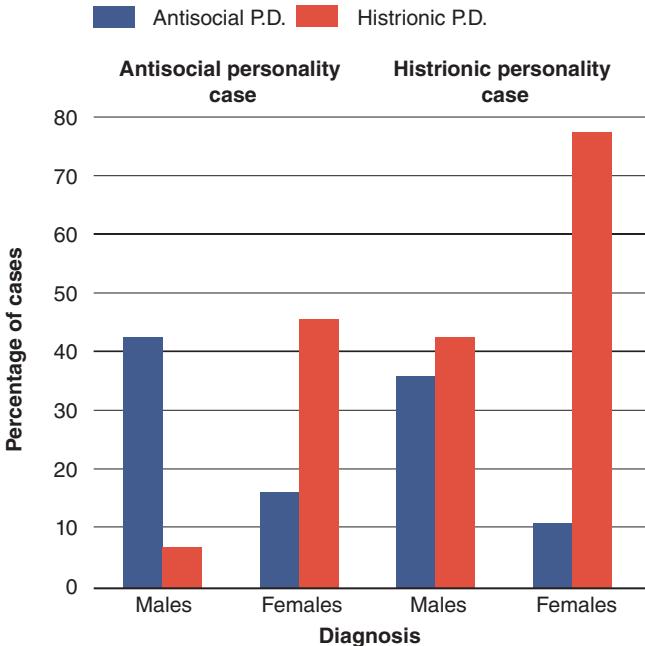

FIGURE 12.1

Gender bias in diagnosing personality disorders (P.D.). Data are shown for the percentage of cases clinicians rated as antisocial personality disorder or histrionic personality disorder, depending on whether the case was described as a male or a female. at different stages of the diagnostic process. Widiger and Spitzer (1991) point out that the criteria for the disorder may themselves be biased (*criterion gender bias*), or the assessment measures and the way they are used may be biased (*assessment gender bias*). In general, the criteria themselves do not appear to have strong gender bias, although there may be some tendency for clinicians to use their own bias when using the criteria and therefore diagnose males and

Personality disorders tend to begin in childhood.

TABLE 12.3 Diagnostic Criteria for “Independent” Personality Disorder

- Puts work (career) above relationships with loved ones (for example, travels a lot on business, works late at night and on weekends).
- Is reluctant to take into account others’ needs when making decisions, especially concerning the individual’s career or use of leisure time, for example, expects spouse and children to relocate to another city because of individual’s career plans.
- Passively allows others to assume responsibility for major areas of social life because of inability to express necessary emotion (for example, lets spouse assume most childcare responsibilities).

females differently (Oltmanns & Powers, 2012). As studies continue, researchers will try to make the diagnosis of personality disorders more accurate with respect to gender and more useful to clinicians.

Comorbidity

Looking at Table 12.2 and adding up the prevalence rates across the personality disorders, you might conclude that up to 25% of all people are affected. In fact, the percentage of people in the population with a personality disorder is likely closer to 10% (Huang et al., 2009; Lenzenweger et al., 2007). What accounts for this discrepancy? A major concern with the personality disorders is that people tend to be diagnosed with more than one. The term *comorbidity* historically describes the condition in which a person has multiple diseases (Caron & Rutter, 1991). A fair amount of disagreement is ongoing

about whether the term should be used with psychological disorders because of the frequent overlap of different disorders (Skodol, 2005). In just one example, Zimmerman, Rothschild, and Chelminski (2005) conducted a study of 859 psychiatric outpatients and assessed how many had one or more personality disorders. Table 12.4 shows the odds that a person with a particular personality disorder would also meet the criteria for other disorders. For example, a person identified with borderline personality disorder is also likely to receive diagnoses of paranoid, schizotypal, antisocial, narcissistic, avoidant, or dependent personality disorders.

[†]The “odds ratio” indicates how likely it is that a person would have both disorders. The odds ratios with an asterisk (*) indicate that, statistically, people are likely to be diagnosed with both disorders—with a higher number meaning people are more likely to have both. Some higher odds ratios are not statistically significant because the number of people with the disorder in this study was relatively small.

Do people really tend to have more than one personality disorder? Are the ways we define these disorders inaccurate, and do we need to improve our definitions so that they do not overlap? Or did we divide the disorders in the wrong way, and do we need to rethink the categories? Complicating this issue is the phenomenon that people will change diagnoses over time (Torgersen, 2012). Such questions about comorbidity are just a few of the important issues faced by researchers who study personality disorders.

Personality Disorders under Study

We started this chapter by noting difficulties in categorizing personality disorders; for example, there is much overlap of the categories, which suggests there may be other ways to arrange these pervasive difficulties of character. It shouldn't surprise you to learn that other personality disorders have been studied for inclusion in the *DSM*—for example, sadistic personality disorder, which includes people who receive pleasure by inflicting pain on others (Levesque, 2012), and passive-aggressive personality disorder, which includes people who are defiant and refuse to cooperate with requests—attempting to undermine authority figures (Wetzler & Jose, 2012). The existence of these disorders as distinct personality disorders remains controversial, however, so they were not included in *DSM-5* (Wetzler & Jose, 2012).

We now review the personality disorders currently in *DSM-5*, 10 in all. Table 12.5 provides a simplified look at how people with different personality disorders view the world.

Concept Check 12.1

Fill in the blanks to complete the following statements about personality disorders.

- _____ refers to meeting diagnostic criteria for multiple disorders, which is particularly common among individuals with personality disorders.
- The personality disorders are divided into three clusters or groups: _____ contains the odd or eccentric disorders; _____ contains the dramatic, emotional, and erratic disorders; and _____ contains the anxious and fearful disorders.
- It's debated whether personality disorders are extreme versions of otherwise normal personality variations (therefore classified as dimensions) or ways of relating that are different from psychologically healthy behavior (classified as _____).
- Personality disorders are described as _____ because unlike many disorders, they originate in childhood and continue throughout adulthood.
- Although gender differences are evident in the research of personality disorders, some differences in the findings may be the result of _____.

TABLE 12.5 Main Beliefs Associated with Specific Personality Disorders

Personality Disorder	Main Belief
Paranoid	I cannot trust people.
Schizotypal	It's better to be isolated from others.
Schizoid	Relationships are messy, undesirable.
Histrionic	People are there to serve or admire me.
Narcissistic	Since I am special, I deserve special rules.
Borderline	I deserve to be punished.
Antisocial	I am entitled to break rules.
Avoidant	If people knew the "real" me, they would reject me.
Dependent	I need people to survive, be happy.
Obsessive-compulsive	People should do better, try harder.

Cluster A Personality Disorders

Three personality disorders—paranoid, schizoid, and schizotypal—share common features that resemble some of the psychotic symptoms seen in schizophrenia. These odd or eccentric personality disorders are described next.

Paranoid Personality Disorder

Although it is probably adaptive to be a little wary of other people and their motives, being too distrustful can interfere with making friends, working with others, and, in general, getting through daily interactions in a functional way. People with **paranoid personality disorder** are excessively mistrustful and suspicious of others, without any justification. They assume other people are out to harm or trick them; therefore, they tend not to confide in others. Consider the case of Jake.

Jake...

Research Victim

Jake grew up in a middle-class neighborhood, and although he never got in serious trouble, he had a reputation in high school for arguing with teachers and classmates. After high school, he enrolled in the local community college, but he flunked out after the first year. Jake's lack of success in school was partly attributable to his failure to take responsibility for his poor grades. He began to develop conspiracy theories about fellow students and professors, believing they worked together to see him fail. Jake bounced from job to job, each time complaining that his employer was spying on him at work and at home.

At age 25—and against his parents' wishes—he moved out of his parents' home to a small town out of state. Unfortunately, the letters Jake wrote home daily confirmed his parents' worst fears. He was becoming increasingly

(Continued next page)

preoccupied with theories about people who were out to harm him. Jake spent enormous amounts of time on his computer, exploring websites, and he developed an elaborate theory about how research had been performed on him in childhood. His letters home described his belief that researchers working with the CIA drugged him as a child and implanted something in his ear that emitted microwaves. These microwaves, he believed, were being used to cause him to develop cancer. Over 2 years, he became increasingly preoccupied with this theory, writing letters to various authorities trying to convince them he was being slowly killed. After he threatened harm to some local college administrators, his parents were contacted, and they brought him to a psychologist who diagnosed him with paranoid personality disorder and major depression. •

TABLE 12.1
Diagnostic Criteria for Paranoid Personality Disorder

- A.** A pervasive distrust and suspiciousness of others such that their motives are interpreted as malevolent, beginning by early adulthood and present in a variety of contexts, as indicated by four (or more) of the following:
- 1.** Suspects, without sufficient basis, that others are exploiting, harming, or deceiving him or her.
 - 2.** Is preoccupied with unjustified doubts about the loyalty or trustworthiness of friends or associates.
 - 3.** Is reluctant to confide in others because of unwarranted fear that the information will be used maliciously against him or her.
 - 4.** Reads hidden demeaning or threatening meanings into benign remarks or events.
 - 5.** Persistently bears grudges, i.e., is unforgiving of insults, injuries, or slights.
 - 6.** Perceives attacks on his or her character or reputation that are not apparent to others and is quick to react angrily or to counterattack.
 - 7.** Has recurrent suspicions, without justification, regarding fidelity of spouse or sexual partner.
- B.** Does not occur exclusively during the course of schizophrenia, a bipolar disorder or depressive disorder with psychotic features, or another psychotic disorder and is not attributable to the physiological effects of another medical condition.

Note: If criteria are met prior to the onset of schizophrenia, add "premorbid," i.e., "paranoid personality disorder (premorbid)."

as a separate disorder from the *DSM* (Triebwasser, Chemerinski, Roussos, & Siever, 2013).

Psychological contributions to this disorder are even less certain, although some interesting speculations have been made. Retrospective research—asking people with this disorder to recall events from their childhood—suggests that early mistreatment or traumatic childhood experiences may play a role in the development of paranoid personality disorder (Iacovino, Jackson, & Oltmanns, 2014). Caution is warranted when interpreting these results because, clearly, there may be strong bias in the recall of these individuals who are already prone to viewing the world as a threat.

Some psychologists point directly to the thoughts (also referred to as "schemas") of people with paranoid personality disorder as a way of explaining their behavior. One view is that people with this disorder have the following basic mistaken assumptions about others: "People are malevolent and deceptive," "They'll attack you if they get the chance," and "You can be okay only if you stay on your toes" (Lobbestael & Arntz, 2012). This is a maladaptive way to view the world, yet it seems to pervade every aspect of the lives of these individuals. Although we don't know why they develop these perceptions, some speculation is that the roots are in their early upbringing. Their parents may teach them to be careful about making mistakes and may impress on them that they are different from other people. This

Causes

Evidence for biological contributions to paranoid personality disorder is limited. Some research suggests the disorder may be slightly more common among the relatives of people who have schizophrenia, although the association does not seem to be strong (Tienari et al., 2003). In other words, relatives of individuals with schizophrenia may be more likely to have paranoid personality disorder than people who do not have a relative with schizophrenia. In general, there appears to be a strong role for genetics in paranoid personality disorder (Kendler et al., 2015). As you will see later with the other odd or eccentric personality disorders in Cluster A, there seems to be some relationship with schizophrenia (Bolinskey et al., 2015), causing some to suggest eliminating it

People with paranoid personality disorder often believe that impersonal situations exist specifically to annoy or otherwise disturb them.

vigilance causes them to see signs that other people are deceptive and malicious (Triebwasser, Chemerinski, Roussos, & Siever, 2013). It is certainly true that people are not always benevolent and sincere, and our interactions are sometimes ambiguous enough to make other people's intentions unclear. Looking too closely at what other people say and do can sometimes lead you to misinterpret them.

Cultural factors have also been implicated in paranoid personality disorder. Certain groups of people, such as prisoners, refugees, people with hearing impairments, and older adults, are thought to be particularly susceptible because of their unique experiences (Iacovino et al., 2014; Ryder, Sunohara, & Kirmayer, 2015; Raza, DeMarce, Lash, & Parker, 2014). Imagine how you might view other people if you were an immigrant who had difficulty with the language and the customs of your new culture. Such innocuous things as other people laughing or talking quietly might be interpreted as somehow directed at you. The late musician Jim Morrison of The Doors described this phenomenon in his song "People Are Strange" (1967): "People are strange, / When you're a stranger, / Faces look ugly, / When you're alone."

You have seen how someone could misinterpret ambiguous situations as malevolent. Therefore, cognitive and cultural factors may interact to produce the suspiciousness observed in some people with paranoid personality disorder.

Treatment

Because people with paranoid personality disorder are mistrustful of everyone, they are unlikely to seek professional help when they need it, and they have difficulty developing the trusting relationships necessary for successful therapy (Sarkar & Adshead, 2012; Skodol & Gunderson, 2008). Establishing a meaningful therapeutic alliance between the client and the therapist therefore becomes an important first step (Bender, 2005). When these individuals finally do seek therapy, the trigger is usually a crisis in their lives—such as Jake's threats to harm strangers—or other problems such as anxiety or depression, not necessarily their personality disorder (Kelly, Casey, Dunn, Ayuso-Mateos, & Dowrick, 2007).

Therapists try to provide an atmosphere conducive to developing a sense of trust (Bender, 2005). They often use cognitive therapy to counter the person's mistaken assumptions about others, focusing on changing the person's beliefs that all people are malevolent and most people cannot be trusted (Beck, Davis, & Freeman, 2015). Be forewarned, however, that to date there are no confirmed demonstrations that any form of treatment can significantly improve the lives of people with paranoid personality disorder. A survey of mental health professionals indicated that only 11% of therapists who treat paranoid personality disorder thought these individuals would continue in therapy long enough to be helped (Quality Assurance Project, 1990).

Schizoid Personality Disorder

Do you know someone who is a "loner"? Someone who would choose a solitary walk over an invitation to a party? A person who comes to class alone, sits alone, and leaves alone? Now, magnify this preference for isolation many times over and you can begin to grasp the impact of **schizoid personality disorder** (Hopwood & Thomas, 2012). People with this personality disorder show a pattern of detachment from social relationships and a limited range of emotions in interpersonal situations. They seem aloof, cold, and indifferent to other people. The term *schizoid* is relatively old, having been used by Bleuler (1924) to describe people who have a tendency to turn inward and away from the outside world. These people were said to lack emotional expressiveness and pursued vague interests. Consider the case of Mr. Z.

Mr. Z... All on His Own

A 39-year-old scientist was referred after his return from a tour of duty in Antarctica where he had stopped cooperating with others, had withdrawn to his room, and had begun drinking on his own. Mr. Z. was orphaned at age 4, raised by an aunt until age 9, and subsequently looked after by an aloof housekeeper. At university, he excelled at physics, but chess was his only contact with others. Throughout his subsequent life, he made no close friends and engaged primarily in solitary activities. Until the tour of duty in Antarctica, he had been quite successful in his research work in physics. He was now, some months after his return, drinking at least a bottle of Schnapps each day, and his work had continued to deteriorate. He presented as self-contained and unobtrusive and was difficult to engage effectively. He was at a loss to explain his colleagues' anger at his aloofness in Antarctica and appeared indifferent to their opinion of him. He did not appear to require any interpersonal relations, although he did complain of some tedium in his life and at one point during the interview became sad, expressing longing to see his uncle in Germany, his only living relation.

Clinical Description

Individuals with schizoid personality disorder seem neither to desire nor to enjoy closeness with others, including romantic or sexual relationships. As a result, they appear cold and detached and do not seem affected by praise or criticism. One of the changes in *DSM-IV-TR* from previous versions was the recognition that at least some people with schizoid personality disorder are sensitive to the opinions of others but are unwilling or unable to express this emotion. For them, social isolation may be extremely painful. Unfortunately, homelessness appears to be prevalent among people with this personality disorder, perhaps as a result of their lack of close friendships and lack of dissatisfaction about not having a sexual relationship with another person (Rouff, 2000; Angstman & Rasmussen, 2011).

The social deficiencies of people with schizoid personality disorder are similar to those of people with paranoid personality disorder, although they are more extreme. As Beck and Freeman (1990, p. 125) put it, they “consider themselves to be observers rather than participants in the world around them.” They do not seem to have the unusual thought processes that characterize the other disorders in Cluster A (Cloninger & Svakic, 2009) (see Table 12.6). For example, people with paranoid and schizotypal personality disorders often have *ideas of reference*, mistaken beliefs that meaningless events relate just to them. In contrast, those with schizoid personality disorder share the social isolation, poor rapport, and constricted affect (showing neither positive nor negative emotion) seen in people with paranoid personality disorder. You will see in Chapter 13 that this distinction among psychotic-like symptoms is important to understanding people with schizophrenia, some of whom show the “positive” symptoms (actively unusual behaviors such as ideas of reference) and others only the “negative” symptoms (the more passive manifestations of social isolation or poor rapport with others).

Causes and Treatment

Extensive research on the genetic, neurobiological, and psychosocial contributions to schizoid personality disorder remains to be conducted. In fact, very little empirical research has been published on the nature and causes of this disorder (Triebwasser et al., 2012). Childhood shyness is reported as a precursor to

later adult schizoid personality disorder. It may be that this personality trait is inherited and serves as an important determinant in the development of this disorder. Abuse and neglect in childhood are also reported among individuals with this disorder (Lobbestael, Arntz, & Bernstein, 2010; Carr, Keenleyside, & Fitzhenry, 2015). Research over the past several decades points to biological causes of autism (a disorder we discuss in more detail in Chapter 14), and research demonstrates significant overlap in the occurrence of autism spectrum disorder and schizoid personality disorder (Lugnegård, Hallerbäck, & Gillberg, 2012; Hummelen, Pedersen, Wilberg, & Karterud, 2014; Coolidge, Marle, Rhoades, Monaghan, & Segal, 2013; Vannucchi et al., 2014). It is possible that a biological dysfunction found in both autism and schizoid personality disorder combines with early learning or early problems with interpersonal relationships to produce the social deficits that define schizoid personality disorder (Hopwood & Thomas, 2012).

It is rare for a person with this disorder to request treatment except in response to a crisis such as extreme depression or losing a job (Kelly et al., 2007). Therapists often begin treatment by pointing out the value in social relationships. The person with the disorder may even need to be taught the emotions felt by others to learn empathy (Skodol & Gunderson, 2008). Because their social skills were never established or have atrophied through lack of use (Caballo, Salazar, Irurtia, Olivares, & Olivares, 2014), people with schizoid personality disorder often receive social skills training.

Diagnostic Criteria for Schizoid Personality Disorder

DSM 5

- A.** A pervasive pattern of detachment from social relationships and a restricted range of expression of emotions in interpersonal settings, beginning by early adulthood and present in a variety of contexts, as indicated by four (or more) of the following:
1. Neither desires nor enjoys close relationships, including being part of a family.
 2. Almost always chooses solitary activities.
 3. Has little, if any, interest in having sexual experiences with another person.
 4. Takes pleasure in few, if any, activities.
 5. Lacks close friends or confidants other than first-degree relatives.
 6. Appears indifferent to the praise or criticism of others.
 7. Shows emotional coldness, detachment, or flattened affectivity.

- B.** Does not occur exclusively during the course of schizophrenia, a bipolar disorder or depressive disorder with psychotic features, another psychotic disorder, or autism spectrum disorder and is not attributable to the physiological effects of another medical condition.

Note: If criteria are met prior to the onset of schizophrenia, add “premorbid,” e.g., “schizoid personality disorder (premorbid).”

The therapist takes the part of a friend or significant other in a technique known as role-playing and helps the patient practice establishing and maintaining social relationships (Skodol & Gunderson, 2008). This type of social skills training is helped by identifying a social network—a person or people who will be supportive (Bender, 2005). Outcome research on this type of approach is unfortunately quite limited, so we must be cautious in evaluating the effectiveness of treatment for people with schizoid personality disorder.

Schizotypal Personality Disorder

People with **schizotypal personality disorder** are typically socially isolated, like those with schizoid personality disorder. In addition, they also behave in ways that would seem unusual to many of us, and they tend to be suspicious and to have odd beliefs (Rosell, Futterman, McMaster, & Siever, 2014; Chemerenski, Triebwasser, Roussos, & Siever, 2013). Schizotypal personality disorder is considered by some to be on a continuum (that is, on the same spectrum) with schizophrenia—the severe disorder we discuss in the next chapter—but without some of the more debilitating symptoms, such as hallucinations and delusions. In fact, because of this close connection, *DSM-5* includes this disorder under both the heading of a personality disorder and under the heading of a schizophrenia spectrum disorder (American Psychiatric Association, 2013). Consider the case of Mr. S.

Mr. S...

All on His Own

Mr. S. was a 35-year-old chronically unemployed man who had been referred by a physician because of a vitamin deficiency. This was thought to have eventuated because Mr. S. avoided any foods that “could have been contaminated by machine.” He had begun to develop alternative ideas about diet in his 20s and soon left his family and began to study an Eastern religion. “It opened my third eye; corruption is all about,” he said.

He now lived by himself on a small farm, attempting to grow his own food, bartering for items he could not grow himself. He spent his days and evenings researching the origins and mechanisms of food contamination and, because of this knowledge, had developed a small band who followed his ideas. He had never married and maintained little contact with his family: “I’ve never been close to my father. I’m a vegetarian.”

He said he intended to do an herbalism course to improve his diet before returning to his life on the farm. He had refused medication from the physician and became uneasy when the facts of his deficiency were discussed with him.

Treatment outlines for paranoid, schizotypal and schizoid personality disorders. *Australian and New Zealand Journal of Psychiatry*, 24, 339–350.) •

Clinical Description

People given a diagnosis of schizotypal personality disorder have psychoticlike (but not psychotic) symptoms (such as believing everything relates to them personally), social deficits, and sometimes cognitive impairments or paranoia (Kwapil & Barrantes-Vidal, 2012). These individuals are often considered odd or bizarre because of how they relate to other people, how they think and behave, and even how they dress. They have *ideas of reference*; for example, they may believe that somehow everyone on a passing city bus is talking about them, yet they may be able to acknowledge this is unlikely (Rosell et al., 2014). Again, as you will see in Chapter 13, some people with schizophrenia also have ideas of reference, but they are usually not able to “test reality” or see the illogic of their ideas.

Individuals with schizotypal personality disorder also have odd beliefs or engage in “magical thinking,” believing, for example, that they are clairvoyant or telepathic (Furnham & Crump, 2014). In addition, they report unusual perceptual experiences, including such illusions as feeling the presence of another person when they are alone. Notice the subtle but important difference between *feeling* as if someone else is in the room and the more extreme perceptual distortion in people with schizophrenia who might report there *is* someone else in the room when there isn’t. Unlike people who simply have unusual interests or beliefs, those with schizotypal personality disorder tend to be suspicious and have paranoid thoughts, express little emotion, and may dress or behave in unusual ways (for example, wear many layers of clothing in the summertime or mumble to themselves) (Chemerinski et al., 2013). Prospective research on children who later develop schizotypal personality disorder found that they tend to be passive and unengaged and are hypersensitive to criticism (Olin et al., 1997).

Because persons with schizotypal personality disorder often have beliefs around religious or spiritual themes (Bennett, Shepherd, & Janca, 2013), clinicians must be aware that different cultural beliefs or practices may lead to a mistaken diagnosis of this disorder. For example, some people who practice certain religious rituals—such as speaking in tongues, practicing voodoo, or mind reading—may do so with such obsessiveness as to make them seem extremely unusual, thus leading to a misdiagnosis (American Psychiatric Association, 2013). Mental health workers have to be particularly sensitive to cultural practices that may differ from their own and can distort their view of certain seemingly unusual behaviors.

Causes

Historically, the word *schizotype* was used to describe people who were predisposed to develop schizophrenia (Meehl, 1962; Rado, 1962). Schizotypal personality disorder is viewed by some to be one phenotype of a schizophrenia genotype. Recall that a *phenotype* is one way a person’s genetics is expressed. A *genotype* is the gene or genes that make up a particular disorder. Depending on a variety of other influences, however, the way you turn out—your phenotype—may vary from other persons with a similar genetic makeup. Some people are thought to have “schizophrenia genes” (the genotype) yet, because of the relative lack of biological influences (for example, prenatal illnesses) or environmental stresses (for example, poverty, maltreatment), some will have the less

severe schizotypal personality disorder (the phenotype) (Kwapil & Barrantes-Vidal, 2012).

The idea of a relationship between schizotypal personality disorder and schizophrenia arises partly from the way people with the disorders behave. Many characteristics of schizotypal personality disorder, including ideas of reference, illusions, and paranoid thinking, are similar but milder forms of behaviors observed among people with schizophrenia. Genetic research also seems to support a relationship. Family, twin, and adoption studies have shown an increased prevalence of schizotypal personality disorder among relatives of people with schizophrenia who do not also have schizophrenia themselves (Siever & Davis, 2004). These studies also tell us, however, that the environment can strongly influence schizotypal personality disorder. Some research suggests that schizotypal symptoms are strongly associated with childhood maltreatment among men, and this childhood maltreatment seems to result in posttraumatic stress disorder (PTSD) symptoms (see Chapter 5) among women (Berenbaum, Thompson, Milanak, Boden, & Bredemeier, 2008).

TABLE 12.3
Diagnostic Criteria for Schizotypal Personality Disorder

- A.** A pervasive pattern of social and interpersonal deficits marked by acute discomfort with, and reduced capacity for, close relationships, as well as by cognitive or perceptual distortions and eccentricities of behavior, beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:
1. Ideas of reference (excluding delusions of reference).
 2. Odd beliefs or magical thinking that influences behavior and is inconsistent with subcultural norms (e.g., superstitiousness, belief in clairvoyance, telepathy, or "sixth sense"; in children and adolescents, bizarre fantasies or preoccupations).
 3. Unusual perceptual experiences, including bodily illusions.
 4. Odd thinking and speech (e.g., vague, circumstantial, metaphorical, overelaborate, or stereotyped).
 5. Suspiciousness or paranoid ideation.
 6. Inappropriate or constricted affect.
 7. Behavior or appearance that is odd, eccentric, or peculiar.
 8. Lack of close friends or confidants other than first-degree relatives.
 9. Excessive social anxiety that does not diminish with familiarity and tends to be associated with paranoid fears rather than negative judgments about self.
- B.** Does not occur exclusively during the course of schizophrenia, a bipolar disorder or depressive disorder with psychotic features, another psychotic disorder, or autism spectrum disorder.

Note: If criteria are met prior to the onset of schizophrenia, add "premorbid," e.g., "schizoid personality disorder (premorbid)." _____

Cognitive assessment of people with this disorder points to mild-to-moderate decrements in their ability to perform on tests involving memory and learning, suggesting some damage in the left hemisphere (Siever & Davis, 2004). Other research, using magnetic resonance imaging, points to generalized brain abnormalities in those with schizotypal personality disorder (Modinos et al., 2009; Lener et al., 2014).

Treatment

People with schizotypal personality disorder who request clinical help often seek assistance due to anxiety or depression. Relatedly, the presence of schizotypal personality disorder significantly increases the risk for developing major depressive disorder even years later (Skodol et al., 2011). Treatment includes some of the medical and psychological treatments for depression (Cloninger & Svakic, 2009; Mulder, Frampton, Luty, & Joyce, 2009).

Controlled studies of attempts to treat groups of people with schizotypal personality disorder are few. There is now growing interest in treating this disorder, however, because it is being viewed as a precursor to schizophrenia (McClure et al., 2010). One study used a combination of approaches, including antipsychotic medication, community treatment (a team of support professionals providing therapeutic services), and social skills training, to treat the symptoms experienced by individuals with this disorder. Researchers found that this combination of approaches either reduced their symptoms or postponed the onset of later schizophrenia (Nordentoft et al., 2006). The idea of treating younger persons who have symptoms of schizotypal personality disorder with some combination of antipsychotic medication, cognitive behavior therapy, and social skills training in order to avoid the onset of schizophrenia is proving to be a promising prevention strategy (Nordentoft et al., 2015; Graff, McClure, & Siever, 2014; Correll, Hauser, Auther, & Cornblatt, 2010; Weiser, 2011).

Concept Check 12.2

Which personality disorders are described here?

1. Heidi trusts no one and wrongly believes other people want to harm her or cheat her out of her life earnings. She is sure her husband is secretly planning to leave her and take their three boys, although she has no proof. She no longer confides in friends or divulges any information to coworkers for fear that it will be used in a plot against her. She is usually tense and ready to argue about harmless comments made by family members. _____
2. Rebecca lives alone out in the country with her birds and has little contact with relatives or any other individuals in a nearby town. She is extremely concerned with pollution, fearing that harmful chemicals are in the air and water around her. She has developed her

own water purification system and makes her own clothes. If it is necessary for her to go outside, she covers her body with excessive clothing and wears a face mask to avoid the contaminated air.

3. Doug is a college student who has no close friends. He comes to class every day and sits in a corner and is sometimes seen having lunch alone on the park bench. Most students find him difficult to engage and complain about his lack of involvement in class activities but he appears indifferent to what others say. He has never had a girlfriend, and expresses no desire to have sex. He is meeting with a therapist only because his family tricked him into going.

Cluster B Personality Disorders

People diagnosed with the Cluster B personality disorders—antisocial, borderline, histrionic, and narcissistic—all have behaviors that have been described as dramatic, emotional, or erratic. These personality disorders are described next.

Antisocial Personality Disorder

People with **antisocial personality disorder** are among the most puzzling of the individuals a clinician will see in a practice and are characterized as having a history of failing to comply with social norms. They perform actions most of us would find unacceptable, such as stealing from friends and family. They also tend to be irresponsible, impulsive, and deceitful (De Brito & Hodgins, 2009). Robert Hare, a pioneer in the study of people with psychopathy (a subgroup of persons with antisocial personality disorder that we outline later in the chapter), describes them as “social predators who charm, manipulate, and ruthlessly plow their way through life, leaving a broad trail of broken hearts, shattered expectations, and empty wallets. Completely lacking in conscience and empathy, they selfishly take what they want and do as they please, violating social norms and expectations without the slightest sense of guilt or regret” (Hare, 1993, p. xi). Although first identified as a “medical” problem by Philippe Pinel at the start of the nineteenth century (1801/1962), descriptions of individuals with these antisocial tendencies can be found in ancient stone texts found in Mesopotamia dating as far back as 670 B.C. (Abdul-Hamid & Stein, 2012). Just who are these people with antisocial personality disorder? Consider the case of Ryan.

Ryan... The Thrill Seeker

I first met Ryan on his 17th birthday. Unfortunately, he was celebrating the event in a psychiatric hospital. He had been truant from school for several months and had gotten into some trouble; the local judge who heard his case had recommended psychiatric evaluation one more time, even though Ryan had been hospitalized six previous times, all for

problems related to drug use and truancy. He was a veteran of the system and already knew most of the staff. I interviewed him to assess why he was admitted this time and to recommend treatment.

My first impression was that Ryan was cooperative and pleasant. He pointed out a tattoo on his arm that he had made himself, saying that it was a “stupid” thing to have done and that he now regretted it. He regretted many things and was looking forward to moving on with his life. I later found out that he was never truly remorseful for anything.

Our second interview was quite different. In the 48 hours since our first interview, Ryan had done a number of things that showed why he needed a great deal of help. The most serious incident involved a 15-year-old girl named Ann who attended class with Ryan in the hospital school. Ryan had told her that he was going to get himself discharged, get in trouble, and be sent to the same prison Ann’s father was in, where he would rape her father. Ryan’s threat so upset Ann that she hit her teacher and several of the staff. When I spoke to Ryan about this, he smiled slightly and said he was bored and that it was fun to upset Ann. When I asked whether it bothered him that his behavior might extend her stay in the hospital, he looked puzzled and said, “Why should it bother me? She’s the one who’ll have to stay in this hell hole!”

Just before Ryan’s admittance, a teenager in his town was murdered. A group of teens went to the local cemetery at night to perform satanic rituals, and a young man was stabbed to death, apparently over a drug purchase. Ryan was in the group, although he did not stab the boy. He told me that they occasionally dug up graves to get skulls for their parties—not because they really believed in the devil but because it was fun and it scared the younger kids. I asked, “What if this was the grave of someone you knew, a relative or a friend? Would it bother you that strangers were digging up the remains?” He shook his head. “They’re dead, man; they don’t care. Why should I?”

Ryan told me he loved PCP, or “angel dust,” and that he would rather be dusted than anything else. He routinely made the 2-hour trip to New York City to buy drugs in a particularly dangerous neighborhood. He denied that he was ever nervous. This wasn’t machismo; he really seemed unconcerned.

Ryan made little progress. I discussed his future in family therapy sessions and we talked about his pattern of showing supposed regret and remorse and then stealing money from his parents and going back onto the street. Most of our discussions centered on trying to give his parents the courage to say no to him and not to believe his lies.

One evening, after many sessions, Ryan said he had seen the “error of his ways” and that he felt bad he had hurt his parents. If they would only take him home this one last time, he would be the son he should have been all these years. His speech moved his parents to tears, and they looked at me gratefully as if to thank me for curing

(Continued next page)

their son. When Ryan finished talking, I smiled, applauded, told him it was the best performance I had ever seen. His parents turned on me in anger. Ryan paused for a second, then he, too, smiled and said, “It was worth a shot!” Ryan’s parents were astounded that he had again tricked them into believing him; he hadn’t meant a word of what he had just said. Ryan was eventually discharged to a drug rehabilitation program. Within 4 weeks, he had convinced his parents to take him home, and within 2 days he had stolen all their cash and disappeared; he apparently went back to his friends and to drugs.

When he was in his 20s, after one of his many arrests for theft, he was diagnosed as having antisocial personality disorder. His parents never summoned the courage to turn him out or refuse him money, and he continues to con them into providing him with a means of buying more drugs. •

Defining Criteria

Hervey Cleckley (1941/1982), a psychiatrist who spent much of his career working with the “psychopathic personality,” identified a constellation of 16 major characteristics, most of which are personality traits and are sometimes referred to as the “Cleckley criteria.” Hare and his colleagues, building on the descriptive work of Cleckley, researched the nature of psychopathy (see, for example, Hare, 1970; Harpur, Hare, & Hakstian, 1989) and developed a 20-item checklist that serves as an assessment tool. Six of the criteria that Hare includes in his Revised Psychopathy Checklist (PCL-R) are as follows:

1. Glibness/superficial charm
2. Grandiose sense of self-worth
3. Pathological lying
4. Conning/manipulative
5. Lack of remorse or guilt
6. Callous/lack of empathy

(Hare et al., 2012; p. 480)

Clinical Description

Individuals with antisocial personality disorder tend to have long histories of violating the rights of others (Black, 2013; Hare et al., 2012). They are often described as being aggressive because they take what they want, indifferent to the concerns of other people. Lying and cheating seem to be second nature to them, and often they appear unable to tell the difference between the truth and the lies they make up to further their own goals. They show no remorse or concern over the sometimes devastating effects of their actions. Substance abuse is common in people with antisocial personality disorder and appears to be a lifelong pattern among these individuals (Hasin et al., 2011). The long-term outcome for people with antisocial personality disorder is usually poor, regardless of gender (Black, 2013; Colman et al., 2009). One classic study, for example, followed 1,000 delinquent and nondelinquent boys over a 50-year period (Laub & Vaillant, 2000). Many of the delinquent boys would today receive a diagnosis of conduct disorder, which you will see later may be a precursor to antisocial personality disorder in adults. The delinquent boys were more than twice as likely to die an unnatural death (for example, accident, suicide, or homicide) as their nondelinquent peers, which may be attributed to factors such as alcohol abuse and poor self-care (for example, infections and reckless behavior).

Antisocial personality disorder has had a number of names over the years. Philippe Pinel (1801/1962) identified what he called *manie sans délire* (mania without delirium) to describe people with unusual emotional responses and impulsive rages but no deficits in reasoning ability (Charland, 2010). Other labels have included moral insanity, egopathy, sociopathy, and psychopathy. A great deal has been written about these labels; we focus on the two that have figured most prominently in psychological research: **psychopathy** and **DSM-5**’s antisocial personality disorder. There continues to be debate in the field if these really are two distinct disorders (Douglas et al., 2015; Wall, Wygant, & Sellbom, 2015; Werner, Few, & Buckholtz, 2015; Anderson, Sellbom, Wygant, Salekin, & Krueger, 2014; Venables, Hall, & Patrick, 2014).

With some training, clinicians are able to gather information from interviews with a person, along with material from significant others or institutional files (for example, prison records), and assign the person scores on the checklist, with high scores indicating psychopathy (Hare & Neumann, 2006).

The Cleckley/Hare criteria focus primarily on underlying *personality traits* (for example, being self-centered or manipulative). Earlier versions of the *DSM* criteria for antisocial personality focused almost entirely on observable *behaviors* (for example, “impulsively and repeatedly changes employment, residence, or sexual partners”). The framers of the previous *DSM* criteria felt that trying to assess a personality trait—for example, whether someone was manipulative—would be more difficult than determining whether the person engaged in certain behaviors, such as repeated fighting. The *DSM-5*, however, moved closer to the trait-based criteria and includes some of the same language included in Hare’s PCL-R (e.g., callousness, manipulativeness, and deceitfulness). Unfortunately, research on identifying persons with antisocial personality disorder suggests that this new definition reduces the reliability of the diagnosis (Regier et al., 2013). Additional work will be needed to improve the reliability of this diagnosis while maintaining the core traits that characterize these individuals.

Antisocial Personality Disorder and Criminality

Although Cleckley did not deny that many psychopaths are at greatly elevated risk for criminal and antisocial behaviors, he did emphasize that some have few or no legal or interpersonal difficulties. In other words, some psychopaths are not criminals and some do not display outward aggressiveness that was included in the *DSM-IV-TR* criteria for antisocial personality disorder. What separates many in this group from those who get into trouble with the law may be their intelligence quotient (IQ). In a classic prospective, longitudinal study, White, Moffitt, and Silva (1989) followed almost 1,000 children, beginning at age 5, to see what predicted antisocial behavior at age 15. They found that, of the 5-year-olds determined

to be at high risk for later delinquent behavior, 16% did indeed have run-ins with the law by the age of 15, and 84% did not. What distinguished these two groups? In general, the at-risk children with lower IQs were the ones who got in trouble. This suggests that having a higher IQ may help protect some people from developing more serious problems, or it may at least prevent them from getting caught.

Some psychopaths function quite successfully in certain segments of society (for example, politics, business, and entertainment). Because of the difficulty in identifying these people, such “successful” or “subclinical” psychopaths (who meet some of the criteria for psychopathy) have not been the focus of much research. In a clever exception, Widom (1977; pg. 677) recruited a sample of subclinical psychopaths through advertisements in underground newspapers that appealed to those with many of the major personality characteristics of psychopathy. For example, one of the advertisements read as follows:

Wanted: charming, aggressive, carefree people who are impulsively irresponsible but are good at handling people and at looking after number one.

Widom found that her sample appeared to possess many of the same characteristics as imprisoned psychopaths; for example, a large percentage of them received low scores on questionnaire measures of empathy and socialization, and their parents tended to have higher rates of psychopathology, including alcoholism. But many of these individuals had stable occupations and had managed to stay out of prison. Widom’s study, although lacking a control group, shows that at least some individuals with psychopathic personality traits avoid repeated contact with the legal system and may even function successfully in society.

Identifying psychopaths among the criminal population seems to have important implications for predicting their future criminal behavior (Vitacco, Neumann, & Pardini, 2014). As you can imagine, having personality characteristics such as a lack of remorse and impulsivity can lead to difficulty staying out of trouble with the legal system. In general, most research has found that people who score high on measures of psychopathy commit crimes at a higher rate than those with lower scores and are at greater risk for more violent crimes and recidivism (repeating offenses) (e.g., Widiger, 2006), although some recent research has found psychopathy to be a less reliable predictor of criminality (Collins, Andershed, & Pardini, 2015).

As we review the literature on antisocial personality disorder, note that the people included in the research may be members of only one of the three groups (those with antisocial personality disorder, psychopathy, and criminals) we have described. For example, genetic research is usually conducted with criminals because they

and their families are easier to identify than members of the other groups. As you now know, the criminal group may include people other than those with anti-social personality disorder or psychopathy. Keep this in mind as you read on.

Conduct Disorder

It is important to note the developmental nature of antisocial behavior. *DSM-5* provides a separate diagnosis for children who engage in behaviors that violate society’s norms: *conduct disorder*. It provides for the designation of two subtypes; *childhood-onset type* (the onset of at least one criterion characteristic of CD prior to age 10 years) or *adolescent-onset type* (the absence of any criteria characteristic of CD prior to age 10 years). An additional subtype, new to the *DSM-5*, is called “with a callous-unemotional presentation” (Barry, Golmaryami, Rivera-Hudson, & Frick, 2012). This designation is an indication that the young person presents in a way that suggests personality characteristics similar to an adult with psychopathy.

Many children with conduct disorder—most often diagnosed in boys—become

juvenile offenders and tend to become involved with drugs. Ryan fits into this category. More important, the lifelong pattern of antisocial behavior is evident because young children who display antisocial behavior are likely to continue these behaviors as they grow older (Black, 2013; Frick, 2012). Data from long-term follow-up research indicate that many adults with antisocial personality disorder or psychopathy had conduct disorder as children (Robins, 1978; Salekin, 2006; Davidson, 2014; Kasen, Cohen, Skodol, Johnson, & Brook, 2014); the likelihood of an adult having antisocial personality disorder increases if, as a child, he or she had both conduct disorder and attention deficit/hyperactivity disorder (Biederman, Mick, Faraone, & Burback, 2001; Moffitt, Caspi, Rutter, & Silva, 2001). In many cases, the types of norm violations that an adult would engage in—irresponsibility regarding work or family—appear as younger versions in conduct disorder, such as truancy from school or running away from home. Some children with conduct disorder do feel remorseful about their behavior, which is why *DSM-5* included the qualifier “with a callous-unemotional presentation” in order to better differentiate these two groups.

TABLE 12.4

Diagnostic Criteria for Antisocial Personality Disorder

- A.** A pervasive pattern of disregard for and violation of the rights of others, occurring since age 15 years, as indicated by three (or more) of the following:
- 1.** Failure to conform to social norms with respect to lawful behaviors, as indicated by repeatedly performing acts that are grounds for arrest.
 - 2.** Deceitfulness, as indicated by repeated lying, use of aliases, or conning others for personal profit or pleasure.
 - 3.** Impulsivity or failure to plan ahead.
 - 4.** Irritability and aggressiveness, as indicated by repeated physical fights or assaults.
 - 5.** Reckless disregard for safety of self or others.
 - 6.** Consistent irresponsibility, as indicated by repeated failure to sustain consistent work behavior or honor financial obligations.
 - 7.** Lack of remorse, as indicated by being indifferent to or rationalizing having hurt, mistreated, or stolen from another.
- B.** The individual is at least age 18 years.
- C.** There is evidence of conduct disorder with onset before age 15 years.
- D.** The occurrence of antisocial behavior is not exclusively during the course of schizophrenia or bipolar disorder.

There is a tremendous amount of interest in studying a group that causes a great deal of harm to society. Research has been conducted for a number of years, and so we know a great deal more about antisocial personality disorder than about most of the other personality disorders.

Genetic Influences

Family, twin, and adoption studies all suggest a genetic influence on both antisocial personality disorder and criminality (Reichborn-Kjennerud et al., 2015; Checknita et al., 2015; Ficks & Waldman, 2014; Delisi & Vaughn, 2015; Kendler et al., 2014). For example, in a classic study, Crowe (1974) examined children whose mothers were felons and who were later adopted by other families and compared them with adopted children of normal mothers. All were separated from their mothers as newborns, minimizing the possibility that environmental factors from their biological families were responsible for the results. Crowe found that the adopted offspring of felons had significantly higher rates of arrests, conviction, and antisocial personality than did the adopted offspring of normal mothers, which suggests at least some genetic influence on criminality and antisocial behavior.

Crowe found something else quite interesting, however: The adopted children of felons who themselves later became criminals had spent more time in interim orphanages than either the adopted children of felons who did not become criminals or the

adopted children of normal mothers. As Crowe points out, this suggests a gene-environment interaction; in other words, genetic factors may be important only in the presence of certain environmental influences (alternatively, certain environmental influences are important only in the presence of certain genetic predispositions). Genetic factors may present a vulnerability, but actual development of criminality may require environmental factors, such as a deficit in early, high-quality contact with parents or parent surrogates.

This gene-environment interaction was demonstrated most clearly by Cadoret, Yates, Troughton, Woodworth, and Stewart (1995), who studied adopted children and their likelihood of developing conduct problems. If the children's biological parents had a history of antisocial personality disorder and their adoptive families exposed them to chronic stress through marital, legal, or psychiatric problems, the children were at greater risk for conduct problems. Again, research shows that genetic influence does not necessarily mean certain disorders are inevitable. Genetic research on conduct disorder points to an interaction between genetic and environmental influences, such as academic difficulty, peer problems, low family income, neglect, and harsh discipline from parents (Beaver, Barnes, May, & Schwartz, 2011; Kendler, Aggen, & Patrick, 2013; Silberg, Maes, & Eaves, 2012; Knopik et al., 2014).

If you remember back to Chapter 4, we introduced the concept of an *endophenotype*—underlying aspects of a disorder that might be more directly influenced by genes. In the case of antisocial personality disorder, gene researchers are looking for genetic differences that may influence factors such as serotonin and dopamine levels or the relative lack of anxiety or fear seen in these individuals (which we discuss next) (Hare et al., 2012). Although this research is at its early stages, it is refining the search for genes—not for ones that “cause” antisocial personality disorder but for genes that create the unusual aspects of an antisocial personality, such as fearlessness, aggressiveness, impulsivity, and lack of remorse.

Neurobiological Influences

A great deal of research has focused on neurobiological influences that may be specific to antisocial personality disorder. One thing seems clear: General brain damage does not explain why some people become psychopaths or criminals; these individuals appear to score as well on neuropsychological tests as the rest of us (Hart, Forth, & Hare, 1990). Such tests are designed to detect only significant damage in the brain, however, and will not pick up subtle changes in chemistry or structure that could affect behavior.

Arousal Theories

The fearlessness, seeming insensitivity to punishment, and thrill-seeking behaviors characteristic of those with antisocial personality disorder (especially those with psychopathy) sparked interest in what neurobiological processes might contribute to these unusual reactions. Early theoretical work on people with antisocial personality disorder emphasized two hypotheses: the underarousal hypothesis and the fearlessness hypothesis. According to the *underarousal hypothesis*, psychopaths have abnormally low levels of cortical arousal (Sylvers, Ryan, Alden,

TABLE 12.5

Diagnostic Criteria for Conduct Disorder

- A.** A repetitive and persistent pattern of behavior in which the basic rights of others or major age-appropriate societal norms or rules are violated, as manifested by the presence of at least three of the following 15 criteria in the past 12 months from any of the categories below, with at least one criterion present in the past 6 months:

Aggression to People and Animals

1. Often bullies, threatens, or intimidates others.
2. Often initiates physical fights.
3. Has used a weapon that can cause serious physical harm to others (e.g., a bat, brick, broken bottle, knife, gun).
4. Has been physically cruel to people.
5. Has been physically cruel to animals.
6. Has stolen while confronting a victim (e.g., mugging, purse snatching, extortion, armed robbery).
7. Has forced someone into sexual activity.

Destruction of Property

8. Has deliberately engaged in fire setting with the intention of causing serious damage.
9. Has deliberately destroyed others' property (other than by fire setting).

Deceitfulness or Theft

10. Has broken into someone else's house, building, or car.
11. Often lies to obtain goods or favors or to avoid obligations (i.e., "cons" others).
12. Has stolen items of nontrivial value without confronting a victim (e.g., shoplifting, but without breaking and entering; forgery).

Serious Violations of Rules

13. Often stays out at night despite parental prohibitions, beginning before age 13 years.
14. Has run away from home overnight at least twice while living in the parental or parental surrogate home, or once without returning for a lengthy period.
15. Is often truant from school, beginning before age 13 years.

- B.** The disturbance in behavior causes clinically significant impairment in social, academic, or occupational functioning.

- C.** If the individual is age 18 years or older, criteria are not met for antisocial personality disorder.

Specify whether:

Childhood-onset type: Individuals show at least one symptom characteristic of conduct disorder prior to age 10 years.

Adolescent-onset type: Individuals show no symptom characteristic of conduct disorder prior to age 10 years.

Unspecified onset: Criteria for a diagnosis of conduct disorder are met, but there is not enough information available to determine whether the onset of the first symptom was before age 10 years.

Specify current severity:

Mild: Few if any conduct problems in excess of those required to make the diagnosis are present, and conduct problems cause relatively minor harm to others (e.g., lying, truancy, staying out after dark without permission, other rule breaking).

Moderate: The number of conduct problems and the effect on others are intermediate between those specified "mild" and those in "severe" (e.g., stealing without confronting a victim, vandalism).

Severe: Many conduct problems in excess of those required to make the diagnosis are present, or conduct problems cause considerable harm to others (e.g., forced sex, physical cruelty, use of a weapon, stealing while confronting a victim, breaking and entering)

& Brennan, 2009). There appears to be an inverted U-shaped relation between arousal and performance, the Yerkes-Dodson curve, which suggests people with either high or low levels of arousal tend to experience negative affect and perform poorly in many situations, whereas individuals with intermediate levels of arousal tend to be relatively content and perform satisfactorily in most situations.

According to the underarousal hypothesis, the abnormally low levels of cortical arousal characteristic of psychopaths are the primary cause of their antisocial and risk-taking behaviors; they seek stimulation to boost their chronically low levels

of arousal. This means that Ryan lied, took drugs, and dug up graves to achieve the same level of arousal we might get from talking on the phone with a good friend or watching television. Several researchers have examined childhood and adolescent psychophysiological predictors of adult antisocial behavior and criminality. Raine, Venables, and Williams (1990), for example, assessed a sample of 15 year olds on a variety of autonomic and central nervous system variables. They found that future criminals had lower skin conductance activity, lower heart rate during rest periods, and more slow-frequency brain wave activity, all indicative of low arousal.

According to the fearlessness hypothesis, psychopaths possess a higher threshold for experiencing fear than most other individuals (Lykken, 1957, 1982). In other words, things that greatly frighten the rest of us have little effect on the psychopath (Syngelaki, Fairchild, Moore, Savage, & Goozen, 2013). Remember that Ryan was unafraid of going alone to dangerous neighborhoods to buy drugs. According to proponents of this hypothesis, the fearlessness of the psychopath gives rise to all the other major features of the syndrome.

Theorists have tried to connect what we know about the workings of the brain with clinical observations of people with antisocial personality disorder, especially those with psychopathy. Several theorists have applied Jeffrey Gray's (1987) model of brain functioning to this population (Fowles, 1988; Quay, 1993). According to Gray, three major brain systems influence learning and emotional behavior: the behavioral inhibition system (BIS), the reward system, and the fight/flight system. Two of these systems, the BIS and the reward system, have been used to explain the behavior of people with psychopathy. The BIS is responsible for our ability to stop or slow down when we are faced with impending punishment, nonreward, or novel situations; activation of this system leads to anxiety and frustration. The BIS is thought to be located in the septohippocampal system and involves the noradrenergic and serotonergic neurotransmitter systems. The reward system is responsible for how we behave—in particular, our approach to positive rewards—and is associated with hope and relief. This system probably involves the dopaminergic system in the mesolimbic area of the brain, which we previously noted as the “pleasure pathway” for its role in substance use and abuse (see Chapter 11).

If you think about the behavior of psychopaths, the possible malfunctioning of these systems is clear. An imbalance between the BIS and the reward system may make the fear and anxiety produced by the BIS less apparent and the positive feelings associated with the reward system more prominent

(Hoppenbrouwers, Neumann, Lewis, & Johansson, 2015; Byrd, Loeber, & Pardini, 2014; Levenston, Patrick, Bradley, & Lang, 2000; Quay, 1993). Theorists have proposed that this type of neurobiological dysfunction may explain why psychopaths aren't anxious about committing the antisocial acts that characterize their disorder.

Researchers continue to explore how differences in neurotransmitter function (for example, serotonin) and neurohormone function (for example, androgens such as testosterone and the stress neurohormone cortisol) in the brains of these individuals can explain the callousness, superficial charm, lack of remorse, and impulsivity that characterize people with psychopathy. Integrative theories that link these differences to both genetic and environmental influences are just now beginning to be outlined (DeLisi & Vaughn, 2015; Poppa & Bechara, 2015; Hyde, Shaw, & Hariri, 2013; Waller, Dotterer, & Hyde, 2015; Hare et al., 2012) and may lead to better understanding and treatments for this debilitating disorder.

Psychological and Social Dimensions

What goes on in the mind of a psychopath? In one of several studies of how psychopaths process reward and punishment, Newman, Patterson, and Kosson (1987) set up a card-playing task on a computer; they provided five-cent rewards and fines for correct and incorrect answers to psychopathic and nonpsychopathic criminal offenders. The game was constructed so that at first players were rewarded about 90% of the time and fined only about 10% of the time. Gradually, the odds changed until the probability of getting a reward was 0%. Despite feedback that reward was no longer forthcoming, the psychopaths continued to play and lose, while those without psychopathy stopped playing. As a result of this and other studies, the researchers hypothesized that once psychopaths set their sights on a reward goal, they are less likely than nonpsychopaths to be deterred despite signs the goal is no longer achievable (Dvorak-Bertscha, Curtin, Rubinstein, & Newman, 2009). Again, considering the reckless and daring behavior of some psychopaths (robbing banks without a mask and getting caught immediately), failure to abandon an unattainable goal fits the overall picture.

Gerald Patterson's influential work suggests that aggression in children with antisocial personality disorder may escalate, partly as a result of their interactions with their parents (Granic & Patterson, 2006; Patterson, 1982). He found that the parents often give in to the problem behaviors displayed by their children. For example, a boy's parents ask him to make his bed and he refuses. One parent yells at the boy. The boy yells back and becomes abusive. At some point, his interchange becomes so aversive that the parent stops fighting and walks away, thereby ending the fight but also letting the son not make his bed. Giving in to these problems results in short-term gains for both the parent (calm is restored in the house) and the child (he gets what he wants), but it results in continuing problems. The child has learned to continue fighting and not give up, and the parent learns that the only way to “win” is to withdraw all demands. This “coercive family process” combines with other factors, such as genetic influences, parental depression, poor monitoring of their child's activities, and less parental

involvement, to help maintain the aggressive behaviors (Chronis et al., 2007; Patterson, DeBaryshe, & Ramsey, 1989). Coercive parenting—along with genetics—appears to be at least modestly involved with the callous-unemotional traits that seem related to later psychopathy (Waller et al., 2015).

Although little is known about which environmental factors play a direct role in causing antisocial personality disorder and psychopathy (as opposed to childhood conduct disorders), evidence from adoption studies strongly suggests that shared environmental factors—that tend to make family members similar—are important to the etiology of criminality and perhaps antisocial personality disorder. For example, in the adoption study by Sigvardsson, Cloninger, Bohman, and von Knorring (1982), low social status of the adoptive parents increased the risk of non-violent criminality among females. Like children with conduct disorders, individuals with antisocial personality disorder come from homes with inconsistent parental discipline (see, for example, Robins, 1966).

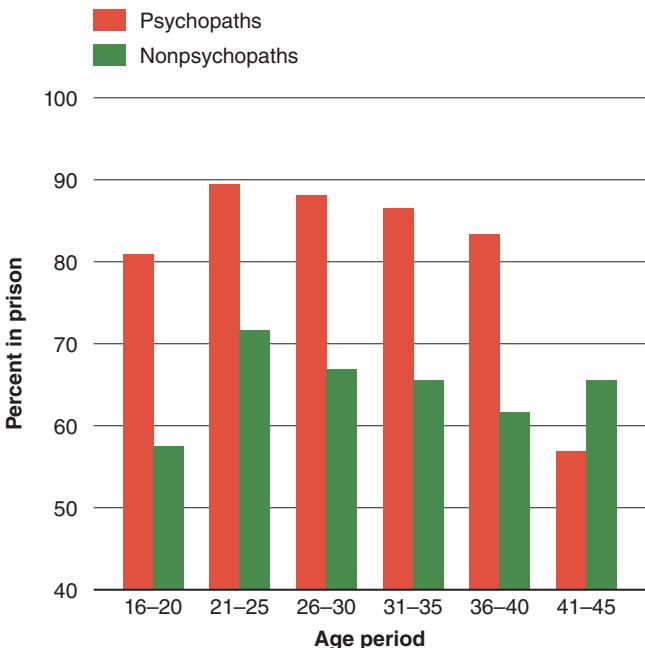

Developmental Influences

As children move into adulthood, the forms of antisocial behaviors change—from truancy and stealing from friends to extortion, assaults, armed robbery, or other crimes. Fortunately, clinical lore, as well as scattered empirical reports (Robins, 1966), suggest that rates of antisocial behavior begin to decline rather markedly around the age of 40. In their classic study, Hare, McPherson, and Forth (1988) provided empirical support for this phenomenon. They examined the conviction rates of male psychopaths and male nonpsychopaths who had been incarcerated for a variety of crimes. The researchers found that between the ages of 16 and 45 the conviction rates of nonpsychopaths remained relatively constant. In contrast, the conviction rates of psychopaths remained relatively constant up until about 40, at which time they decreased markedly (see Figure 12.2). Why antisocial behavior often declines around middle age remains unanswered (Hare et al., 2012).

An Integrative Model

How can we put all this information together to get a better understanding of people with antisocial personality disorder? Remember that the research just discussed sometimes involved people labeled as having antisocial personality disorder but at other times included people labeled as psychopathic or even criminals. Whatever the label, it appears these people have a genetic vulnerability to antisocial behaviors and personality traits. As you have seen, genetics may lead to differences in neurotransmitter and neurohormone (dopamine and serotonin) function that influences aggressiveness, as well as differences in neurohormone (cortisol) function that affects the way people deal with stress; these brain differences may lead to personality traits such as callousness, impulsivity, and aggressiveness that characterize people with psychopathy (Hare et al., 2012).

One potential gene–environment interaction may be seen in the role of fear conditioning in children. If you remember back

● FIGURE 12.2

to Chapter 1 and Chapter 5, we discussed how we learn to fear things that can harm us (for example, a hot stove) through the pairing of an unconditioned stimulus (e.g., heat from burner) and a conditioned stimulus (e.g., parent's warning to stay away), resulting in avoidance of the conditioned stimulus. But what if this conditioning is somehow impaired and you do not learn to avoid things that can harm you? An important study looked at whether abnormal responses to fear conditioning as a young child could be responsible for later antisocial behavior in adults (Gao, Raine, Venables, Dawson, & Mednick, 2010). This large 20-year study assessed fear conditioning in a group of 1,795 children at age 3, and then looked to see who had a criminal record at age 23. They found that offenders showed significantly reduced fear conditioning at age 3 compared with matched comparison participants, with many of these children showing no fear conditioning at all. Deficits in amygdala functioning are thought to make individuals unable to recognize cues that signal threat, making them relatively fearless, which suggests that these children had problems in this area of the brain (Sterzer, 2010). These findings may point to a mechanism by which genetic influences (leading to damage in the amygdala) interact with environmental influences (learning to fear threats) to produce adults who are relatively fearless and therefore engage in behaviors that cause harm to themselves and others.

Biological influences further interact with other environmental experiences such as early childhood adversity. In a family that may already be under stress because of divorce or substance abuse, there may be an interaction style that encourages antisocial behavior on the part of the child (Thomas, 2009).

The child's antisocial and impulsive behavior—partly caused by the child's difficult temperament and impulsivity (Chronis et al., 2007; Kochanska, Aksan, & Joy, 2007)—alienates other children who might be good role models and attracts others who encourage antisocial behavior. These behaviors may also result in the child's dropping out of school and a poor occupational history in adulthood, which help create increasingly frustrating life circumstances that further incite acts against society (Thomas, 2009).

This is, admittedly, an abbreviated version of a complex scenario. The important element is that in this integrative model of antisocial behavior, biological, psychological, and cultural factors combine in intricate ways to create someone like Ryan.

Treatment

One of the major problems with treating people in this group is typical of numerous personality disorders: They rarely identify themselves as needing treatment. Because of this, and because they can be manipulative even with their therapists, most clinicians are pessimistic about the outcome of treatment for adults who have antisocial personality disorder, and there are few documented success stories (National Collaborating Centre for Mental Health, 2010). In general, therapists agree with incarcerating these people to deter future antisocial acts. Clinicians encourage identification of high-risk children so that treatment can be attempted before they become adults (National Collaborating Centre for Mental Health, 2010; Thomas, 2009). One large study with violent offenders found that cognitive behavior therapy could reduce the likelihood of violence 5 years after treatment (Olver, Lewis, & Wong, 2013). Importantly, however, treatment success was negatively correlated with ratings on the PCL-R for traits of "selfish, callous, and remorseless use of others." In other words, the higher the score on this trait (which we have seen is related to psychopathy), the less successful this group was in refraining from violence after their treatment.

The most common treatment strategy for children involves parent training (Scott, Briskman, & O'Connor, 2014; Presnall, Webster-Stratton, & Constantino, 2014; Patterson, 1986). Parents are taught to recognize behavior problems early and to use praise and privileges to reduce problem behavior and encourage prosocial behaviors. Treatment studies typically show that these types of programs can significantly improve the behaviors of many children who display antisocial behaviors (Conduct Problems Prevention Research Group, 2010). A number of factors, however, put families at risk either for not succeeding in treatment or for dropping out early; these include cases with a high degree of family dysfunction, socioeconomic disadvantage, high family stress, a parent's history of antisocial behavior, and severe conduct disorder on the part of the child (Kaminski, Valle, Filene, & Boyle, 2008).

Prevention

We have seen a dramatic increase in the amount of research on prevention strategies focused on children at risk for later antisocial personality disorder. The aggressive behaviors of young children are remarkably stable, meaning that children who hit, insult, and threaten others are likely to continue these behaviors as they grow older. Unfortunately, these behaviors become more serious over time and, though some individuals become less aggressive after adolescence (Jennings & Reingle, 2012) are oftentimes early signs of the homicides and assaults seen among some adults (Wright, Tibbetts, & Daigle, 2015; Eron & Huesmann, 1990; Singer & Flannery, 2000).

Approaches to change this aggressive course are being implemented mainly in school and preschool settings and emphasize behavioral supports for good behavior and skills training to improve social competence (Reddy, Newman, De Thomas, & Chun, 2009). A number of types of these programs are under evaluation, and the results look promising. For example, research using parent training for young children (toddlers from 1½ to 2½ years) suggests that early intervention may be particularly helpful (Shaw, Dishion, Supplee, Gardner, & Arnds, 2006). Aggression can be reduced and social competence (for example, making friends and sharing) can be improved among young children, and these results generally are maintained over a few years (Conduct Problems Prevention Research, 2010; Reddy et al., 2009). One recent study found that the association between childhood conduct disorder and adult antisocial behavior was weaker among those adolescents who participated in high school sports, pointing to the possible utility of activities that disrupt delinquent habits (Samek, Elkins, Keyes, Iacono, & McGue, 2015). It is too soon to assess the impact of targeted prevention programs on adult antisocial behaviors typically observed among people with this personality disorder (Ingoldsby, Shelleby, Lane, & Shaw, 2012). Given the ineffectiveness of treatment for adults, however, prevention may be the best approach to this problem.

Children with conduct disorder may become adults with antisocial personality disorder.

Borderline Personality Disorder

People with **borderline personality disorder** lead tumultuous lives. Their moods and relationships are unstable, and usually they have a poor self-image. These people often feel empty and are at great risk of dying by their own hands. Consider the case of Claire.

Claire... A Stranger Among Us

I have known Claire for more than 40 years and have watched her through the good but mostly bad times of her often shaky and erratic life as a person with borderline personality disorder. Claire and I went to school together from the eighth grade through high school, and we've kept in touch periodically. My earliest memory of her is of her hair, which was cut short and rather unevenly. She told me that when things were not going well, she cut her own hair severely, which helped to "fill the void." I later found out that the long sleeves she usually wore hid scars and cuts that she had made herself.

Claire was the first of our friends to smoke. What was unusual about this and her later drug use was not that they occurred (this was in the 1960s when "If it feels good, do it" hadn't been replaced by "Just say no") or that they began early; it was that she didn't seem to use them to get attention, like everyone else. Claire was also one of the first whose parents divorced, and both of them seemed to abandon her emotionally. She later told me that her father was an alcoholic who had regularly beaten her and her mother. She did poorly in school and had a low opinion of herself. She often said she was stupid and ugly, yet she was neither.

Throughout our school years, Claire left town periodically, without any explanation. I learned many years later that she was in psychiatric facilities to get help with her suicidal depression. She often threatened to kill herself, although we didn't guess that she was serious.

In our later teens, we all drifted away from Claire. She had become increasingly unpredictable, sometimes berating us for a perceived slight ("You're walking too fast. You don't want to be seen with me!"), and at other times desperate to be around us. We were confused by her behavior. With some people, emotional outbursts can bring you closer together. Unfortunately for Claire, these incidents and her overall demeanor made us feel that we didn't know her. As we all grew older, the "void" she described in herself became overwhelming and eventually shut us all out.

Claire married twice, and both times had passionate but stormy relationships interrupted by hospitalizations. She tried to stab her first husband during a particularly violent rage. She tried a number of drugs but mainly used alcohol to "deaden the pain."

Now, in her mid-50s, things have calmed down some, although she says she is rarely happy. Claire does feel a little better about herself and is doing well as a travel agent. Although she is seeing someone, she is reluctant to become involved because of her personal history. Claire was ultimately diagnosed with depression and borderline personality disorder. •

Clinical Description

Borderline personality disorder is one of the most common personality disorders observed in clinical settings; it is observed in every culture and is seen in about 1% to 2% of the general population (Torgersen, 2012). Claire's life illustrates the instability characteristic of people with borderline personality disorder. They tend to have turbulent relationships, fearing abandonment but lacking control over their emotions (Hooley, Cole, & Gironde, 2012). They often engage in behaviors that are suicidal, self-mutilative, or both, cutting, burning, or punching themselves. Claire sometimes used her cigarette to burn her palm or forearm, and she carved her initials in her arm. As mentioned previously, a significant proportion—nearly 10%—die by suicide (Gunderson, 2011; Björkenstam, Björkenstam, Holm, Gerdin, & Ekselius, 2015). Fortunately, the long-term outcome for people with borderline personality disorder is encouraging (Zanarini, Frankenburg, Reich, & Fitzmaurice, 2012). Approximately nine out of ten patients with borderline personality disorder achieve remission in the decade after seeking treatment (Gunderson et al., 2011; Keuroghlian et al., 2015).

People with this personality disorder are often intense, going from anger to deep depression in a short time. Dysfunction in the area of emotion is sometimes considered one of the core features of borderline personality disorder (Linehan & Dexter-Mazza, 2008) and is one of the best predictors of suicide in this group (McGirr et al., 2009). The characteristic of instability (in emotion, interpersonal relationships, self-concept, and behavior) is seen as a core feature with some describing this group as being "stably unstable" (Hooley et al., 2012).

This instability extends to impulsivity, which can be seen in their drug abuse and self-mutilation. Although not so obvious as to why, the self-injurious behaviors, such as cutting, sometimes are described as tension-reducing by people who engage in these behaviors (McKenzie & Gross, 2014; Nock, 2010). Claire's empty feeling is also common; these people are sometimes described as chronically bored and have difficulties with their own identities (Linehan & Dexter-Mazza, 2008). The mood disorders we discussed in Chapter 7 are common among people with borderline personality disorder; one study of inpatients with this disorder found that more than 80% also had major depression and approximately 10% had bipolar II disorder (Zanarini et al., 1998). Eating disorders are also common, particularly bulimia (see Chapter 8): Approximately 25% of people with borderline personality disorder also have bulimia, while 20% meet criteria for anorexia (Zanarini et al., 1998). Up to 64% of the people with borderline personality disorder are also diagnosed with at least one substance use disorder (Zanarini et al., 1998). As with antisocial personality disorder, people with borderline personality disorder tend to improve during their 30s and 40s, although they may continue to have difficulties into old age (Zanarini et al., 2012).

Causes

The results from numerous family studies suggest that borderline personality disorder is more prevalent in families with the disorder

Borderline personality disorder is often accompanied by self-mutilation.

and somehow linked with mood disorders (Amad, Ramoz, Thomas, Jardri, & Gorwood, 2014). Studies of monozygotic (identical) and dizygotic (fraternal) twins indicated a higher concordance rate among monozygotic twins, further supporting the role of genetics in the expression of borderline personality disorder (Calati, Gressier, Balestri, & Serretti, 2013).

The emotional reactivity that is a central aspect of borderline personality disorder has led researchers to look at this personality trait for clues about inherited influences (endophenotypes). Important genetic studies are investigating genes associated with the neurochemical serotonin because dysfunction in this system has been linked to the emotional instability, suicidal behaviors, and impulsivity seen in people with this disorder (Soloff, Chiappetta, Mason, Becker, & Price, 2014; Joyce, Stephenson, Kennedy, Mulder, & McHugh, 2013). This research is in its early stages, and there are, as yet, no solid answers for how genetic differences lead to the symptoms of borderline personality disorder (Amad et al., 2014).

Neuroimaging studies, designed to locate areas in the brain contributing to borderline personality disorder, point to the limbic network (Schulze, Schmahl, & Niedtfeld, 2016; Stone,

DSM
5

TABLE 12.6

Diagnostic Criteria for Borderline Personality Disorder

- A pervasive pattern of instability of interpersonal relationships, self-image, and affects, and marked impulsivity, beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:
1. Frantic efforts to avoid real or imagined abandonment. (Note: Do not include suicidal or self-mutilating behavior covered in Criterion 5.)
 2. A pattern of unstable and intense interpersonal relationships characterized by alternating between extremes of idealization and devaluation.
 3. Identity disturbance: markedly and persistently unstable self-image or sense of self.
 4. Impulsivity in at least two areas that are potentially self-damaging (e.g., spending, sex, substance abuse, reckless driving, binge eating). (Note: Do not include suicidal or self-mutilating behavior covered in criterion 5.)
 5. Recurrent suicidal behavior, gestures, or threats, or self-mutilating behavior.
 6. Affective instability due to a marked reactivity of mood (e.g., intense episodic dysphoria, irritability, or anxiety usually lasting a few hours and only rarely more than a few days).
 7. Chronic feelings of emptiness.
 8. Inappropriate, intense anger or difficulty controlling anger (e.g., frequent displays of temper, constant anger, recurrent physical fights).
 9. Transient, stress-related paranoid ideation or severe dissociative symptoms.

From American Psychiatric Association. (2013). *Diagnostic and statistical manual of mental disorders* (5th ed.). Washington, DC

2013). Significantly, this area in the brain is involved in emotion regulation and dysfunctional serotonin transmission, linking these findings with genetic research. Low serotonergic activity is involved with the regulation of mood and impulsivity, making it a target for extensive study in this group (Hooley et al., 2012).

To further “zero in” on the nature of this disorder, it is necessary to refine the concept of emotional reactivity in borderline personality disorder. When asked about their experiences, people with this disorder will report greater emotional fluctuations and greater emotional intensity, primarily in negative emotions such as anger and anxiety (Dixon-Gordon et al., 2015; Chapman, Dixon-Gordon, Butler, & Walters, 2015; Linehan, 2015). Some research—using “morphing” technology—is looking at how sensitive these individuals are to the emotions of others. One study tested how people with and without borderline personality disorder could correctly identify the emotion of a face that was morphing on screen (changing slowly from a neutral expression to an emotional expression such as anger) and found those with borderline personality disorder were more accurate than controls (Fertuck et al., 2009).

In one study, the emotion “shame” was explored in people with this disorder (Rusch et al., 2007). For example, people were given the following scenario:

You attend your coworker’s housewarming party and you spill red wine on a new cream-colored carpet, but you think no one notices.

Participants are then asked to say which of the following four reactions they would have:

- “You would wish you were anywhere but at the party.” (indicating shame proneness)
- “You would stay late to help clean up the stain after the party.” (guilt proneness)
- “You think your coworker should have expected some accidents at such a big party.” (detachment)
- “You would wonder why your coworker chose to serve red wine with the new light carpet.” (externalization) (p. 317)

This study found that women with borderline personality disorder (no men were included in this study) were more likely to report shame than healthy women and women with social phobia. Importantly, the researchers also found that this elevated tendency to experience shame was associated with low self-esteem, low quality of life, and high levels of anger and hostility (Rusch et al., 2007). Shame has also been found to be related to self-inflicted injury (for example, cutting) in this population (Wiklander et al., 2012). This incorporation of shame in interpreting certain situations has also been observed in children and youth with characteristics of borderline personality disorder (Hawes, Helyer, Herlianto, & Willing, 2013).

Cognitive factors in borderline personality disorder are just beginning to be explored. Here, the questions are, just how do people with this disorder process information, and does this contribute to their difficulties? One study that looked at the thought processes of these individuals asked people with and without borderline personality disorder to look at words projected on a computer screen and try to remember some of the words and try to forget others (Korfine & Hooley, 2000). When the words were not related to the symptoms of borderline personality disorder—for example, “celebrate,” “charming,” and “collect”—both groups performed equally well. However, when they were presented with words that might be relevant to the disorder—for example, “abandon,” “suicidal,” and “emptiness”—individuals with borderline personality disorder remembered more of these words despite being instructed to forget them. This preliminary evidence for a memory bias may hold clues to the nature of this disorder and may someday be helpful in designing more effective treatment (Winter, Elzinga, & Schmahl, 2013; Baer, Peters, Eisenlohr-Moul, Geiger, & Sauer, 2012).

An important environmental risk factor in a gene–environment interaction explanation for borderline personality disorder is the possible contribution of early trauma, especially sexual and physical abuse. Numerous studies show that people with this disorder are more likely to report abuse than are healthy individuals or those with other psychiatric conditions (see, for example, Bandelow et al., 2005; Kuo, Khoury, Metcalf, Fitzpatrick, & Goodwill, 2015; Zanarini et al., 2014). Unfortunately, these types of studies (based on recollection and a correlation between the two phenomena)

do not tell us directly whether abuse and neglect cause later borderline personality disorder. In an important study, researchers followed 500 children who had documented cases of childhood physical and sexual abuse and neglect and compared them in adulthood with a control group (no history of reported abuse or neglect) (Widom, Czaja, & Paris, 2009). Significantly more abused and neglected children went on to develop borderline personality disorder compared with controls. This finding is particularly significant for girls and women because girls are 2 or 3 times more likely to be sexually abused than boys (Bebbington et al., 2009).

It is clear that a majority of people who receive the diagnosis of borderline personality disorder have suffered terrible abuse or neglect from parents, sexual abuse, physical abuse by others, or a combination of these (Ball & Links, 2009). For those who have not reported such histories, some research is examining just how they could develop borderline personality disorder. For example, factors such as temperament (emotional nature, such as being impulsive, irritable, or hypersensitive) or neurological impairments (being exposed prenatally to alcohol or drugs) and how they interact with parental styles may account for some cases of borderline personality disorder (Graybar & Boutilier, 2002).

Symptoms of borderline personality disorder have been observed among people who have gone through rapid cultural changes. The problems of identity, emptiness, fears of abandonment, and low anxiety threshold have been found in child and adult immigrants (Laxenaire, Ganne-Vevonec, & Streiff, 1982; Skhiri, Annabi, Bi, & Allani, 1982). These observations further support the possibility that prior trauma may, in some individuals, lead to borderline personality disorder.

Remember, however, that a history of childhood trauma, including sexual and physical abuse, occurs in people with other disorders, such as schizoid personality disorder, somatic symptom disorder (see Chapter 6), panic disorder (see Chapter 5), and dissociative identity disorder (see Chapter 6). In addition, a portion of individuals with borderline personality disorder have no apparent history of such abuse (Cloninger & Svakic, 2009). Although childhood sexual abuse and physical abuse and neglect seem to play an important role in the etiology of borderline personality disorder (Zanarini & Wedig, 2014), neither appears to be necessary or sufficient to produce the syndrome.

An Integrative Model

Although there is no currently accepted integrative model for this disorder, it is tempting to borrow from the work on anxiety disorders to outline a possible view. If you recall from Chapter 5, we describe the “triple vulnerability” theory (Barlow, 2002; Suárez, Bennett, Goldstein, & Barlow, 2008). The first vulnerability (or diathesis) is a generalized biological vulnerability. We can see the genetic vulnerability to emotional reactivity in people with borderline personality disorder and how this affects specific brain function. The second vulnerability is a generalized psychological vulnerability. In the case of people with this personality disorder, they tend to view the world as threatening and to react strongly to real and perceived threats. The third vulnerability is a specific psychological vulnerability, learned from early environmental experiences; this is where early trauma, abuse, or both may advance this

sensitivity to threats. When a person is stressed, his or her biological tendency to be overly reactive interacts with the psychological tendency to feel threatened. This may result in the outbursts and suicidal behaviors commonly observed in this group. This preliminary model awaits validation and further research.

Treatment

In stark contrast to individuals with antisocial personality disorder, who rarely acknowledge requiring help, those with borderline personality disorder appear quite distressed and are more likely to seek treatment even than people with anxiety and mood disorders (Bender et al., 2014; Ansell, Sanislow, McGlashan, & Grilo, 2007). Reviews of research on the use of medical treatment for people with this disorder suggest that symptomatic treatment can sometimes be helpful. For disturbances in affect (e.g., anger, sadness) a class of drugs known as mood stabilizers (e.g., some anticonvulsive and antipsychotic drugs) can be effective (Silk & Feurino III, 2012). Efforts to provide successful treatment are complicated by problems with drug abuse, compliance with treatment, and suicide attempts. As a result, many clinicians are reluctant to work with people who have borderline personality disorder.

One of the most thoroughly researched cognitive-behavioral treatments was developed by Marsha Linehan (Linehan et al., 2006; Linehan et al., 1999; Linehan & Dexter-Mazza, 2008). This approach—called **dialectical behavior therapy (DBT)**—involves helping people cope with the stressors that seem to trigger suicidal behaviors and other maladaptive responses. Priority in treatment is first given to those behaviors that may result in harm (suicidal behaviors), then those behaviors that interfere with therapy, and, finally, those that interfere with the patient's quality of life. Weekly individual sessions provide support, and patients are taught how to identify and regulate their emotions. Problem solving is emphasized so that patients can handle difficulties more effectively. In addition, they receive treatment similar to that used for people with PTSD, in which prior traumatic events are reexperienced to help extinguish the fear associated with them (see Chapter 5). In the final stage of therapy, clients learn to trust their own responses rather than depend on the validation of others, sometimes by visualizing themselves not reacting to criticism (Lynch & Cuper, 2012).

Results from a number of studies suggest that DBT may help reduce suicide attempts, dropouts from treatment, and hospitalizations (Linehan et al., 2015; Linehan & Dexter-Mazza, 2008; McMain, Guimond, Streiner, Cardish, & Links, 2013). A follow up of 39 women who received either dialectical behavior therapy or general therapeutic support (called “treatment as usual”) for 1 year showed that, during the first 6 months of follow up, the women in the DBT group were less suicidal, less angry, and better adjusted socially (Linehan & Kehrer, 1993). Another study examined how treating these individuals with DBT in an inpatient setting (a psychiatric hospital) for approximately 5 days would improve their outcomes (Yen, Johnson, Costello, & Simpson, 2009). The participants improved in a number of areas, such as with a reduction in depression, hopelessness, anger expression, and dissociation. A growing body of evidence is now available to document the effectiveness of this approach to aid many individuals with this debilitating disorder (Linehan, 2014).

Probably some of the most intriguing research we describe in this book involves using the techniques in brain imaging to see how psychological treatments influence brain function. One pilot study examined emotional reactions to upsetting photos (for example, pictures of women being attacked) in controls and in women with borderline personality disorder (Schnell & Herpertz, 2007). This study found that among the women who benefited from treatment, arousal (in the amygdala and hippocampus) to the upsetting photos improved over time as a function of treatment. No changes occurred in controls or in women who did not have positive treatment experiences. This type of integrative research holds enormous promise for our understanding of borderline personality disorder and the mechanisms underlying successful treatment.

Histrionic Personality Disorder

Individuals with **histrionic personality disorder** tend to be overly dramatic and often seem almost to be acting, which is why the term *histrionic*, which means theatrical in manner, is used. Consider the case of Pat.

Pat... Always Onstage

When we first met, Pat seemed to radiate enjoyment of life. She was single, in her mid-30s, and was going to night school for her master's degree. She often dressed flamboyantly. During the day she taught children with disabilities, and when she didn't have class, she was often out late on a date. When I first spoke with her, she enthusiastically told me how impressed she was with my work in the field of developmental disabilities and that she had been extremely successful in using some of my techniques with her students. She was clearly overdoing the praise, but who wouldn't appreciate such flattering comments?

Because some of our research included children in her classroom, I saw Pat often. Over a period of weeks, however, our interactions grew strained. She often complained of various illnesses and injuries (falling in the parking lot, twisting her neck looking out a window) that interfered with her work. She was disorganized, often leaving to the last minute tasks that required considerable planning. Pat made promises to other people that were impossible to keep but seemed to be aimed at winning their approval; when she broke the promise, she usually made up a story designed to elicit sympathy and compassion. For example, she promised the mother of one of her students that she would put on a “massive and unique” birthday party for her daughter but forgot about it until the mother showed up with cake and juice. Upon seeing her, Pat flew into a rage and blamed the principal for keeping her late after school, although there was no truth to this accusation.

Pat often interrupted meetings about research to talk about her latest boyfriend. The boyfriends changed almost weekly, but her enthusiasm (“Like no other man I have ever met!”) and optimism about the future (“He’s the guy I want to spend the rest of my life with!”) remained high for each of

them. Wedding plans were seriously discussed with almost every one, despite their brief acquaintance. Pat was ingratiating, especially to the male teachers, who often helped her out of trouble she got into because of her disorganization.

When it became clear that she would probably lose her teaching job because of her poor performance, Pat managed to manipulate several of the male teachers and the assistant principal into recommending her for a new job in a nearby school district. A year later, she was still at the new school but had been moved twice to different classrooms. According to teachers she worked with, Pat still lacked close interpersonal relationships, although she described her current romantic relationship as “deeply involved.” After a rather long period of depression, Pat sought help from a psychologist, who diagnosed her as also having histrionic personality disorder. •

Clinical Description

People with histrionic personality disorder are inclined to express their emotions in an exaggerated fashion, for example, hugging someone they have just met or crying uncontrollably during a sad movie (Ferguson & Negy, 2014; Blashfield, Reynolds, & Stennett, 2012). They also tend to be vain, self-centered, and uncomfortable when they are not in the limelight. They are often seductive in appearance and behavior, and they are typically concerned about their looks. (Pat, for example, spent a great deal of money on unusual jewelry and was sure to point it out to anyone who would listen.) In addition, they seek reassurance and approval constantly and may become upset or angry when others do not attend to them or praise them. People with histrionic personality disorder also tend to be impulsive and have great difficulty delaying gratification.

The cognitive style associated with histrionic personality disorder is impressionistic (Beck, Freeman, & Davis, 2007), characterized by a tendency to view situations in global, black-and-white terms. Speech is often vague, lacking in detail, and characterized by exaggeration (APA, 2013; Nestadt et al., 2009). For example, when Pat was asked about a date she had had the night before, she might say it was “amazing” but fail to provide more detailed information.

The high rate of this diagnosis among women versus men raises questions about the nature of the disorder and its diagnostic criteria (Boysen, Ebersole, Casner, & Coston, 2014). As we first discussed in the beginning of this chapter, there is some thought that the features of histrionic personality disorder, such as over-dramatization, vanity, seductiveness, and overconcern with physical appearance, are characteristic of the Western “stereotypical female” and may lead to an overdiagnosis among women. Srock (2000) examined this important question and found some evidence for a bias among psychologists and psychiatrists to associate the diagnosis with women rather than men.

Causes

Despite its long history, little research has been done on the causes or treatment of histrionic personality disorder. The ancient

People with histrionic personality disorder tend to be vain, extravagant, and seductive.

Greek philosophers believed that many unexplainable problems of women were caused by the uterus (hysteria) migrating within the body (Abse, 1987; Ussher, 2013). As you have seen, however, histrionic personality disorder also occurs among men.

One hypothesis involves a possible relationship with antisocial personality disorder. Evidence suggests that histrionic personality and antisocial personality co-occur more often than chance would account for. Lilienfeld and colleagues (1986), for example, found that roughly two-thirds of people with a histrionic personality also met criteria for antisocial personality disorder. The evidence for this association has led to the suggestion (see, for example, Cloninger, 1978; Lilienfeld, 1992) that histrionic personality and antisocial personality may be sex-typed alternative expressions of the same unidentified underlying condition. Females with the

underlying condition may be predisposed to exhibit a predominantly histrionic pattern, whereas males with the underlying condition may be predisposed to exhibit a predominantly antisocial pattern. Whether this association exists remains a controversial issue, however, and further research on this potential relationship is needed (Dolan & Völlm, 2009; Salekin, Rogers, & Sewell, 1997), particularly given that borderline personality disorder has also been conceptualized as a female variant of psychopathy (Sprague, Javdani, Sadeh, Newman, & Verona, 2012).

Treatment

Although a great deal has been written about ways of helping people with histrionic personality disorder, little of the research demonstrates success (Cloninger & Svakic, 2009). Some therapists have tried to modify the attention-getting behavior. Kass, Silvers, and Abrams (1972) worked with five women, four of whom had been hospitalized for suicide attempts and all of whom were later diagnosed with histrionic personality disorder. The women were rewarded for appropriate interactions and fined for attention-getting behavior. The therapists noted improvement after an 18-month follow up, but they did not collect scientific data to confirm their observation.

A large part of therapy for these individuals usually focuses on the problematic interpersonal relationships. They often manipulate others through emotional crises, using charm, sex, seductiveness, or complaining (Beck et al., 2007). People with histrionic personality disorder often need to be shown how the short-term gains derived from this interactional style result in long-term costs, and they need to be taught more appropriate ways of negotiating their wants and needs.

Narcissistic Personality Disorder

We all know people who think highly of themselves—perhaps exaggerating their real abilities. They consider themselves somehow different from others and deserving of special treatment. In **narcissistic personality disorder**, this tendency is taken to its extreme. In Greek mythology, Narcissus was a youth who spurned the love of Echo, so enamored was he of his own beauty. He spent his days admiring his own image reflected in a pool of water. Psychoanalysts, including Freud, used the term *narcissistic* to describe people who show an exaggerated sense of self-importance and are preoccupied with receiving attention (Ronningstam, 2012). Consider the case of Willie.

Willie... It's All About Me

Willie was an office assistant in a small law firm. Now in his early 30s, Willie had an extremely poor job history. He never stayed employed at the same place for more than 2 years, and he spent considerable time working through temporary employment agencies. Your first encounter, however, would make you believe that he was extremely competent and that he ran the office. If you entered the waiting

room, you were greeted by Willie, even though he wasn't the receptionist. He would be extremely solicitous, asking how he could be of assistance, offer you coffee, and ask you to make yourself comfortable in "his" reception area. Willie liked to talk, and any conversation was quickly redirected in a way that kept him the center of attention.

This type of ingratiating manner was welcomed at first but soon annoyed other staff. This was especially true when he referred to the other workers in the office as his staff, even though he was not responsible for supervising any of them. The conversations with visitors and staff often consumed a great deal of his time and the time of other staff, and this was becoming a problem.

He quickly became controlling in his job—a pattern revealed in his other positions as well—eagerly taking charge of duties assigned to others. Unfortunately, he did not complete these tasks well, and this created a great deal of friction.

When confronted with any of these difficulties, Willie would first blame others. Ultimately, however, it would become clear that Willie's self-centeredness and controlling nature were at the root of many of the office inefficiencies. During a disciplinary meeting with all of the law firm's partners, an unusual step, Willie became explosively abusive and blamed them for being out to get him. He insisted that his performance was exceptional at all of his previous positions—something contradicted by his previous employers—and that they were at fault. After calming down, he revealed a previous drinking problem, a history of depression, and multiple family problems, all of which he believed contributed to any difficulties he experienced.

The firm recommended he be seen at a university clinic as a condition of his continued employment, where he was diagnosed with major depression, as well as narcissistic personality disorder. Ultimately, his behavior—including lateness and incomplete work—resulted in his termination. In a revealing turn of events, Willie reapplied for another position at the same firm 2 years later. A mix-up in records failed to reveal his previous termination, but he lasted only 3 days—showing up late to work on his second and third days. He was convinced he could be successful, yet he could not change his behavior to conform to even the minimal standards needed to be successful at work. •

Clinical Description

People with narcissistic personality disorder have an unreasonable sense of self-importance and are so preoccupied with themselves that they lack sensitivity and compassion for other people (Caligor, Levy, & Yeomans, 2015; Ronningstam, 2012). They aren't comfortable unless someone is admiring them. Their exaggerated feelings and their fantasies of greatness, called *grandiosity*, create a number of negative attributes. They require and expect a great deal of special attention—the best table in the restaurant,

the illegal parking space in front of the movie theater. They also tend to use or exploit others for their own interests and show little empathy. When confronted with other successful people, they can be extremely envious and arrogant. And because they often fail to live up to their own expectations, they are often depressed.

Causes and Treatment

We start out as infants being self-centered and demanding, which is part of our struggle for survival. Part of the socialization process, however, involves teaching children empathy and altruism. Some writers, including Kohut (1971, 1977), believe that narcissistic personality disorder arises largely from a profound failure by the parents of modeling empathy early in a child's development. As a consequence, the child remains fixated at a self-centered, grandiose stage of development. In addition, the child (and later the adult) becomes involved in an essentially endless and fruitless search for the ideal person who will meet her unfulfilled empathic needs.

In a sociological view, Christopher Lasch (1978) wrote in his popular book *The Culture of Narcissism* that this personality disorder is increasing in prevalence in most Western societies, primarily as a consequence of large-scale social changes, including greater emphasis on short-term hedonism, individualism, competitiveness, and success. According to Lasch, the "me generation"

("Baby Boomers" born between 1946 and 1954) produced more than its share of individuals with narcissistic personality disorder. Indeed, reports confirm that narcissistic personality disorder is increasing in prevalence (Huang et al., 2009). However, this apparent rise may be a consequence of increased interest in and research on the disorder.

Research on treatment options is extremely limited in both number of studies and reports of success (Ronningstam, 2014; Cloninger & Svakic, 2009; Dhawan, Kunik, Oldham, & Coverdale, 2010). When therapy is attempted with these individuals, it often focuses on their grandiosity, their hypersensitivity to evaluation, and their lack of empathy toward others (Campbell & Miller, 2011; Beck et al., 2007). Cognitive therapy strives to replace their fantasies with a focus on the day-to-day pleasurable experiences that are truly attainable. Coping strategies such as relaxation training are used to help them face and accept criticism. Helping them focus on the feelings of others is also a goal. Because individuals with this disorder are vulnerable to severe depressive episodes, particularly in middle age, treatment is often initiated for the depression. It is impossible to draw any conclusions, however, about the impact of such treatment on the actual narcissistic personality disorder.

Diagnostic Criteria for Narcissistic Personality Disorder

A pervasive pattern of grandiosity (in fantasy or behavior), need for admiration, and lack of empathy, beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:

1. Has a grandiose sense of self-importance (e.g., exaggerates achievements and talents, expects to be recognized as superior without commensurate achievements).
2. Is preoccupied with fantasies of unlimited success, power, brilliance, beauty, or ideal love.
3. Believes that he or she is "special" and unique and can only be understood by, or should associate with, other special or high-status people (or institutions).
4. Requests excessive admiration.
5. Has a sense of entitlement (i.e., unreasonable expectations of especially favorable treatment or automatic compliance with his or her expectations).
6. Is interpersonally exploitative (i.e., takes advantage of others to achieve his or her own ends).
7. Lacks empathy: is unwilling to recognize or identify with the feelings and needs of others.
8. Is often envious of others or believes that others are envious of him or her.
9. Shows arrogant, haughty behaviors or attitudes.

Concept Check 12.3

Correctly identify the type of personality disorder described here.

1. Elaine has low self-esteem and usually feels empty unless she does dangerous and exciting things. She is involved in drugs and has casual sexual encounters, even with strangers. She threatens to commit suicide if her boyfriend suggests getting help or if he talks about leaving her. She alternates between passionately loving and hating him, sometimes going from one extreme to the next in a short time. _____
2. Lance is 19 and has been in trouble with the law for the past 2 years. He lies to his parents, vandalizes buildings in the community, and often fights with others. He shows no remorse for the people he injures or the grief that he causes his ailing parents. _____
3. Nancy thinks she is the best at everything. She thinks her performance is always excellent, and is extremely critical of anyone else's success. She constantly looks for admiration and reassurance from others. _____
4. Samantha is known for being overly dramatic. She cries uncontrollably during sad movies, and we sometimes think that she is acting. She is vain and self-centered, interrupting many of our class conversations to discuss her personal life. _____

Cluster C Personality Disorders

People diagnosed with the next three personality disorders we highlight—avoidant, dependent, and obsessive-compulsive—share common features with people who have anxiety disorders. These anxious or fearful personality disorders are described next.

Avoidant Personality Disorder

As the name suggests, people with **avoidant personality disorder** are extremely sensitive to the opinions of others and although they desire social relationships, their anxiety leads them to avoid such associations. Their extremely low self-esteem—coupled with a fear of rejection—causes them to be limited in their friendships and dependent on those they feel comfortable with (Eikenaes, Pedersen, & Wilberg, 2015; Sanislow, da Cruz, Gianoli, & Reagan, 2012). Consider the case of Jane.

Jane... Not Worth Noticing

Jane was raised by an alcoholic mother who had borderline personality disorder and who abused her verbally and physically. As a child, she made sense of her mother's abusive treatment by believing that she (Jane) must be an intrinsically unworthy person to be treated so badly. As an adult in her late 20s, Jane still expected to be rejected when others found out that she was inherently unworthy and bad.

Jane was highly self-critical and predicted that she would not be accepted. She thought that people would not like her, that they would see she was a loser, and that she would not have anything to say. She became upset if she perceived that someone in even the most fleeting encounter was reacting negatively or neutrally. If a newspaper vendor failed to smile at her, or a sales clerk was slightly curt, Jane automatically thought it must be because she (Jane) was somehow unworthy or unlikable. She then felt quite sad. Even when she was receiving positive feedback from a friend, she discounted it. As a result, Jane had few friends and certainly no close ones.

Clinical Description

Theodore Millon (1981), who initially proposed this diagnosis, notes that it is important to distinguish between individuals who are asocial because they are apathetic, affectively flat, and relatively uninterested in interpersonal relationships (comparable to what DSM-5 terms schizoid personality disorder) and individuals who are asocial because they are interpersonally anxious and fearful of

rejection. It is the latter who fit the criteria of avoidant personality disorder (Millon & Martinez, 1995). These individuals feel chronically rejected by others and are pessimistic about their future.

Causes

Some evidence has found that avoidant personality disorder is related to other schizophrenia-related disorders, occurring more often in relatives of people who have schizophrenia (Fogelson et al., 2010, 2007). A number of theories have been proposed that integrate biological and psychosocial influences as the cause of avoidant personality disorder. Millon (1981), for example, suggests that these individuals may be born with a difficult temperament or personality characteristics. As a result, their parents may reject them, or at least not provide them with enough early, uncritical love. This rejection, in turn, may result in low self-esteem and social alienation, conditions that persist into adulthood. Limited support does exist for psychosocial influences in the cause of avoidant personality disorder. For example, Stravynski, Elie, and Franche (1989) questioned a group of people with avoidant personality disorder and a group of control participants about their early treatment by their parents. Those with the disorder remembered their parents as more rejecting, more guilt engendering, and less affectionate than the control group, suggesting parenting may contribute to the development of this disorder. Similarly, research has consistently found that these individuals are more likely to report childhood experiences of neglect, isolation, rejection, and conflict with others (Eikenaes, Egeland, Hummelen, & Wilberg, 2015; Meyer & Carver, 2000).

A pervasive pattern of social inhibition, feelings of inadequacy, and hypersensitivity to negative evaluation, beginning by early adulthood and present in a variety of contexts, as indicated by four (or more) of the following:

1. Avoids occupational activities that involve significant interpersonal contact because of fears of criticism, disapproval, or rejection.
2. Is unwilling to get involved with people unless certain of being liked.
3. Shows restraint within intimate relationships because of the fear of being shamed or ridiculed.
4. Is preoccupied with being criticized or rejected in social situations.
5. Is inhibited in new interpersonal situations because of feelings of inadequacy.
6. Views self as socially inept, personally unappealing, or inferior to others.
7. Is unusually reluctant to take personal risks or to engage in any new activities because they may prove embarrassing.

From American Psychiatric Association. (2013). *Diagnostic and statistical manual of mental disorders* (5th ed.). Washington, DC.

Treatment

In contrast to the scarcity of research into most other personality disorders, there are a number of well-controlled studies on approaches to therapy for people with avoidant personality disorder (Leahy & McGinn, 2012). Behavioral intervention techniques for anxiety and social skills problems have had some success (e.g., Borge et al., 2010; Emmelkamp et al., 2006). Because the problems experienced by people with avoidant personality disorder resemble those of people with social phobia, many of the same treatments are used for both groups (see Chapter 5). Therapeutic alliance—the collaborative connection between therapist and client—appears to be an important predictor for treatment success in this group (Strauss et al., 2006).

Dependent Personality Disorder

We all know what it means to be dependent on another person. People with **dependent personality disorder**, however, rely on others to make ordinary decisions as well as important ones, which results in an unreasonable fear of abandonment. Consider the case of Karen.

Karen...

Whatever You Say

Karen was a 45-year-old married woman who was referred for treatment by her physician for problems with panic attacks. During the evaluation, she appeared to be worried, sensitive, and naive. She was easily overcome with emotion and cried on and off throughout the session. She was self-critical at every opportunity throughout the evaluation. For example, when asked how she got along with other people, she reported that “others think I’m dumb and inadequate,” although she could give no evidence as to what made her think that. She reported that she didn’t like school because “I was dumb” and that she always felt that she was not good enough.

Karen described staying in her first marriage for 10 years, even though “it was hell.” Her husband had affairs with many other women and was verbally abusive. She tried to leave him many times but gave in to his repeated requests to return. She was finally able to divorce him, and shortly afterward she met and married her current husband, whom she described as kind, sensitive, and supportive. Karen stated that she preferred to have others make important decisions and agreed with other people to avoid conflict. She worried about being left alone without anyone to take care of her and reported feeling lost without other people’s reassurance. She also reported that her feelings were easily hurt, so she worked hard not to do anything that might lead to criticism.

(Case and excerpt reprinted, with permission, from Beck, A. T., & Freeman, A. (1990). *Cognitive therapy of personality disorders*. New York: Guilford Press, © 1990 by Guilford Press.) •

Clinical Description

Individuals with dependent personality disorder sometimes agree with other people when their own opinion differs so as not to be rejected (Bornstein, 2012). Their desire to obtain and maintain supportive and nurturant relationships may lead to their other behavioral characteristics, including submissiveness, timidity, and passivity. People with this disorder are similar to those with avoidant personality disorder in their feelings of inadequacy, sensitivity to criticism, and need for reassurance. However, people with avoidant personality disorder respond to these feelings by avoiding relationships, whereas those with dependent personality disorder respond by clinging to relationships (Disney, 2013; Bornstein, 2012). It is important to note that in certain cultures (e.g., East Asian Confucianism) dependence and submission may be viewed as a desired interpersonal state (Chen, Nettles, & Chen, 2009).

Causes and Treatment

We are all born dependent on other people for food, physical protection, and nurturance. Part of the socialization process in most cultures involves helping us live independently (Bornstein, 1992). It was thought that such disruptions as the early death of a parent or neglect or rejection by caregivers could cause people to grow up fearing abandonment (Stone, 1993). It also is clear, however, that genetic influences are important in the development of this disorder (e.g., Gjerde et al., 2012). What is not yet understood are the

A pervasive and excessive need to be taken care of that leads to submissive and clinging behavior and fears of separation, beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:

1. Has difficulty making everyday decisions without an excessive amount of advice and reassurance from others.
2. Needs others to assume responsibility for most major areas of his or her life.
3. Has difficulty expressing disagreement with others because of fear of loss of support or approval. (Note: Do not include realistic fears of retribution.)
4. Has difficulty initiating projects or doing things on his or her own (because of a lack of self-confidence in judgment or abilities rather than a lack of motivation or energy).
5. Goes to excessive lengths to obtain nurturance and support from others, to the point of volunteering to do things that are unpleasant.
6. Feels uncomfortable or helpless when alone because of exaggerated fears of being unable to care of himself or herself.
7. Urgently seeks another relationship as a source of care and support when a close relationship ends.
8. Is unrealistically preoccupied with fears of being left to take care of himself or herself.

physiological factors underlying this genetic influence and how they interact with environmental influences (Sanislow et al., 2012).

The treatment literature for this disorder is mostly descriptive; little research exists to show whether a particular treatment is effective (Borge et al., 2010; Paris, 2008). On the surface, because of their attentiveness and eagerness to give responsibility for their problems to the therapist, people with dependent personality disorder can appear to be ideal patients. That very submissiveness, however, negates one of the major goals of therapy, which is to make the person more independent and personally responsible (Leahy & McGinn, 2012). Therapy therefore progresses gradually as the patient develops confidence in his ability to make decisions independently (Beck et al., 2007). There is a particular need for care that the patient does not become overly dependent on the therapist.

Obsessive-Compulsive Personality Disorder

People who have **obsessive-compulsive personality disorder** are characterized by a fixation on things being done “the right way” (Diedrich & Voderholzer, 2015). Although many might envy their persistence and dedication, this preoccupation with details prevents them from completing much of anything. Consider the case of Daniel.

Daniel... Getting It Exactly Right

Each day at exactly 8 A.M., Daniel arrived at his office at the university where he was a graduate student in psychology. On his way, he always stopped at the 7-Eleven for coffee and the *New York Times*. From 8 A.M. to 9:15 A.M., he drank his coffee and read the paper. At 9:15 A.M., he reorganized the files that held the hundreds of papers related to his doctoral dissertation, now several years overdue. From 10 A.M. until noon, he read one of these papers, highlighting relevant passages. Then he took the paper bag that held his lunch (always a peanut butter and jelly sandwich and an apple) and went to the cafeteria to purchase a soda and eat by himself. From 1 P.M. until 5 P.M., he held meetings, organized his desk, made lists of things to do, and entered his references into a new database program on his computer. At home, Daniel had dinner with his wife and then worked on his dissertation until after 11 P.M., although much of the time was spent trying out new features of his home computer.

Daniel was no closer to completing his dissertation than he had been 4.5 years ago. His wife was threatening to leave him because he was equally rigid about everything at home and she didn't want to remain in this limbo of graduate school forever. When Daniel eventually sought help from a therapist for his anxiety over his deteriorating marriage, he was diagnosed as having obsessive-compulsive personality disorder. •

Clinical Description

Like many with this personality disorder, Daniel is work oriented, spending little time going to movies or parties or doing anything that isn't related to his graduate studies. Because of their general rigidity, these people tend to have poor interpersonal relationships (Samuels & Costa, 2012).

This personality disorder seems to be only distantly related to obsessive-compulsive disorder, one of the anxiety disorders we described in Chapter 5 (Samuels & Costa, 2012). People like Daniel tend not to have the obsessive thoughts and the compulsive behaviors seen in the like-named obsessive-compulsive disorder. Although people with the anxiety disorder sometimes show characteristics of the personality disorder, they show the characteristics of other personality disorders as well (for example, avoidant, histrionic, or dependent) (Melca, Yücel, Mendlowicz, de Oliveira-Souza, & Fontenelle, 2015; Trull, Scheiderer, & Tomko, 2012).

An intriguing theory suggests that the psychological profiles of many serial killers point to the role of obsessive-compulsive personality disorder. Ferreira (2000) notes that these individuals do not often fit the definition of someone with a severe mental illness—such as schizophrenia—but are “masters of control” in manipulating their victims. Their need to control all aspects of the crime fits the pattern of people with obsessive-compulsive personality disorder, and some combination of this disorder and unfortunate childhood experiences may lead to this disturbing behavior pattern. Obsessive-compulsive personality disorder may also play a role among some sex offenders—in particular, pedophiles. Brain-imaging research on pedophiles suggests that brain functioning in these individuals is similar to those with obsessive-compulsive personality disorder (Schiffer et al., 2007).

A pervasive pattern of preoccupation with orderliness, perfectionism, and mental and interpersonal control, at the expense of flexibility, openness, and efficiency, beginning by early adulthood and present in a variety of contexts, as indicated by four (or more) of the following:

1. Is preoccupied with details, rules, lists, order, organization, or schedules to the extent that the major point of the activity is lost.
2. Shows perfectionism that interferes with task completion (e.g., is unable to complete a project because his or her own overly strict standards are not met).
3. Is excessively devoted to work and productivity to the exclusion of leisure activities and friendships (not accounted for by obvious economic necessity).
4. Is overconscientious, scrupulous, and inflexible about matters of morality, ethics, or values (not accounted for by cultural or religious identification).
5. Is unable to discard worn-out or worthless objects even when they have no sentimental value.
6. Is reluctant to delegate tasks or to work with others unless they submit to exactly his or her way of doing things.
7. Adopts a miserly spending style toward both self and others; money is viewed as something to be hoarded for future catastrophes.
8. Shows rigidity and stubbornness.

At the other end of the behavioral spectrum, it is also common to find obsessive-compulsive personality disorder among gifted children, whose quest for perfectionism can be quite debilitating (Nugent, 2000).

Causes and Treatment

There seems to be a moderate genetic contribution to obsessive-compulsive personality disorder (Gjerde et al., 2015; Cloninger & Svakic, 2009). Some people may be predisposed to favor structure in their lives, but to reach the level it did in Daniel may require parental reinforcement of conformity and neatness.

Therapy often attacks the fears that seem to underlie the need for orderliness (Pinto, 2015). These individuals are often afraid that what they do will be inadequate, so they procrastinate and

excessively ruminate about important issues and minor details alike. Therapists help the individual relax or use cognitive reappraisal techniques to reframe compulsive thoughts. This form of cognitive-behavioral therapy—following along the lines of treatment for obsessive-compulsive disorder (see Chapter 5)—appears to be effective for people with this personality disorder (Svartberg, Stiles & Seltzer, 2004).

People with obsessive-compulsive personality disorder are preoccupied with doing things “the right way.”

Concept Check 12.4

Match the following scenarios with the correct personality disorder.

1. During a therapy session John gets up for a glass of water. Ten minutes later, John still is not back. He first had to clean the fountain area and neatly arrange the glasses before pouring his glass of water. _____
2. Whitney is self-critical and claims she is unintelligent and has no skills. She is also afraid to be alone and seeks constant reassurance from her family and friends. She says and does nothing about her cheating husband because she thinks that if she shows any resolve or initiative, she will be abandoned and will have to take care of herself. _____
3. Mike has no social life because of his great fear of rejection. He disregards compliments and reacts excessively to criticism, which only feeds his pervasive feelings of inadequacy. Mike takes everything personally. _____

DSM Controversies: *The Battle for the Personality Disorders*

Discussion about the personality disorders in DSM-5 included proposals for a number of major changes to this category. As we have seen, the elimination of the distinction between “Axis I” and “Axis II” disorders elevated the personality disorders into the mainstream of problems experienced by individuals. However, other major changes that appeared to be ready for inclusion in DSM-5 never occurred. The goal of creating dimensions of different personality traits along the lines of the “Big 5” rather than the specific disorders outlined in this chapter (e.g., borderline personality disorder, antisocial personality disorder) never materialized. In part, this proposal was not included in DSM-5 due

to the difficulty in making a diagnosis (too many permutations) and potential problems in using that information to design treatments (Skodol, 2012).

However, one of the biggest changes proposed was to completely eliminate four of the personality disorders (paranoid, schizoid, histrionic, avoidant, and dependent personality disorders). Instead, people previously diagnosed with these disorders would be identified as having a general personality disorder with the traits specified (e.g., suspiciousness, emotional lability, hostility, etc.). The rationale for their removal included a relative lack of research on these disorders and significant overlap

among the disorders (comorbidity) (Skodol, 2012). In anticipation of this significant change, one set of researchers authored a paper with the title “The Death of Histrionic Personality Disorder” (Blashfield et al., 2012) and the personality disorders community of researchers in general was divided over this change (Pull, 2013). Ultimately, the final draft retained these disorders and left for a later time proposals for dealing with the problems of lack of research and specificity. This back and forth on how to carve up diagnoses exemplifies the difficulties that continue to exist for any diagnostic system, even after decades of arduous and dedicated research.

An Overview of Personality Disorders

- The personality disorders represent long-standing and ingrained ways of thinking, feeling, and behaving that can cause significant distress. Because people may display two or more of these maladaptive ways of interacting with the world, considerable disagreement remains over how to categorize the personality disorders.
- *DSM-5* includes 10 personality disorders that are divided into three clusters: Cluster A (odd or eccentric) includes paranoid, schizoid, and schizotypal personality disorders; Cluster B (dramatic, emotional, or erratic) includes antisocial, borderline, histrionic, and narcissistic personality disorders; and Cluster C (anxious or fearful) includes avoidant, dependent, and obsessive-compulsive personality disorders.

Cluster A Personality Disorders

- People with paranoid personality disorder are excessively mistrustful and suspicious of other people, without any justification. They tend not to confide in others and expect other people to do them harm.
- People with schizoid personality disorder show a pattern of detachment from social relationships and a limited range of emotions in interpersonal situations. They seem aloof, cold, and indifferent to other people.
- People with schizotypal personality disorder are typically socially isolated and behave in ways that would seem unusual to most of us. In addition, they tend to be suspicious and have odd beliefs about the world.

Cluster B Personality Disorders

- People with antisocial personality disorder have a history of failing to comply with social norms. They perform actions most of us would find unacceptable, such as stealing from friends and family. They also tend to be irresponsible, impulsive, and deceitful.
- In contrast to the *DSM-5* criteria for antisocial personality, which focus almost entirely on observable behaviors (for example,

impulsively and repeatedly changing employment, residence, or sexual partners), the related concept of psychopathy primarily reflects underlying personality traits (for example, self-centeredness or manipulativeness).

- People with borderline personality disorder lack stability in their moods and in their relationships with other people, and they usually have poor self-esteem. These individuals often feel empty and are at great risk of suicide.
- Individuals with histrionic personality disorder tend to be overly dramatic and often appear almost to be acting.
- People with narcissistic personality disorder think highly of themselves—beyond their real abilities. They consider themselves somehow different from others and deserving of special treatment.

Cluster C Personality Disorders

- People with avoidant personality disorder are extremely sensitive to the opinions of others and therefore avoid social relationships. Their extremely low self-esteem, coupled with a fear of rejection, causes them to reject the attention of others.
- Individuals with dependent personality disorder rely on others to the extent of letting them make everyday decisions, as well as major ones; this results in an unreasonable fear of being abandoned.
- People who have obsessive-compulsive personality disorder are characterized by a fixation on things being done “the right way.” This preoccupation with details prevents them from completing much of anything.
- Treating people with personality disorders is often difficult because they usually do not see that their difficulties are a result of the way they relate to others.
- Personality disorders are important for the clinician to consider because they may interfere with efforts to treat more specific problems such as anxiety, depression, or substance abuse. Unfortunately, the presence of one or more personality disorders is associated with a poor treatment outcome and a generally negative prognosis.

Perspectives on Schizophrenia

A middle-aged man walks the streets of New York City with aluminum foil on the inside of his hat so Martians can't read his mind. A young woman sits in her college classroom and hears the voice of God telling her she is a vile and disgusting person. You try to strike up a conversation with the supermarket bagger, but he stares at you vacantly and will say only one or two words in a flat, toneless voice. Each of these people may have **schizophrenia**, the startling disorder characterized by a broad spectrum of cognitive and emotional dysfunctions including delusions and hallucinations, disorganized speech and behavior, and inappropriate emotions.

Schizophrenia is a complex syndrome that inevitably has a devastating effect on the lives of the person affected and on family members. This disorder can disrupt a person's perception, thought, speech, and movement: almost every aspect of daily functioning. Society often devalues these individuals. People with these severe mental health problems are more likely to be stigmatized and discriminated against than those without schizophrenia (Corker et al., 2015; Farelly et al., 2014). And despite important advances in treatment, full recovery from schizophrenia has a low base rate of 1 in 7 patients (Jääskeläinen et al., 2013). This catastrophic disorder takes a tremendous emotional toll on everyone involved. In addition to the emotional costs, the financial drain is considerable. The annual cost of schizophrenia in the United States is estimated to exceed \$60 billion when factors such as family caregiving, lost wages, and treatment are considered (Kennedy, Altar, Taylor, Degtiar, & Hornberger, 2014; Wu et al., 2005). Because schizophrenia is so widespread, affecting approximately 1 of every 100 people at some point in their lives, and because its consequences are so severe, research on its causes and treatment has expanded rapidly. Given the attention it has received, you would think the

question "What is schizophrenia?" would by now be answered easily. It is not.

In this chapter, we explore this intriguing disorder and review efforts to determine whether schizophrenia is distinct or a combination of disorders. The search is complicated by the presence of subtypes: different presentations and combinations of symptoms such as hallucinations, delusions, and disorders of speech, emotion, and socialization. After discussing the characteristics of people with schizophrenia, we describe research into its causes and treatment.

Early Figures in Diagnosing Schizophrenia

The history of schizophrenia as it has evolved over the years is unparalleled by any other disorder covered in this book. Knowing something about this history will help you understand that the nature of the disorder is multifaceted and treatment is correspondingly complex.

In *Observations on Madness and Melancholy*, published in 1809, John Haslam eloquently portrayed what he called "a form of insanity." In the following passage, Haslam mentions some symptoms that inform our current conception of schizophrenia:

The attack is almost imperceptible; some months usually elapse before it becomes the subject of particular notice; and fond relatives are frequently deceived by the hope that it is only an abatement of excessive vivacity, conducting to a prudent reserve, and steadiness of character. A degree of apparent thoughtfulness and inactivity precede, together with a diminution of the ordinary curiosity, concerning that which is passing before them; and they therefore neglect those objects and pursuits which formerly proved

courses of delight and instruction. The sensibility appears to be considerably blunted: they do not bear the same affection towards their parents and relations: they become unfeeling to kindness, and careless of reproof. . . . I have painfully witnessed this hopeless and degrading change, which in a short time has transformed the most promising and vigorous intellect into a slavering and bloated idiot. (Haslam, 1809/1976, pp. 64–67)

About the same time Haslam was writing his description in England, the French physician Philippe Pinel was writing about people we would describe as having schizophrenia (Pinel, 1801/1962, 1809). Some 50 years later, another physician, Benedict Morel, used the French term *démence* (loss of mind) *précoce* (early, premature), because the onset of the disorder is often during adolescence.

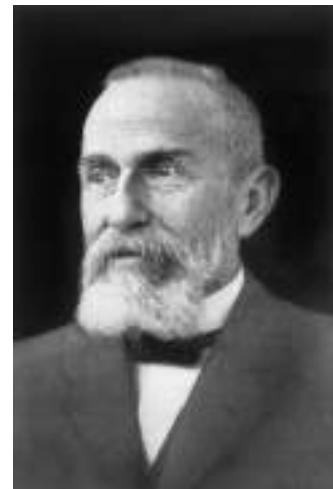

Toward the end of the 19th century, the German psychiatrist Emil Kraepelin (1899) built on the writings of Haslam, Pinel, and Morel (among others) to give us what stands today as the most enduring description and categorization of schizophrenia. Two of Kraepelin's accomplishments are especially important. First, he combined several symptoms of insanity that had usually been viewed as reflecting separate and distinct disorders: **catatonia** (alternating immobility and excited agitation), **hebephrenia** (silly and immature emotionality), and **paranoia** (delusions of grandeur or persecution). Kraepelin thought these symptoms shared similar underlying features and included them under the Latin term **dementia praecox**. Although the clinical manifestation might differ from person to person, Kraepelin believed an early onset at the heart of each disorder develops into "mental weakness."

In a second important contribution, Kraepelin (1898) distinguished dementia praecox from manic-depressive illness (now called bipolar disorder). For people with dementia praecox, an early age of onset and a poor outcome were characteristic; in contrast, these patterns were not essential to manic depression (Lewis, Escalona, & Keith, 2009). Kraepelin also noted the numerous symptoms in people with dementia praecox, including hallucinations, delusions, negativism, and stereotyped behavior.

A second major figure in the history of schizophrenia was Kraepelin's contemporary, Eugen Bleuler (1908), a Swiss

psychiatrist who introduced the term *schizophrenia* (Berrios, 2011; Fusar-Poli & Politi, 2008). The label was significant because it signaled Bleuler's departure from Kraepelin on what he thought was the core problem. *Schizophrenia*, which comes from the combination of the Greek words for "split" (*skhizein*) and "mind" (*phren*), reflected Bleuler's belief that underlying all the unusual behaviors shown by people with this disorder was an **associative splitting** of the basic functions of personality. This concept emphasized the "breaking of associative threads," or the destruction of the forces that connect one function to the next. Furthermore, Bleuler believed that a difficulty keeping a consistent train of thought characteristic of all people with this disorder led to the many and diverse symptoms they displayed. Whereas Kraepelin focused on early onset and poor outcomes, Bleuler highlighted what he believed to be the universal underlying problem. Unfortunately, the concept of "split mind" inspired the common but incorrect use of the term *schizophrenia* to mean split or multiple personality. (For a summary of the early contributors to the concept of schizophrenia, see Table 13.1.)

Eugen Bleuler (1857–1939), a Swiss psychiatrist, introduced the term *schizophrenia* and was a pioneer in the field.

Identifying Symptoms

It is not easy to point to one thing that makes a person "schizophrenic." As you read about different disorders in this book, you have learned that a particular behavior, way of thinking, or emotion usually defines or is characteristic of each disorder. For example, depression always includes feelings of sadness, and panic disorder is always accompanied by intense feelings of anxiety. Surprisingly, this isn't the case for schizophrenia. Schizophrenia is a number of behaviors or symptoms that aren't necessarily shared by all people who are given this diagnosis. Kraepelin described

the situation when he outlined his view of dementia praecox in the late 1800s:

The complexity of the conditions which we observe in the domain of dementia praecox is very great, so that their inner connection is at first recognizable only by their occurring one after the other in the course of the same disease. In any case certain fundamental disturbances, even though they cannot for the most part be regarded as characteristic, yet return frequently in the same form, but in the most diverse combinations. (Kraepelin, 1919, p. 5)

This mix of symptoms was also highlighted by Bleuler in the title of his 1911 book, *Dementia Praecox or the Group of Schizophrenias*, which emphasizes the complexity of the disorder. The varied nature of schizophrenia is something we come back to throughout this chapter. Individuals who have schizophrenia have varying symptoms, and we find that the causes vary as well.

Despite these complexities, researchers have identified clusters of symptoms that make up the disorder of schizophrenia. Later we describe these dramatic symptoms, such as seeing or hearing things that others do not (*hallucinations*) or having beliefs that are unrealistic, bizarre, and not shared by others in the same culture (*delusions*). But first, consider the following case of an individual who had an intense but relatively rare short-term episode of psychotic behavior.

Arthur... Saving the Children

We first met 22-year-old Arthur at an outpatient clinic in a psychiatric hospital. Arthur's family was extremely concerned and upset by his unusual behavior and was desperately seeking help for him. They said that he was "sick" and "talking like a crazy man," and they were afraid he might harm himself.

Arthur had a normal childhood in a middle-class suburban neighborhood. His parents had been happily married until his father's death several years earlier. Arthur was an average student throughout school and had completed an associate's degree in junior college. His family seemed to think he regretted not continuing on to receive a bachelor's degree. Arthur had worked in a series of temporary jobs, and his mother reported that he seemed satisfied with what he was doing. He lived and worked in a major city, some 15 minutes from his mother and his married brother and sister.

Arthur's family said that about 3 weeks before he came to the clinic, he had started speaking strangely. He had been laid off from his job a few days before because of cutbacks and hadn't communicated with any of his family members for several days. When they next spoke with him, his behavior startled them. Although he had always been idealistic and anxious to help other people, he now talked about saving all the starving children in the world with his "secret plan." At first, his family assumed this was just an example of Arthur's sarcastic wit, but his demeanor changed to one of extreme concern and he spoke nonstop about his plans.

He began carrying several spiral notebooks that he claimed contained his scheme for helping starving children; he said he would reveal it only at the right time to the right person. Suspecting that Arthur might be taking drugs, which could explain the sudden and dramatic change in his behavior, his family searched his apartment. Although they didn't find any evidence of drug use, they did find his checkbook and noticed a number of strange entries. Over the past several weeks, Arthur's handwriting had deteriorated, and he had written notes instead of the usual check information ("Start to begin now"; "This is important!"; "They must be saved"). He had also made unusual notes in several of his most prized books, a particularly alarming development given his reverence for these books.

As the days went on, Arthur showed dramatic changes in emotion, often crying and acting apprehensive. He stopped wearing socks and underwear and, despite the extremely cold weather, wouldn't wear a jacket when he went outdoors. At the family's insistence, he moved into his mother's apartment. He slept little, and kept the family up until the early morning. His mother said it was like being in a living nightmare. Each morning she would wake up with a knot in her stomach, not wanting to get out of bed because she felt so helpless to do anything to rescue Arthur from his obvious distress.

The family's sense of alarm grew as Arthur revealed more details of his plan. He said that he was going to the German embassy because that was the only place people would listen to him. He would climb the fence at night when everyone was asleep and present his plan to the German ambassador. Fearing that Arthur would be hurt trying to enter the embassy grounds, his family contacted a local psychiatric hospital, described Arthur's condition, and asked that he be admitted. Much to their surprise and disappointment, they were told that Arthur could commit himself but that they couldn't bring him in involuntarily unless he was in danger of doing harm to himself or others. The fear that Arthur might be harmed wasn't sufficient reason to admit him involuntarily.

His family finally talked Arthur into meeting the staff at the outpatient clinic. In our interview, it was clear he was delusional, firmly believing in his ability to help all starving children. After some cajoling, I finally convinced him to let me see his books. He had written random thoughts (for example, "The poor, starving souls"; "The moon is the only place") and made drawings of rocket ships. Parts of his plan involved building a rocket ship that would go to the moon, where he would create a community for all malnourished children, a place where they could live and be helped. After a few brief comments on his plan, I began to ask him about his health.

"You look tired; are you getting enough sleep?"

"Sleep isn't really needed," he noted. "My plans will take me through, and then they can all rest."

(Continued next page)

"Your family is worried about you," I said. "Do you understand their concern?"

"It's important for all concerned to get together, to join together," he replied.

With that, he got up and walked out of the room and out of the building, after telling his family that he would be right back. After 5 minutes they went to look for him, but he had disappeared. He was missing for 2 days, which caused his family a great deal of concern about his health and safety. In an almost miraculous sequence of events, they found him walking the streets of the city. He acted as if nothing had happened. Gone were his notebooks and the talk of his secret plan. •

What caused Arthur to act so strangely? Was it being laid off from his job? Was it the death of his father? Was it a genetic predisposition to have schizophrenia or another disorder that kicked in during a period of stress? Unfortunately, we will never know exactly what happened to Arthur to make him behave so bizarrely and then recover so quickly and completely. Research that we discuss next may shed some light on schizophrenia and potentially help other Arthurs and their families.

Clinical Description, Symptoms, and Subtypes

The case of Arthur shows the range of problems experienced by people with schizophrenia or other psychotic disorders. The term **psychotic behavior** has been used to characterize many unusual behaviors, although in its strictest sense, it usually involves delusions (irrational beliefs) and/or hallucinations (sensory experiences in the absence of external events). Schizophrenia is one of the disorders that involve psychotic behavior; we describe others in more detail later.

Schizophrenia can affect all the functions we rely on each day. Before we describe the symptoms, it is important to look carefully at the specific characteristics of people who exhibit these behaviors, partly because we constantly see distorted images of people with schizophrenia. Headlines such as "Ex-Mental Patient Kills Family" falsely imply that everyone with schizophrenia is dangerous and violent. Popular accounts also contribute to this misinformation. Evidence for violence among people with schizophrenia suggests that although they may be more likely to commit violent acts than the general population, traits such as anger and antisocial personality are better predictors of violence than psychosis (Skeem, Kennealy, Monahan, Peterson, & Appelbaum, 2016). Despite this information, the majority of characters with schizophrenia in English language movies between 1990 and 2010 were portrayed as violent, with more than one third depicted as murderers and one fourth as suicidal (Owen, 2012). As in mistakenly assuming that *schizophrenia* means "split personality," the popular press misrepresents abnormal psychology to the detriment of people who experience these debilitating disorders.

Schizophrenia spectrum disorder constitutes the group of diagnoses we cover in this chapter, as recognized by those in the field of schizophrenia. In fact, Eugen Bleuler, who coined the term schizophrenia, identified the different variants that were all included within this spectrum (Ritsner & Gottesman, 2011). Previous editions of the *DSM* struggled with this concept in its varied presentations over the years, and, as we describe in this chapter, *DSM-5* currently includes schizophrenia as well as other related psychotic disorders that fall under this heading (including schizopreniform, schizoaffective, delusional, and brief psychotic disorders). In addition, a personality disorder (schizotypal personality disorder, discussed in Chapter 12) is also considered to be included under this umbrella category of schizophrenia spectrum disorders. All of these difficulties seem to share features of extreme reality distortion (for example, hallucinations, delusions). Later we discuss the symptoms the person experiences during the disorder (active phase symptoms), the course of the disorder, and spectrum of disorders included in this category.

Mental health workers typically distinguish between *positive* and *negative* symptoms of schizophrenia. A third dimension, *disorganized* symptoms, also appears to be an important aspect of the disorder (Liddle, 2012). Positive symptoms generally refer to symptoms around distorted reality. Negative symptoms involve deficits in normal behavior in such areas as speech, blunted affect (or lack of emotional reactivity), and motivation (Foussias et al., 2014). Disorganized symptoms include rambling speech, erratic behavior, and inappropriate affect (for example, smiling when you are upset). A diagnosis of schizophrenia requires that two or more positive, negative, and/or disorganized symptoms be present for at least 1 month, with at least one of these symptoms including delusions, hallucinations, or disorganized speech. *DSM-5* also includes a dimensional assessment that rates the severity of the individual's symptoms on a 0 to 4 scale with 0 indicating a symptom is not present, 1 indicating equivocal evidence (i.e., not sure), 2 indicating it is present but mild, 3 that it is present and moderate, and 4 that it is present and severe (American Psychiatric Association, 2013). A great deal of research has focused on the different symptoms of schizophrenia, each of which is described here in some detail.

Positive Symptoms

We next describe the **positive symptoms** of schizophrenia, which are the more obvious signs of psychosis. These include the disturbing experiences of delusions and hallucinations. Between 50% and 70% of people with schizophrenia experience hallucinations, delusions, or both (Lindenmayer & Khan, 2006).

Delusions

A belief that would be seen by most members of a society as a misrepresentation of reality is called a *disorder of thought content*, or a **delusion**. Because of its importance in schizophrenia, delusion has been called "the basic characteristic of madness" (Jaspers, 1963, p. 93). If, for example, you believe that squirrels are aliens sent to Earth on a reconnaissance mission, you would be considered delusional. The media often portray people with schizophrenia as

believing they are famous or important people (such as Napoleon or Jesus Christ), although this is only one type of delusion. Arthur's belief that he could end starvation for all the world's children is also a *delusion of grandeur* (a mistaken belief that the person is famous or powerful) (Knowles, McCarthy-Jones, & Rowse, 2011).

A common delusion in people with schizophrenia is that others are "out to get them." Called *delusions of persecution*, these beliefs can be most disturbing. One of us worked with a world-class cyclist who was on her way to making the Olympic team. Tragically, however, she developed a belief that other competitors were determined to sabotage her efforts, which forced her to stop riding for years. She believed opponents would spray her bicycle with chemicals that would take her strength away, and they would slow her down by putting small pebbles in the road that only she would ride over. These thoughts created a great deal of anxiety, and she refused even to go near her bicycle for some time.

Other more unusual delusions include Capgras syndrome, in which the person believes someone he or she knows has been replaced by a double, and Cotard's syndrome, in which the person believes he or she is dead (Debruyne & Audenaert, 2012; Salvatore et al., 2014).

One man struggling to understand and come to grips with his strange thoughts frankly describes his delusional experiences (Timlett, 2013):

I once considered that I was a kind of human-robot (perhaps severely autistic), and had been stuck in the same routine for years which meant that everyone knew me

and recognized me and always knew exactly what I was thinking. I thought that I was in fact the subject of some kind of experiment designed to cure me from being so predictable and obvious in my behavior and thoughts. On my way home and at work this explained why it is I thought that people I didn't know actually recognized me, and why I also believed they were secretly all wishing me well and why they now thought I might have been cured because I was now behaving differently and less predictably (p. 245).

Why would someone come to believe such obviously improbable things (for example, that you were a human robot repeating the same things endlessly)? A number of theories exist and can be summarized into two themes—motivational or deficit theories (McKay, Langdon, & Coltheart, 2007). A *motivational view of delusions* would look at these beliefs as attempts to deal with and relieve anxiety and stress. A person develops "stories" around some issue—for example, a famous person is in love with her (erotomania)—that in a way helps the person make sense out of uncontrollable anxieties in a tumultuous world. Preoccupation with the delusion distracts the individual from the upsetting aspects of the world, such as hallucinations. In contrast, a *deficit view of delusion* sees these beliefs as resulting from brain dysfunction that creates these disordered cognitions or perceptions. Much work remains to develop an integrative account for these intriguing but debilitating symptoms of schizophrenia (Howes & Murray, 2014).

DSM
5 TABLE 13.1

Diagnostic Criteria for Schizophrenia

- A.** Two (or more) of the following, each present for a significant portion of time during a 1-month period (or less if successfully treated). At least one of these must be (1), (2), or (3):
1. Delusions
 2. Hallucinations
 3. Disorganized speech (e.g., frequent derailment or incoherence)
 4. Grossly disorganized or catatonic behavior
 5. Negative symptoms (i.e., diminished emotional expression or avolition)
- B.** For a significant portion of the time since the onset of the disturbance, level of functioning in one or more major areas, such as work, interpersonal relations, or self-care, is markedly below the level achieved prior to the onset (or when the onset is in childhood or adolescence, there is failure to achieve expected level of interpersonal, academic, or occupational functioning).
- C.** Continuous signs of the disturbance persist for at least 6 months. This 6-month period must include at least 1 month of symptoms (or less if successfully treated) that meet Criterion A (i.e., active-phase symptoms) and may include periods of prodromal or residual symptoms. During these prodromal or residual periods, the signs of the disturbance may be manifested by only negative symptoms or by two or more symptoms listed in Criterion A present in an attenuated form (e.g., odd beliefs, unusual perceptual experiences).
- D.** Schizoaffective disorder and depressive or bipolar disorder with psychotic features have been ruled out because either 1) no major depressive or manic episodes have occurred concurrently with the active-phase symptoms; or 2) if mood episodes have occurred during active-phase symptoms, they have been present for a minority of the total duration of the active and residual periods of the illness.
- E.** The disturbance is not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication) or another medical condition.
- F.** If there is a history of autistic spectrum disorder or a communication disorder of childhood onset, the additional diagnosis of schizophrenia is made only if prominent delusions or hallucinations, in addition to the other required symptoms of schizophrenia, are also present for at least 1 month (or less if successfully treated).

Hallucinations

Have you ever thought you heard someone call your name, only to discover that no one was there? Did you ever think you saw something move by you, yet nothing did? We all have fleeting moments when we think we see or hear something that isn't there. For many people with schizophrenia, however, these perceptions are real and occur regularly. The experience of sensory events without any input from the surrounding environment is called a **hallucination**. The case of David illustrates the phenomena of hallucinations, as well as other disorders of thought that are common among people with schizophrenia.

David... Missing Uncle Bill

David was 25 years old when I met him; he had been living in a psychiatric hospital for about 3 years. He was a little overweight and of average height; he typically dressed in a T-shirt and jeans and tended to be active. I first encountered him while I was talking to another man who lived on the same floor. David interrupted us by pulling on my shoulder. "My Uncle Bill is a good man. He treats me well." Not wanting to be impolite, I said, "I'm sure he is. Maybe after I've finished talking to Michael here, we can talk about your uncle." David persisted, "He can kill fish with a knife. Things can get awfully sharp in your mind, when you go down the river. I could kill you with my bare hands—taking things into my own hands. . . . I know you know!" He was now speaking quickly and had gained emotionality, along with speed, as he spoke. I talked to him quietly until he calmed down for the moment; later, I looked into David's file for some information about his background.

David was brought up on a farm by his Aunt Katie and Uncle Bill. His father's identity is unknown and his mother, who had mental retardation, couldn't care for him. David, too, was diagnosed as having mental retardation, although his functioning was only mildly impaired, and he attended school. The year David's Uncle Bill died, his high school teachers first reported unusual behavior. David occasionally talked to his deceased Uncle Bill in class. Later, he became increasingly agitated and verbally aggressive toward others and was diagnosed as having schizophrenia. He managed to graduate from high school but never obtained a job after that; he lived at home with his aunt for several years. Although his aunt sincerely wanted him to stay with her, his threatening behavior escalated to the point that she requested he be seen at the local psychiatric hospital.

I spoke with David again and had a chance to ask him a few questions. "Why are you here in the hospital, David?" "I really don't want to be here," he told me. "I've got other things to do. The time is right, and you know, when opportunity knocks." He continued for a few minutes until I interrupted him. "I was sorry to hear that your Uncle Bill died a few years ago. How are you feeling about him these days?" "Yes, he died. He was sick and now he's gone. He likes to fish with me, down at the river. He's going to take me hunting. I have guns. I can shoot you, and you'd be dead in a minute."

David's conversational speech resembled a ball rolling down a rocky hill. Like an accelerating object, his speech gained momentum the longer he went on and, as if bouncing off obstacles, the topics almost always went in unpredictable directions. If he continued for too long, he often became agitated and spoke of harming others. David also told me that his uncle's voice spoke to him repeatedly. He heard other voices also, but he couldn't identify them or tell me what they said. We return to David's case later in this chapter when we discuss causes and treatments. •

Hallucinations can involve any of the senses, although hearing things that aren't there, or *auditory hallucination*, is the most common form experienced by people with schizophrenia, with 70% of those with the diagnosis endorsing this type (Liddle, 2012; Waters et al., 2012). David had frequent auditory hallucinations, usually of his uncle's voice. When David heard a voice that belonged to his Uncle Bill, he often couldn't understand what his uncle was saying; on other occasions, the voice was clearer. "He told me to turn off the TV. He said, 'It's too damn loud, turn it down, turn it down.'" This is consistent with recent views of hallucinations as being related to metacognition or "thinking about thinking." In other words, metacognition is a phrase to describe examining your own thoughts. Most of us have had an occasional intrusive thought that we try not to focus on (for example, thinking, "I wish she were dead!" when you know that's not appropriate). People who experience hallucinations appear to have intrusive thoughts, but they believe they are coming from somewhere or someone else (David thinking he is hearing his uncle's voice when it is probably his own thoughts he is "hearing"). They then worry about having these thoughts and engage in meta-worry—or worrying about worrying. Unfortunately, meta-worry has been linked to increased anxiety and depression symptoms for those suffering from hallucinations (Oosterhout, Krabbendam, Smeets, & Gaag, 2013).

Exciting research on hallucinations uses sophisticated brain-imaging techniques to try to localize these phenomena in the brain. In one of the first studies of its kind, researchers in London used single photon emission computed tomography (SPECT) to study the cerebral blood flow of men with schizophrenia who also had auditory verbal hallucinations and made a surprising discovery (McGuire, Shah, & Murray, 1993). The researchers used the brain-imaging technique while the men were experiencing hallucinations and while they were not, and they found that the part of the brain most active during hallucinations was Broca's area (see ● Figure 13.1). This is surprising because Broca's area is known to be involved in speech *production*, rather than language *comprehension*. Because auditory verbal hallucinations usually involve understanding the "speech" of others, you might expect more activity in Wernicke's area, which involves language comprehension. These observations support the metacognition theory that people who are hallucinating are *not* hearing the voices of others but are listening to their own thoughts or their own voices and cannot recognize the difference (Allen & Modinos, 2012). One possible explanation for this problem is referred to as poor "emotional prosody comprehension." Prosody is that aspect of our spoken language that communicates meaning and emotion

through our pitch, amplitude, pauses, etc. We can often tell when a person is asking a question, for example, not just by the words themselves but also by the way it is said (e.g., “Hungry?”). Research suggests that emotional prosody is deficient in persons with auditory verbal hallucinations, contributing to the confusion both with others as well as when interpreting “inner voices” (Alba-Ferrara, Fernyough, Weis, Mitchell, & Hausmann, 2012).

Negative Symptoms

In contrast to the active presentations that characterize the positive symptoms of schizophrenia, the **negative symptoms** usually indicate the absence or insufficiency of normal behavior. They include apathy, poverty of (i.e., limited) thought or speech, and emotional and social withdrawal, and approximately 25% of people with schizophrenia display these symptoms (Cohen, Natarajan, Araujo, & Solanki, 2013; Millan, Fone, Steckler, & Horan, 2014).

Avolition

Combining the prefix *a*, meaning “without,” and *volition*, which means “an act of willing, choosing, or deciding,” **avolition** is the inability to initiate and persist in activities. People with this symptom (also referred to as *apathy*) show little interest in performing even the most basic day-to-day functions, including those associated with personal hygiene.

Alogia

Derived from the combination of *a* (“without”) and *logos* (“words”), **alogia** refers to the relative absence of speech. A person with alogia may respond to questions with brief replies that have little content and may appear uninterested in the conversation. For example, to the question, “Do you have any children?” most parents might reply, “Oh yes, I have two beautiful children, a boy and a girl. My son is 6 and my daughter is 12.” In the following exchange, someone with alogia responds to the same question:

INTERVIEWER: Do you have any children?

CLIENT: Yes.

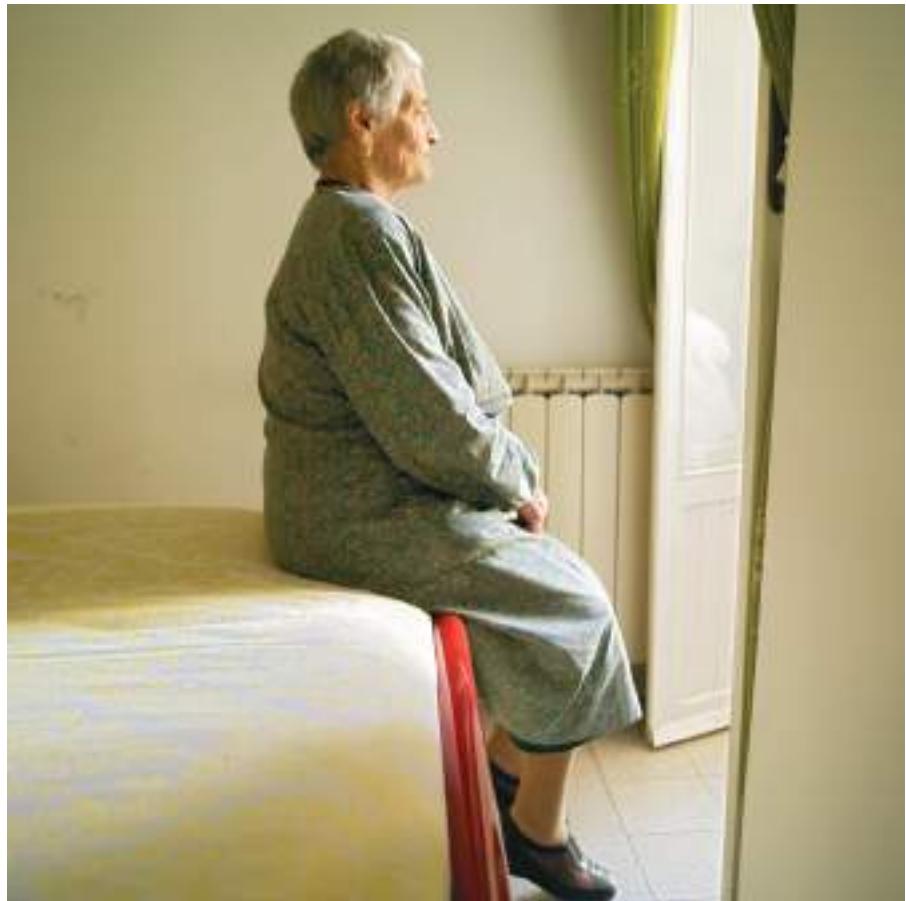

I: How many children do you have?

C: Two.

I: How old are they?

C: Six and twelve.

Such deficiency in communication is believed to reflect a negative thought disorder rather than inadequate communication skills. Some researchers, for example, suggest that people with alogia may have trouble finding the right words to formulate their thoughts (Andreasen, 2012). Sometimes alogia takes the form of delayed comments or slow responses to questions. Talking with individuals who manifest this symptom can be extremely frustrating, making you feel as if you are “pulling teeth” to get them to respond.

Negative symptoms of schizophrenia include social withdrawal and apathy

Anhedonia

A related symptom is called **anhedonia**, which derives from the combination of *a* (“without”) and the word *hedonic* (“pertaining to pleasure”). Anhedonia is the presumed lack of pleasure experienced by some people with schizophrenia. Like some mood disorders, anhedonia signals an indifference to activities that would typically be considered pleasurable, including eating, social interactions, and sexual relations.

Asociality

This symptom may seem very similar to avolition or related to anhedonia. However, asociality (*a* meaning “without” and *social* meaning “relating to society or its organization”) has been recognized as a separate symptom of schizophrenia spectrum disorders. This symptom captures a lack of interest in social interactions (APA, 2013). Unfortunately, this symptom can also result from or be worsened by limited opportunities to interact with others, particularly for severely ill patients (Reddy, Horan, & Green, 2016).

Affective Flattening

Imagine that people wore masks at all times: You could communicate with them verbally, but you wouldn’t be able to see their emotional reactions. Approximately one quarter of the people with schizophrenia exhibit what is called **flat affect** (Lewis et al., 2009; Simonsen et al., 2012). They are similar to people wearing masks because they do not show emotions when you would normally expect them to. They may stare at you vacantly, speak in a flat and toneless manner, and seem unaffected by things going on around them. However, although they do not react openly to emotional situations, they may be responding on the inside.

Howard Berenbaum and Thomas Oltmanns (1992) compared people with schizophrenia who had flat (or “blunted”) affect with those who did not. The two groups were shown clips from comedies and dramas selected to create emotional reactions in the viewer. Berenbaum and Oltmanns found that the people with flat affect showed little change in facial expression, although they reported experiencing the appropriate emotions. The authors concluded that the flat affect in schizophrenia may represent difficulty expressing emotion, not a lack of feeling. Researchers can now use computer analyses of facial expressions to more objectively assess the emotional expressiveness of people with disorders such as schizophrenia (Kring & Elis, 2013). One such study confirmed the difficulty of people with this disorder to express themselves properly with facial expressions (Hamm, Pinkham, Gur, Verma, & Kohler, 2014). The

expression of affect—or the lack of this expression—may be an important symptom of the development of schizophrenia. In a particularly innovative study, researchers videotaped high-risk children (those with one or more parents who had schizophrenia) eating lunch in 1972 and followed them up almost 20 years later (Schiffman et al., 2004). The researchers were able to show that children who later went on to develop schizophrenia typically displayed less positive and more negative affect than those children who did not develop the disorder. This suggests that emotional expression may be one way to identify potential schizophrenia in children.

Disorganized Symptoms

Perhaps the least studied and therefore the least understood symptoms of schizophrenia are referred to as the “disorganized symptoms.” These include a variety of erratic behaviors that affect speech, motor behavior, and emotional reactions. The prevalence of these behaviors among those with schizophrenia is unclear.

Disorganized Speech

A conversation with someone who has schizophrenia can be particularly frustrating. If you want to understand what is bothering or upsetting this person, eliciting relevant information is especially difficult. For one thing, people with schizophrenia often lack *insight*, an awareness that they have a problem. In addition, they experience what Bleuler called “associative splitting” and what researcher Paul Meehl called “cognitive slippage” (Bleuler, 1908; Meehl, 1962). These phrases help describe the speech problems of people with schizophrenia: Sometimes they jump from topic to topic, and at other times they talk illogically. *DSM-5* uses the term **disorganized speech** to describe such communication problems. Let’s go back to our conversation with David to demonstrate the symptom.

THERAPIST: Why are you here in the hospital, David?
DAVID: I really don’t want to be here. I’ve got other things to do. The time is right, and you know, when opportunity knocks . . .

David didn’t really answer the question he was asked. This type of response is called *tangentiality*—that is, going off on a tangent instead of answering a specific question. David also abruptly changed the topic of conversation to unrelated areas, a behavior that has variously been called *loose association* or *derailment* (Liddle, 2012).

Therapist: I was sorry to hear that your Uncle Bill died a few years ago. How are you feeling about him these days?
David: Yes, he died. He was sick, and now he’s gone. He likes to fish with me, down at the river. He’s going to take

me hunting. I have guns. I can shoot you, and you'd be dead in a minute.

Again, David didn't answer the question. It was unclear whether he didn't understand the question, couldn't focus his attention, or found it too difficult to talk about his uncle. You can see why people spend a great deal of time trying to interpret all the hidden meanings behind this type of conversation. Unfortunately, however, such analyses have yet to provide us with useful information about the nature of schizophrenia or its treatment.

Inappropriate Affect and Disorganized Behavior

Occasionally, people with schizophrenia display **inappropriate affect**, laughing or crying at improper times. Sometimes they exhibit bizarre behaviors such as hoarding objects or acting in unusual ways in public. People with schizophrenia engage in a number of other “active” behaviors that are usually viewed as unusual. For example, catatonia is one of the most curious symptoms in some individuals with schizophrenia; it involves motor dysfunctions that range from wild agitation to immobility. *DSM-5* now includes catatonia as a separate schizophrenia spectrum disorder. On the active side of the continuum, some people pace excitedly or move their fingers or arms in stereotyped ways. At the other end of the extreme, people hold unusual postures, as if they were fearful of something terrible happening if they moved (**catatonic immobility**). This manifestation can also involve *waxy flexibility*,

 - 2.** Cataplexy (i.e., passive induction of a posture held against gravity)
 - 3.** Waxy flexibility (i.e., slight, even resistance to positioning by examiner)
 - 4.** Mutism (i.e., no, or very little, verbal response [exclude if known aphasia])

flexibility, or the tendency to keep their bodies and limbs in the position they are put in by someone else.

Again, to receive a diagnosis of schizophrenia, a person must display two or more of the major symptoms (i.e., delusions, hallucinations, disorganized speech, grossly abnormal psychomotor behavior—including catatonia—or negative symptoms such as diminished emotional expression or avolition) for a significant portion of time for 1 month. At least one of the symptoms must include delusions, hallucinations, or disorganized speech. Depending on the combination of symptoms displayed, two people could receive the same diagnosis but behave differently, for example, one having marked hallucinations and delusions and the other displaying disorganized speech and some negative symptoms. Proper treatment depends on differentiating individuals in terms of their varying symptoms.

Historic Schizophrenia Subtypes

As we noted earlier, the search for subtypes of schizophrenia began before Kraepelin described his concept of schizophrenia. Three divisions have historically been identified: paranoid (delusions of

grandeur or persecution), disorganized (or hebephrenic; silly and immature emotionality), and catatonic (alternate immobility and excited agitation). Although these categories continued to be used in *DSM-IV-TR*, they were dropped from the diagnostic criteria for *DSM-5* (American Psychiatric Association, 2013). Part of the rationale for omitting these subtypes was that they were not used frequently in clinical work, and the nature of an individual's symptoms can change over the course of his or her illness; so people could move from one category to another (Tandon et al., 2013). The dimensional assessment of severity is now used instead of the three schizophrenia subtypes (Pagsberg, 2013).

In the next section, we describe the disorders which are included under the broader heading of "Schizophrenia Spectrum and Other Psychotic Disorders."

Other Psychotic Disorders

The psychotic behaviors of some individuals do not fit neatly under the heading of schizophrenia as we have just described. Several other categories of disorders depict these significant variations.

Schizophreniform Disorder

Some people experience the symptoms of schizophrenia for a few months only; they can usually resume normal lives. The symptoms sometimes disappear as the result of successful treatment, but they often do so for reasons unknown. The label **schizophreniform disorder** classifies these symptoms, but because relatively few studies are available on this disorder, data on important aspects of it are sparse. It appears, however, that the lifetime prevalence is approximately 0.2% (Erlich, Smith, Horwath, & Courno, 2014). The *DSM-5* diagnostic criteria for schizophreniform disorder include onset of psychotic symptoms within 4 weeks of the first noticeable change in usual behavior, confusion at the height of the psychotic episode, good *premorbid* (before the psychotic episode) social and occupational functioning, and the absence of blunted or flat affect (Garrabe & Cousin, 2012).

Schizoaffective Disorder

Historically, people who had symptoms of schizophrenia and who exhibited the characteristics of mood disorders (for example, depression or bipolar disorder) were lumped in the category of schizophrenia. Now, however, this mixed bag of problems is diagnosed as **schizoaffective disorder** (Tsuang, Stone, & Faraone, 2012). The prognosis is similar to the prognosis for people with schizophrenia—that is, individuals tend not to get better on their own and are likely to continue experiencing major life difficulties for many years. *DSM-5* criteria for schizoaffective disorder require, in addition to the presence of a mood disorder, delusions or hallucinations for at least 2 weeks in the absence of prominent mood symptoms (American Psychiatric Association, 2013).

Delusional Disorder

Delusions are beliefs that are not generally held by other members of a society. The major feature of **delusional disorder** is a

 - 3.** Disorganized speech (e.g., frequent derailment or incoherence)
 - 4.** Grossly disorganized or catatonic behavior
 - 5.** Negative symptoms (i.e., diminished emotional expression or avolition)
- B.** An episode of the disorder lasts at least 1 month but less than 6 months. When the diagnosis must be made without waiting for recovery, it should be qualified as "provisional."
- C.** Schizoaffective disorder and depressive or bipolar disorder with psychotic features have been ruled out because either 1) no major depressive or manic episodes have occurred concurrently with the active-phase symptoms; or 2) if mood episodes have occurred during active-phase symptoms, they have been present for a minority of the total duration of the active and residual periods of the illness.

persistent belief that is contrary to reality, in the absence of other characteristics of schizophrenia. For example, a woman who believes without any evidence that coworkers are tormenting her by putting poison in her food and spraying her apartment with harmful gases may have a delusional disorder. This disorder is characterized by a persistent delusion that is not the result of an organic factor such as brain seizures or of any severe psychosis. Individuals with delusional disorder tend not to have flat affect, anhedonia, or other negative symptoms of schizophrenia; importantly, however, they may become socially isolated because they are suspicious of others. The delusions are often long-standing, sometimes persisting over several years (Munro, 2012).

DSM-5 recognizes the following delusional subtypes: erotomaniac, grandiose, jealous, persecutory, and somatic. An *erotomaniac* type of delusion is the irrational belief that one is loved by another person, usually of higher status. Some individuals who stalk celebrities appear to have erotomaniac delusional disorder.

The *grandiose type* of delusion involves believing in one's inflated worth, power, knowledge, identity, or special relationship to a deity or famous person (Knowles et al., 2011). A person with the *jealous type* of delusion believes the sexual partner is unfaithful. The *persecutory type* of delusion involves believing oneself (or someone close) is being malevolently treated in some way. Finally, with the *somatic delusions* the person feels afflicted by a physical defect or general medical condition. Typically these delusions differ from the more bizarre types often found in people with schizophrenia because in delusional disorder *the imagined events could be happening but aren't* (for example, mistakenly believing you are being followed); in schizophrenia, however, delusions tend to fall in the bizarre category (for example, believing your brain waves broadcast your thoughts to other people around the world). DSM-5 allows for one bizarre delusion, which separates it from a diagnosis of schizophrenia, which requires more than one delusion to be present (Heckers et al., 2013).

Previous versions of DSM included a separate delusional disorder—**shared psychotic disorder (folie à deux)**, the condition in which an individual develops delusions simply as a result of a close relationship with a delusional individual. The content and nature of the delusion originate with the partner and can range from the relatively bizarre, such as believing enemies are sending harmful gamma rays through your house, to the fairly ordinary, such as believing you are about to receive a major promotion despite evidence to the contrary. DSM-5 now includes this type of delusion under delusional disorder with a specifier to indicate if the delusion is shared (American Psychiatric Association, 2013).

Delusional disorder seems to be relatively rare, affecting 24 to 60 people out of every 100,000 in the general population (de

Erotomaniac type: This subtype applies when the central theme of the delusion is that another person is in love with the individual.

Grandiose type: This subtype applies when the central theme of the delusion is the conviction of having some great (but unrecognized) talent or insight or having made some important discovery.

Jealous type: This subtype applies when the central theme of the individual's delusion is that his or her spouse or lover is unfaithful.

Persecutory type: This subtype applies when the central theme of the delusion involves the individual's belief that he or she is being conspired against, cheated, spied on, followed, poisoned or drugged, maliciously maligned, harassed, or obstructed in the pursuit of long-term goals.

Somatic type: This subtype applies when the central theme of the delusion involves bodily functions or sensations.

Mixed type: This subtype applies when no delusional theme predominated.

Unspecified type: This subtype applies when the dominant delusional belief cannot be clearly determined or is not described in the specific types (e.g., referential delusions without a prominent persecutory or grandiose component).

Portugal, González, Haro, Autonell, & Cervilla, 2008; Ibanez-Casas & Cervilla, 2012). Among those people with psychotic disorders in general, between 2% and 8% are thought to have delusional disorder (Vahia & Cohen, 2009; Blaney, 2015). Researchers can't be confident about the percentages because they know that many of these individuals have no contact with the mental health system.

The onset of delusional disorder is relatively late: The average age of first admission to a psychiatric facility is between 35 and 55 (Ibanez-Casas & Cervilla, 2012). Because many people with this disorder can lead relatively typical lives, they may not seek treatment until their symptoms become most disruptive. Delusional disorder seems to afflict more females than males (55% and 45%, respectively, of the affected population).

In an important longitudinal study, Opjordsmoen (1989) followed 53 people with delusional disorder for an average of

- A.** Presence of one or both of the following symptoms:
 - 1.** Delusions
 - 2.** Hallucinations
 - B.** There is evidence from the history, physical examination, or laboratory findings of both (1) and (2):
 - 1.** The symptoms in Criterion A developed during, or soon after, substance intoxication or withdrawal or after exposure to a medication.
 - 2.** The involved substance/medication is capable of producing the symptoms in Criterion A.
 - C.** The disturbance is not better explained by a psychotic disorder that is not substance/medication-induced. Such evidence of an independent psychotic disorder could include the following: The symptoms preceded the onset of substance/medication use; the symptoms persist for a substantial period of time (e.g., about 1 month) after the cessation of acute withdrawal or severe intoxication; or there is other evidence of an independent non-substance/medication-induced psychotic disorder (e.g., a history of recurrent non-substance/medication-related episodes).
 - D.** The disturbance does not occur exclusively during the course of a delirium.
 - E.** The disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- Note:** This diagnosis should be made instead of a diagnosis of substance intoxication or substance withdrawal only when the symptoms in Criterion A predominate in the clinical picture and when they are sufficiently severe to warrant clinical attention.

30 years and found they tended to fare better in life than people with schizophrenia but not as well as those with some other psychotic disorders, such as schizoaffective disorder. About 80% of the 53 individuals had been married at some time, and half were employed, which demonstrates an ability to function relatively well despite delusions.

There is much conflicting evidence about either the biological or the psychosocial influences on delusional disorder (Ibanez-Casas & Cervilla, 2012). Research on families suggests that the characteristics of suspiciousness, jealousy, and secretiveness may occur more often among the relatives of people with delusional disorder than among the population at large, suggesting some aspect of this disorder may be inherited (Kendler & Walsh, 2007).

A number of other disorders can cause delusions, and their presence should be ruled out before diagnosing delusional disorder. For example, abuse of amphetamines, alcohol, and cocaine can cause delusions, as can brain tumors, Huntington's disease, and Alzheimer's disease (Blaney, 2015). DSM-5 includes two categories of these disorders: **substance-induced psychotic**

disorder and psychotic disorder associated with another medical condition—so that clinicians can qualify the nature of these difficulties.

Brief Psychotic Disorder

Recall the puzzling case of Arthur, who suddenly experienced the delusion that he could save the world and whose intense emotional swings lasted for only a few days. He would receive the *DSM-5* diagnosis of **brief psychotic disorder**, which is characterized by the presence of one or more positive symptoms such as delusions, hallucinations, or disorganized speech or behavior lasting 1 month or less. Individuals like Arthur regain their previous ability to function well in day-to-day activities. Brief psychotic disorder is often precipitated by extremely stressful situations.

Attenuated Psychosis Syndrome

Some individuals who start to develop psychotic symptoms such as hallucinations or delusions are often sufficiently distressed to seek help from mental health professionals. They can be at high risk for developing schizophrenia and may be at an early stage of the disorder (called prodromal). Although they may not meet the full criteria for schizophrenia, they may be good candidates for early intervention in an effort to prevent symptoms from worsening. To focus attention on these individuals, *DSM-5* is proposing a potentially new psychotic disorder for further study—**attenuated psychosis syndrome** (Fusar-Poli, Carpenter, Woods, & McGlashan, 2014). Again, these people may have some of the symptoms of schizophrenia but are aware of the troubling and bizarre nature of these symptoms.

Schizotypal personality disorder, discussed in Chapter 12, is a related psychotic disorder. As you may recall, the characteristics are similar to those experienced by people with schizophrenia but are less severe. Some evidence also suggests that schizophrenia and schizotypal personality disorder may be genetically related as part of a “schizophrenia spectrum.”

Remember that although people with related psychotic disorders display many of the characteristics of schizophrenia, these disorders differ significantly.

Concept Check 13.1

Part A

Determine which symptoms or types of schizophrenia spectrum disorders are described in each scenario.

1. Jane has spent the past half hour staring in the mirror. As you approach her, she turns away and giggles. When you ask what she's laughing at, she answers, but you're having difficulty understanding what she says.

2. Drew has experienced hallucinations and bizarre delusions for the past four months. _____
3. Greg's cognitive skills and affect are relatively intact. He, however, often has delusions and hallucinations that convince him enemies are out to persecute him.

4. Alice usually holds an unusual posture and is sometimes seen grimacing. _____
5. Cameron has started to hear voices, and this is very disturbing to him. He told his parents and recognizes that he needs to see a mental health professional for help. _____

Part B

Diagnose the type of psychotic disorders described in each of the following. Choose from (a) schizopreniform disorder, (b) schizoaffective disorder, (c) delusional disorder, and (d) shared psychotic disorder.

6. Lately Dom has become more isolated because he believes his coworkers are conspiring to get him fired. He becomes agitated whenever he sees a group of employees talking and laughing, because he believes that they are plotting against him. _____
7. Natalie reveals to her therapist that she hears numerous voices talking to her and giving her orders. Her doctor has just sent her to this therapist for what he believes to be a major depressive episode. She had begun to sleep all the time and contemplated suicide often. _____
8. If Shawn's schizophrenic symptoms disappeared after about 4 months and he returned to his normal life, what diagnosis might he have received? _____
9. Elias believes the government is out to get him. He thinks agents follow him daily, monitor his calls, and read his mail. His roommate Cedric tried to convince him otherwise. After a year of this, however, Cedric began to believe Elias was correct and the government was out to get him, too. _____

TABLE 13.8

Diagnostic Criteria for Brief Psychotic Disorder

- A. Presence of one (or more) of the following symptoms. At least one of these must be (1), (2), or (3):
 1. Delusions
 2. Hallucinations
 3. Disorganized speech (e.g., frequent derailment or incoherence)
 4. Grossly disorganized or catatonic behavior

Note: Do not include a symptom if it is a culturally sanctioned response

- B. Duration of an episode of the disturbance is at least 1 day but less than 1 month, with eventual full return to premorbid level of functioning.
- C. The disturbance is not better explained by major depressive or bipolar disorder with psychotic features, or another psychotic disorder such as schizophrenia or catatonia, and is not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication) or another medical condition.

Specify if:

With marked stressor(s) (brief reactive psychosis): If symptoms occur in response to events that, singly or together, would be markedly stressful to almost anyone in similar circumstances in the individual's culture.

Without marked stressor(s): If symptoms do not occur in response to events that, singly or together, would be markedly stressful to almost anyone in similar circumstances in the individual's culture.

With postpartum onset: If onset is during pregnancy or within 4 weeks postpartum.

Specify if: With catatonia

Prevalence and Causes of Schizophrenia

Studying schizophrenia reveals the many levels on which we must decipher what makes us behave the way we do. To uncover the causes of this disorder, researchers look in several areas: (1) the possible genes involved in schizophrenia, (2) the chemical action of the drugs that help many people with this disorder, (3) abnormalities in the working of the brains of people with schizophrenia, and (4) environmental risk factors that may precipitate the onset of the symptoms (Harrison, 2012; Murray & Castle, 2012). As we survey the work of many specialists, we examine many state-of-the-art techniques for studying both biological and psychosocial influences, a process that may be slow going at times but will bring new insight to your understanding of psychopathology. We now examine the nature of schizophrenia and learn how researchers have attempted to understand and treat people who have it.

Statistics

Schizophrenia sometimes defies our desire for simplicity. We have seen how different symptoms can be displayed by individuals who would all be considered to have the disorder; in some people, the

symptoms develop slowly, and in others they occur suddenly. Schizophrenia is generally chronic, and most people with the disorder have a difficult time functioning in society. This is especially true of their ability to relate to others; they tend not to establish or maintain significant relationships, so many people with schizophrenia never marry or have children. Unlike the delusions of people with other psychotic disorders, the delusions of people with schizophrenia are likely to be outside the realm of possibility. Finally, even when individuals with schizophrenia improve with treatment, they are likely to experience difficulties throughout their lives.

Worldwide, the lifetime prevalence rate of schizophrenia is roughly equivalent for men and women, and it is estimated to be 0.2% to 1.5% in the general population, which means the disorder will affect about 1% of the population at some point (Erlich et al., 2014). Life expectancy is slightly less than average, partly because of the higher rate of suicide and accidents among people with schizophrenia. Although there is some disagreement about the distribution of schizophrenia between men and women, the difference between the sexes in age of onset is clear. For men, the likelihood of onset diminishes with age, but it can still first occur after the age of 75. The frequency of onset for women is lower than for men until age 36, when the relative risk for onset switches, with more women than men being affected later in life (Jablensky, 2012). Women appear to have more favorable outcomes than do men.

Development

The more severe symptoms of schizophrenia first occur in late adolescence or early adulthood, although we saw that there may be signs of the development of the disorder in early childhood (Murray & Castle, 2012). Children who go on to develop schizophrenia show early clinical features such as mild physical abnormalities, poor motor coordination, and mild cognitive and social problems (Golemboski et al., 2012; Matheson et al., 2013; Welham et al., 2008). Unfortunately, these types of early problems are not specific enough to schizophrenia—meaning they could also be signs of other problems, such as the neurodevelopmental disorders we review in Chapter 14—to be able to say for sure that a particular child will later develop schizophrenia.

Up to 85% of people who later develop schizophrenia go through a **prodromal stage**—a 1- to 2-year period before the serious symptoms occur but when less severe yet unusual behaviors start to show themselves (Jablensky, 2012). These behaviors (which you should recognize from Chapter 12 as symptoms seen in schizotypal personality disorders) include ideas of reference (thinking insignificant events relate directly to them), magical thinking (believing they have special abilities such as being clairvoyant or telepathic), and illusions (such as feeling the presence of another person when they are alone). In addition, other symptoms are common, such as isolation, marked impairment in functioning, and a lack of initiative, interests, or energy (Addington et al., 2015).

Once symptoms begin to appear, it can take anywhere from 2 years to around 10 years before a person at high risk (e.g., mild positive symptoms) meets full criteria for a psychotic disorder (Nelson et al., 2013). The highest period of risk for patients to develop a full-fledged psychotic disorder is during the first two years following their first displays of mild symptoms. Risk factors for going from high risk to developing the disorder include the length of duration of symptoms before seeking help, baseline functioning, as well as the presence of negative symptoms and disorganized symptoms (Addington et al., 2015; Nelson et al., 2013). Part of the delay in seeking help may be the result of hiding symptoms from others (sometimes because of increasing paranoia). Personality factors and the amount and quality of social support may also play a role in the amount of time it takes a person to first seek treatment for psychotic symptoms (Ruiz-Veguilla et al., 2012). Once treated, patients with this disorder will often improve. Unfortunately, most will also go through a pattern of relapse and recovery (Emsley, Chiliza, Asmal & Harvey, 2013). This relapse rate is important when discussing the course of schizophrenia. For example, the data from one classic study show the course of schizophrenia among four prototypical groups (Zubin, Steinhauer, & Condry, 1992). About 22% of the group had one episode of schizophrenia and improved without lasting impairment. The remaining 78% experienced several episodes with differing degrees of impairment between them. People with schizophrenia have a poorer prognosis than those with most of the other disorders we describe in this book—including a high risk of suicide—although a significant number of individuals can experience long periods of recovery (Jablensky, 2012). Relapses are an important subject in the field of schizophrenia; we return to this phenomenon when we discuss causes and treatment. To illustrate this complex developmental picture, Figure 13.2 graphically depicts the developmental course of schizophrenia. Life stages (from before birth to the end of life) are listed across

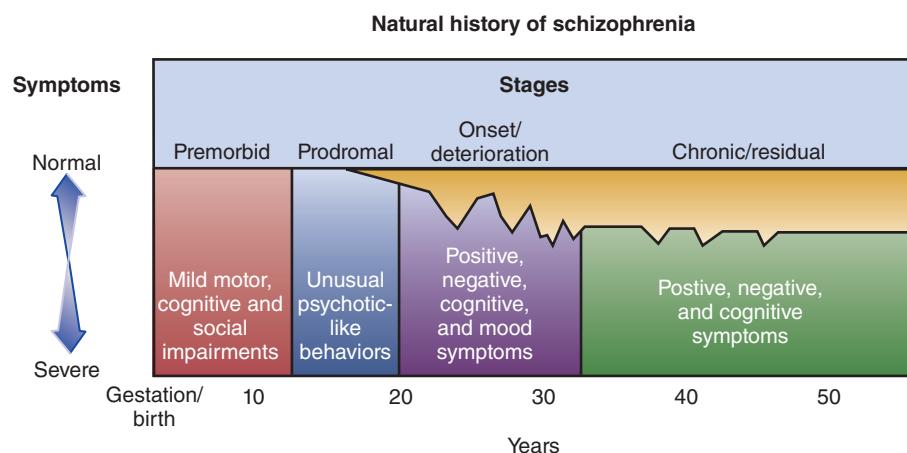

FIGURE 13.2

The longitudinal course of schizophrenia is depicted starting at birth through old age. The severity of the symptoms is shown on the left axis, and the changes in symptoms across each phase (premorbid, prodromal, onset, and chronic) are labeled. (Adapted from Lieberman, J. Cultural Factors

Because schizophrenia is so complex, the diagnosis itself can be controversial. Some have argued that “schizophrenia” does not really exist but is a derogatory label for people who behave in ways outside the cultural norm (see, for example, Laing, 1967; Sarbin & Mancuso, 1980; Szasz, 1961). This concern takes us back to our discussions in the first chapter about the difficulty defining what is abnormal. Although the idea that schizophrenia exists only in the minds of mental health professionals is certainly provocative, this extreme view is contradicted by experience. We have both had a great deal of contact with people who have this disorder and with their families and friends, and the tremendous amount of emotional pain resulting from schizophrenia gives definite credence to its existence. In an interesting historical note, Kraepelin, who we described as developing the modern-day view of schizophrenia, traveled to Asia at the turn of the past century to confirm that this unusual set of behaviors was experienced by cultures other than those of Western Europe (Lauriello, Bustillo, & Keith, 2005). We now know that people in widely diverging cultures have the symptoms of schizophrenia, which supports the notion that it is a reality for many people worldwide. Schizophrenia is thus universal, affecting all racial and cultural groups studied so far. There are even shared neuroanatomical similarities that provide evidence of schizophrenia’s presence across individuals from different cultures (Gong et al., 2015).

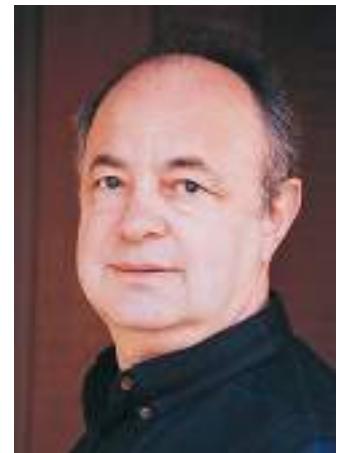

The course and outcome of schizophrenia vary from culture to culture. For example, the stressors associated with significant political, social, and economic problems that are prevalent in many areas of Africa, Latin America, and Asia may contribute to poorer outcomes for people with schizophrenia in these countries (Jablensky, 2012). The lack of an adequate mental health infrastructure in low- and middle-income countries is also a problem for providing appropriate and consistent care to those suffering from schizophrenia. Efforts to increase several countries’ capacity to care for those with schizophrenia have had some preliminary success in upper middle-income countries like China and Brazil (Patel, 2015). More initiatives focused on schizophrenia and other mental health disorders worldwide are starting to gain momentum.

In the United States, proportionately more African Americans receive the diagnosis of schizophrenia than Caucasians (Schwartz & Feisthamel, 2009). Research from both England and the United States suggests that people from devalued ethnic minority groups (Afro-Caribbean in England and African Americans and Puerto Ricans in the United States) may be victims of bias and stereotyping (Jones & Gray, 1986; Lewis, Croft-Jeffreys, & Anthony, 1990); in other words, they may be more likely to receive a diagnosis of schizophrenia than members of a dominant group. One prospective study of schizophrenia among different ethnic groups in London found that although the outcomes of schizophrenia appear similar across these groups, blacks were more likely to be detained against their will, brought to the hospital by police, and given emergency injections (Goater et al., 1999). The differing rates of schizophrenia, therefore, may

be partially the result of *misdiagnosis* rather than the result of any real cultural distinctions. An additional factor contributing to this imbalance may be the levels of stress associated with factors such as stigma, isolation, and discrimination (Anglin, Lighty, Greenspoon, & Ellman, 2014; Pinto, Ashworth, & Jones, 2008).

Genetic Influences

We could argue that few areas of abnormal psychology so clearly illustrate the enormous complexity and intriguing mystery of genetic influences on behavior as does the phenomenon of schizophrenia (Murray & Castle, 2012). Despite the possibility that schizophrenia may be several different disorders, we can safely make one generalization: *Genes are responsible for making some individuals vulnerable to schizophrenia*. We look at a range of research findings from family, twin, adoptee, offspring of twins, and linkage and association studies. We conclude by discussing the compelling reasons that no one gene is responsible for schizophrenia; rather, multiple gene variances combine to produce vulnerability (Murray & Castle, 2012).

Family Studies

In 1938, Franz Kallmann published a major study of the families of people with schizophrenia (Kallmann, 1938). Kallmann examined family members of more than 1,000 people diagnosed with schizophrenia in a Berlin psychiatric hospital. Several of his observations continue to guide research on schizophrenia. Kallmann showed that the severity of the parent’s disorder influenced the likelihood of the child’s having schizophrenia: The more severe the parent’s schizophrenia, the more likely the children were to develop it. Another observation was important: All forms of schizophrenia (for example, the historic categories such as catatonic and paranoid) were seen within the families. In other words, it does not appear that you inherit a predisposition for what was previously diagnosed as paranoid schizophrenia. Instead, you may inherit a general predisposition for schizophrenia that manifests in the same form or differently from that of your parent. More recent research confirms this observation and suggests that families that have a member with schizophrenia are at risk not just for schizophrenia alone or for all psychological disorders; instead, there appears to be some familial risk for a spectrum of psychotic disorders related to schizophrenia.

In a classic analysis, Gottesman (1991) summarized the data from about 40 studies of schizophrenia, as shown in Figure 13.3. The most striking feature of this graph is its orderly demonstration that the risk of having schizophrenia varies according to how many genes an individual shares with someone who has the disorder.

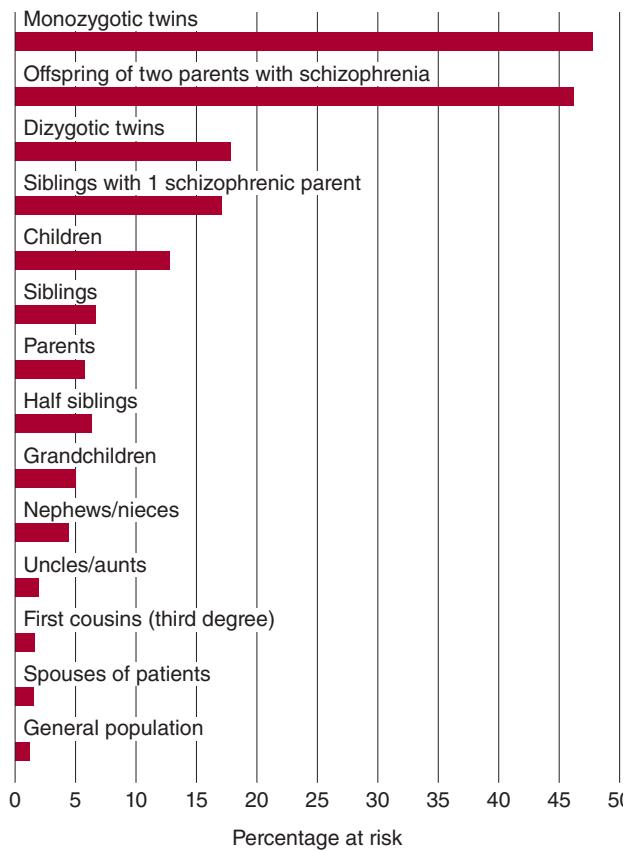

FIGURE 13.3

Risk of developing schizophrenia. (Based on Gottesman, I. I. (1991). *Schizophrenia genesis: The origins of madness*. New York, NY: W. H. Freeman.)

For example, you have the greatest chance (approximately 48%) of having schizophrenia if it has affected your identical (monozygotic) twin, a person who shares 100% of your genetic information. Your risk drops to about 17% with a fraternal (dizygotic) twin, who shares about 50% of your genetic information. And having any relative with schizophrenia makes you more likely to have the disorder than someone without such a relative (about 1% if you have no relative with schizophrenia). Because family studies can't separate genetic influence from the impact of the environment, we use twin and adoption studies to help us evaluate the role of shared experiences in the cause of schizophrenia.

Twin Studies

If they are raised together, identical twins share 100% of their genes and 100% of their environment, whereas fraternal twins share only about 50% of their genes and 100% of their environment. If the environment is solely responsible for schizophrenia, we would expect little difference between identical and fraternal twins with regard to this disorder. If only genetic factors are relevant, both identical twins would always have schizophrenia (be concordant), and the fraternal twins would both have it about 50% of the time. Research from twin studies indicates that the truth is somewhere in the middle (Braff et al., 2007; van Os, Kenis, & Rutten, 2010).

In one of the most fascinating of “nature’s experiments,” identical quadruplets, all of whom have schizophrenia, have been studied extensively. Nicknamed the “Genain” quadruplets (from the Greek, meaning “dreadful gene”), these women have been followed by David Rosenthal and his colleagues at the National Institute of Mental Health for a number of years (Rosenthal, 1963). The fictitious names of the girls reported in studies of their lives—Nora, Iris, Myra, and Hester—represent the letters NIMH for the National Institute of Mental Health. In a sense, the women represent the complex interaction between genetics and environment. All four shared the same genetic predisposition, and all were brought up in the same particularly dysfunctional household; yet the time of onset for schizophrenia, the symptoms and diagnoses, the course of the disorder, and, ultimately, their outcomes, differed significantly from sister to sister.

One genetic explanation for these differences may be the presence of *de novo* mutations in the sisters. These are genetic mutations that can occur as a result of a mutation in a germ cell (egg or sperm) of one of the parents or, perhaps in the case of these sisters, in the fertilized egg after conception. The case of the Genain quadruplets also reveals an important consideration in studying genetic influences on behavior—*unshared environments* (Plomin, 1990). We tend to think that siblings, and especially identical multiples, are brought up exactly the same way. The impression is that “good” parents expose their children to favorable environments and “bad” parents give them unstable experiences. Even identical siblings can have different prenatal and family experiences and can therefore be exposed to varying degrees of biological and environmental stress. For example, Hester, one of the Genain sisters, was described by her disturbed parents as a habitual masturbator, and she had more social problems than her sisters as she grew up. Hester was the first to experience severe symptoms of schizophrenia, at age 18, but her sister Myra was not hospitalized until 6 years later. This unusual case demonstrates that even siblings who are close in every aspect of their lives can still have considerably different experiences physically and socially as they grow up, which may result in vastly different outcomes. A follow up on the lives of these women showed the progression of their disorder stabilized and in some cases improved when they were assessed at age 66 (Mirsky et al., 2000).

Adoption Studies

Several adoption studies have distinguished the roles of the environment and genetics as they affect schizophrenia. These studies often span many years; because people often do not show the first signs of schizophrenia until middle age, researchers need to be sure all the offspring reach that point before drawing conclusions. Many schizophrenia studies are conducted in Europe, primarily because of the extensive and comprehensive records kept in countries where socialized medicine is practiced.

The largest adoption study was conducted in Finland (Tienari, 1991). From a sample of almost 20,000 women with schizophrenia, the researchers found 190 children who had been given up for adoption. The data from this study support the idea that schizophrenia represents a spectrum of related disorders, all of which overlap genetically. If an adopted child had a biological mother

Dr. Allan F. Mirsky/National Institute of Mental Health

The Genain quadruplets all had schizophrenia but exhibited different symptoms over the years.

with schizophrenia, that child had about a 5% chance of having the disorder (compared to about only 1% in the general population). However, if the biological mother had schizophrenia or one of the related psychotic disorders (for example, delusional disorder or schizopreniform disorder), the risk that the adopted child would have one of these disorders rose to about 22% (Tienari et al., 2003; Tienari, Wahlberg, & Wynne, 2006). Even when raised away from their biological parents, children of parents with schizophrenia have a much higher chance of having the disorder themselves. At the same time, there appears to be a protective factor if these children are brought up in healthy supportive homes. In other words, a gene-environment interaction was observed in this study, with a good home environment reducing the risk of schizophrenia (Gilmore, 2010; Wynne et al., 2006).

The Offspring of Twins

Twin and adoption studies strongly suggest a genetic component for schizophrenia, but what about children who develop schizophrenia even though their parents do not? For example, the study by Tienari and colleagues (2003, 2006) we just discussed found that 1.7% of the children with nonschizophrenic parents developed schizophrenia. Does this mean you can develop schizophrenia without “schizophrenic genes”? Or are some people carriers, having the genes for schizophrenia but for some reason not showing the disorder themselves? An important clue to this question comes from research on the children of twins with schizophrenia.

In a study begun in 1971 by Margit Fischer and later continued by Irving Gottesman and Aksel Bertelsen, 21 identical twin pairs and 41 fraternal twin pairs with a history of schizophrenia were identified, along with their children (Fischer, 1971; Gottesman & Bertelsen, 1989). The researchers wanted to determine the relative likelihood that a child would have schizophrenia if her parent did and if the parent's twin had schizophrenia but the parent did not.

Figure 13.4 illustrates the findings from this study. For example, if your parent is an identical (monozygotic) twin with schizophrenia, you have about a 17% chance of having the disorder yourself,

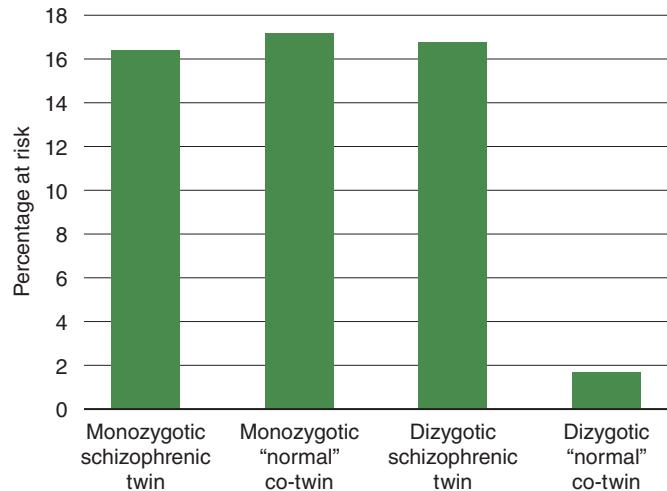

FIGURE 13.4

Risk for schizophrenia among children of twins.

a figure that holds if you are the child of an unaffected identical twin whose co-twin has the disorder.

On the other hand, look at the risks for the child of a fraternal (dizygotic) twin. If your parent is the twin with schizophrenia, you have about a 17% chance of having schizophrenia yourself. If your parent does not have schizophrenia but your parent's fraternal twin does, your risk is only about 2%. The only way to explain this finding is through genetics. The data clearly indicate that you can have genes that predispose you to schizophrenia, not show the disorder yourself, but still pass on the genes to your children. In other words, you can be a “carrier” for schizophrenia. This is some of the strongest evidence yet that people are genetically vulnerable to schizophrenia. Remember, however, there is only a 17% chance of inheritance if your parent has schizophrenia, meaning that other factors help determine who will have this disorder.

Linkage and Association Studies

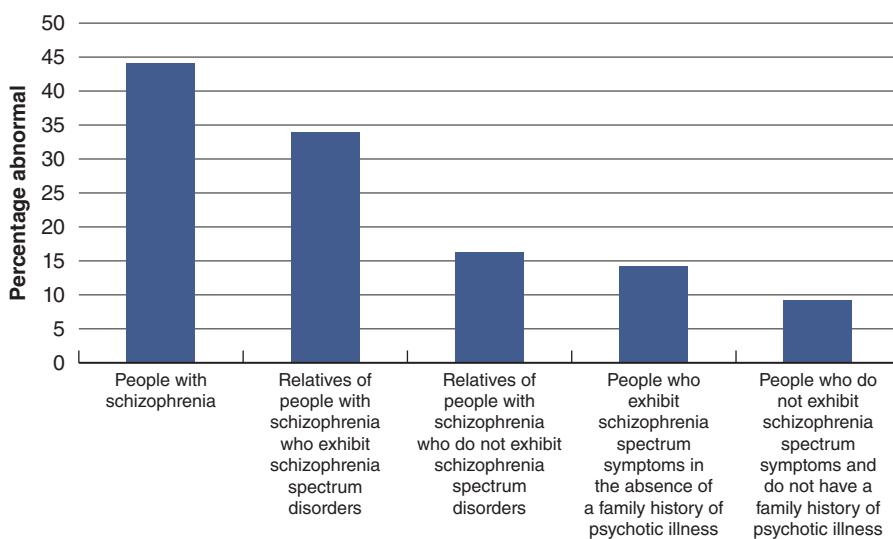

Recall from Chapter 4 that genetic linkage and association studies rely on traits such as blood types (whose exact location on the chromosome is already known) inherited in families with the disorder you are looking for—in this case, schizophrenia. Because researchers have determined the location of the genes for these traits (called *marker genes*), they can make a rough guess about the location of the disorder genes inherited with them. To date, researchers have looked at several sites for genes that may be responsible for schizophrenia. For example, regions of chromosomes 1, 2, 3, 5, 6, 8, 10, 11, 13, 20, and 22 are implicated in this disorder (Kirov & Owen, 2009). Three of the most reliable genetic influences that make one susceptible to schizophrenia include sections on chromosome 8 (called Neuregulin 1 or NRG1), chromosome 6 (called dystrobrevin-binding protein 1 or DTNBP1), and chromosome 22 (called catecholamine O-methyl transferase or COMT) (Murray & Castle, 2012). The COMT gene is of particular interest to scientists because it plays a role in dopamine metabolism, which we will see appears to be disrupted in persons with this disorder. A recent study that combined one of the largest samples

(i.e., 36,989 cases of individuals with schizophrenia and 113,075 controls) identified 128 independent associations and 108 loci that meet genome-wide significance, 83 of which were new. This further strengthens that genetic risk arises from a large number of common genes each with a small effect that might be detected by genome-wide association studies (Ripke et al., 2014).

Endophenotypes

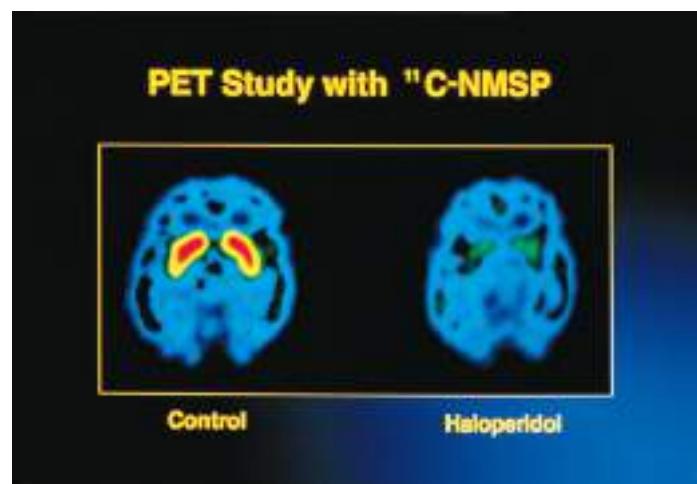

Genetic research on schizophrenia is evolving, and the information on the findings from these sophisticated studies is now being combined with advances in our understanding of specific deficits found in people with this disorder. Remember, in complex disorders such as this, researchers are not looking for a “schizophrenia gene” or genes. Instead, researchers try to find basic processes that contribute to the behaviors or symptoms of the disorder and then find the gene or genes that cause these difficulties—a strategy called *endophenotyping* (Braff et al., 2007).

Several potential candidates for endophenotypes for schizophrenia have been studied over the years. One of the more highly researched is called *smooth-pursuit eye movement*, or eye-tracking. Keeping their head still, typical people are able to track a moving pendulum, back and forth, with their eyes. The ability to track objects smoothly across the visual field is deficient in many people who have schizophrenia (Clementz & Sweeney, 1990; Holzman & Levy, 1977; Iacono, Bassett, & Jones, 1988); it does not appear to be the result of drug treatment or institutionalization (Lieberman et al., 1993). It also seems to be a problem for relatives of those with schizophrenia (Ivleva et al., 2014). ● Figure 13.5 shows the decreasing likelihood of observing this abnormal eye-tracking ability the further a person is genetically from someone with schizophrenia. When all these observations are combined, they suggest an eye-tracking deficit may be an endophenotype for schizophrenia that could be used in further study.

These PET images show the brain of a man with schizophrenia who had never been medicated (left) and after he received haloperidol (right). The red and yellow areas indicate activity in the D₂ receptors; haloperidol evidently reduced dopamine activity.

Other such research focuses on the social, cognitive, and emotional deficits characteristic of schizophrenia. One study, for example, looked at multiple generations of families who had someone with schizophrenia (Gur et al., 2007). They tested them on a variety of skills for identified cognitive deficits in areas we described previously—such as emotion identification—and showed that specific problems were inherited in the same manner as schizophrenia (suggesting that these cognitive deficits might be endophenotypes for schizophrenia). Currently, a number of endophenotypes are being explored by a large group of scientists (*The Consortium on the Genetics of Schizophrenia*) which is studying more than 1,200 individuals with schizophrenia and their families (Greenwood et al., 2013).

Neurobiological Influences

The belief that schizophrenia involves a malfunctioning brain goes back as far as the writings of Kraepelin (1856–1926). It is therefore not surprising that a great deal of research has focused on the brain.

Dopamine

One of the most enduring yet controversial theories of the cause of schizophrenia involves the neurotransmitter *dopamine* (Harrison, 2012). Before we consider the research, however, let’s review briefly how neurotransmitters operate in the brain and how they are affected by neuroleptic medications, which reduce hallucinations and delusions. In Chapter 2, we discussed the sensitivity of specific neurons to specific neurotransmitters and described how they cluster throughout the brain. The top of ● Figure 13.6 shows two neurons and the important synaptic gap that separates them. Neurotransmitters are

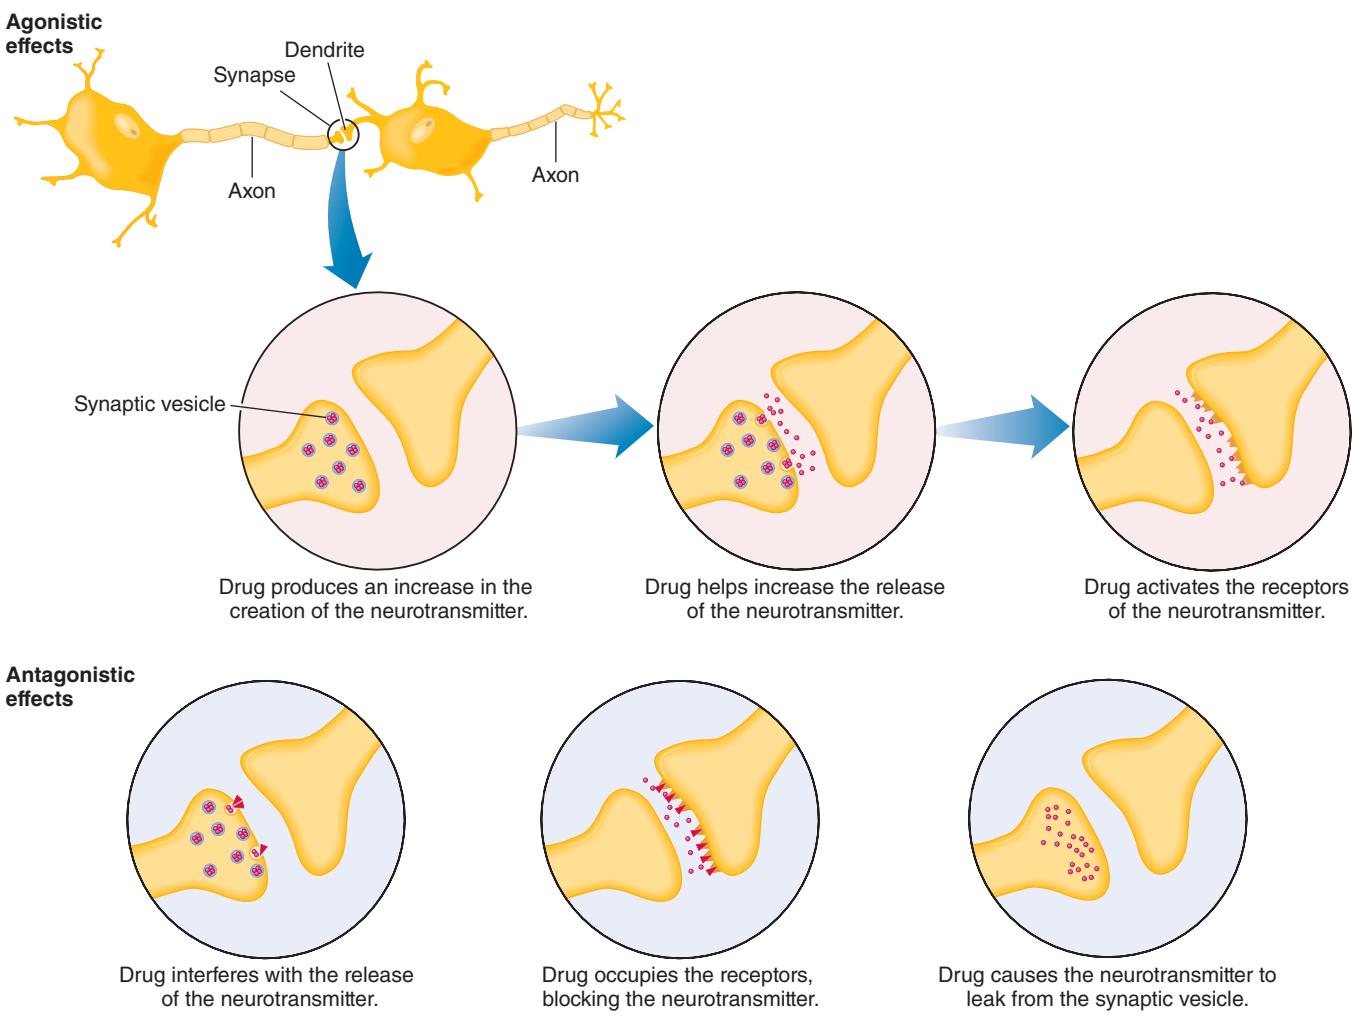

FIGURE 13.6

Some ways drugs affect neurotransmission.

released from the storage vessels (synaptic vesicles) at the end of the axon, cross the gap, and are taken up by receptors in the dendrite of the next axon. Chemical “messages” are transported in this way from neuron to neuron throughout the brain.

This process can be influenced in a number of ways, and the rest of Figure 13.6 illustrates some of them. The chemical messages can be increased by agonistic agents or decreased by antagonistic agents. (Remember the word *antagonistic* means hostile or unfriendly; in some way, this is the effect of antagonistic agents on the chemical messenger service.) Antagonistic effects slow or stop messages from being transmitted by preventing the release of the neurotransmitter, blocking uptake at the level of the dendrite, or causing leaks that reduce the amount of neurotransmitter released. On the other hand, agonistic effects assist with the transference of chemical messages and, if extreme, can produce too much neurotransmitter activity by increasing production or release of the neurotransmitter and by affecting more receptors at the dendrites.

What we’ve learned about antipsychotic medications points to the possibility that the dopamine system is too active in people with schizophrenia. The simplified picture in Figure 13.6 does not show that there are different receptor sites and that a chemical such as

dopamine produces different results depending on which of those sites it affects. In schizophrenia, attention has focused on several dopamine sites, in particular those referred to simply as D_1 and D_2 .

In a story that resembles a mystery plot, several pieces of “circumstantial evidence” are clues to the role of dopamine in schizophrenia:

1. Antipsychotic drugs (neuroleptics) often effective in treating people with schizophrenia are dopamine antagonists, partially blocking the brain’s use of dopamine (Creese, Burt, & Snyder, 1976; Seeman, Lee, Chau Wong, & Wong, 1976).
2. These neuroleptic drugs can produce negative side effects similar to those in Parkinson’s disease, a disorder known to be caused by insufficient dopamine.
3. The drug L-dopa, a dopamine agonist used to treat people with Parkinson’s disease, produces schizophrenia-like symptoms in some people (Davidson et al., 1987).
4. Amphetamines, which also activate dopamine, can make psychotic symptoms worse in some people with schizophrenia (van Kammen, Docherty, & Bunney, 1982).

In other words, when drugs are administered that are known to increase dopamine (agonists), there is an increase in

schizophrenic behavior; when drugs that are known to decrease dopamine activity (antagonists) are used, schizophrenic symptoms tend to diminish. Taking these observations together, researchers theorized that schizophrenia in some people was attributable to excessive dopamine activity.

Despite these observations, some evidence contradicts the dopamine theory (Javitt & Laruelle, 2006):

1. A significant number of people with schizophrenia are not helped by the use of dopamine antagonists.
2. Although the neuroleptics block the reception of dopamine quite quickly, the relevant symptoms subside only after several days or weeks, more slowly than we would expect.
3. These drugs are only partly helpful in reducing the negative symptoms (for example, flat affect or anhedonia) of schizophrenia.

In addition to these concerns, there is evidence of a “double-edged sword” with respect to schizophrenia. A medication called *olanzapine*—along with a family of similar drugs—is effective with many people who were not helped with traditional neuroleptic medications (Kane, Stroup, & Marder, 2009). That’s the good news. The bad news for the dopamine theory is that olanzapine and these other new medications are weak dopamine antagonists, much less able to block the sites than other drugs (Javitt & Laruelle, 2006). Why would a medication inefficient at blocking dopamine be effective as a treatment for schizophrenia if schizophrenia is caused by excessive dopamine activity?

The answer may be that although dopamine is involved in the symptoms of schizophrenia, the relationship is more complicated than once thought (Harrison, 2012). Current thinking—based on growing evidence from highly sophisticated research techniques—points to *at least three specific neurochemical abnormalities simultaneously at play in the brains of people with schizophrenia*.

Strong evidence now leads us to believe that schizophrenia is partially the result of excessive stimulation of striatal dopamine D₂ receptors (Harrison, 2012). Recall that the striatum is part of the basal ganglia found deep within the brain. These cells control movement, balance, and walking, and they rely on dopamine to function. Current work on Huntington’s disease (which involves a deterioration of motor function) is pointing to deterioration in this area of the brain. How do we know that excessive stimulation of D₂ receptors is involved in schizophrenia? One clue is that the most effective antipsychotic drugs all share dopamine D₂ receptor antagonism—meaning they help block the stimulation of the D₂ receptors (Ginovart & Kapur, 2010). Using brain-imaging techniques such as SPECT, scientists can view the living brain of a person with schizophrenia and can observe how the newer, “second generation” antipsychotic medications work on these specific dopamine sites. For example, a summary of these brain-imaging studies has shown the importance of abnormalities in presynaptic regions that increase dopamine. This discovery can have important implications for developing drugs that target presynaptic dopamine synthesis (Howes et al., 2012).

A second area of interest to scientists investigating the cause of schizophrenia is the observation of a deficiency in the stimulation of prefrontal dopamine D₁ receptors (Howes & Kapur, 2009).

Therefore, while some dopamine sites may be overactive (for example, striatal D₂), a second type of dopamine site in the part of the brain that we use for thinking and reasoning (prefrontal D₁ receptors) appears to be less active and may account for other symptoms common in schizophrenia. As you will see later in this chapter, people with schizophrenia display a range of deficits in the prefrontal section of the brain, and this area may be less active in people with schizophrenia (a condition known as *hypofrontality*, discussed later).

Finally, a third area of neurochemical interest involves research on alterations in prefrontal activity involving glutamate transmission (Harrison, 2012). Glutamate is an excitatory neurotransmitter that is found in all areas of the brain and is only now being studied in earnest. Just as we saw with dopamine (for example, D₁ and D₂ receptors), glutamate has different types of receptors, and the ones being studied for their role in schizophrenia are the N-methyl-d-aspartate (NMDA) receptors. And, just as researchers were led to the study of dopamine by observations from the effects of dopamine-specific drugs on behavior, the effects of certain drugs that affect NMDA receptors point to clues to schizophrenia. Two recreational drugs described in Chapter 11—phencyclidine (PCP) and ketamine—can result in psychotic-like behavior in people without schizophrenia and can exacerbate psychotic symptoms in those with schizophrenia. Both PCP and ketamine are also NMDA antagonists, suggesting that a deficit in glutamate or blocking of NMDA sites may be involved in some symptoms of schizophrenia (Goff & Coyle, 2001).

You can see that research on these two neurotransmitters and their relationship to each other is complex and awaits further clarification. However, advances in technology are leading us closer to the clues behind this enigmatic disorder and closer still to better treatments.

Brain Structure

Evidence for neurological damage in people with schizophrenia comes from a number of observations. Many children with a parent who has the disorder, and who are therefore at risk, tend to show subtle but observable neurological problems, such as abnormal reflexes and inattentiveness (Buka, Seidman, Tsuang, & Goldstein, 2013). These difficulties are persistent: Adults who have schizophrenia show deficits in their ability to perform certain tasks and to attend during reaction time exercises (Cleghorn & Albert, 1990). Such findings suggest that brain damage or dysfunction may cause or accompany schizophrenia, although no one site is probably responsible for the whole range of symptoms (Harrison, 2012).

One of the most reliable observations about the brain in people with schizophrenia involves the size of the ventricles (see ● Figure 13.7). As early as 1927, these liquid-filled cavities showed enlargement in some brains examined in people with schizophrenia (Jacobi & Winkler, 1927). Since then, more sophisticated techniques have been developed for observing the brain, and in the dozens of studies conducted on ventricle size, the great majority show abnormally large lateral and third ventricles in people with schizophrenia (Harrison, 2012). Ventricle

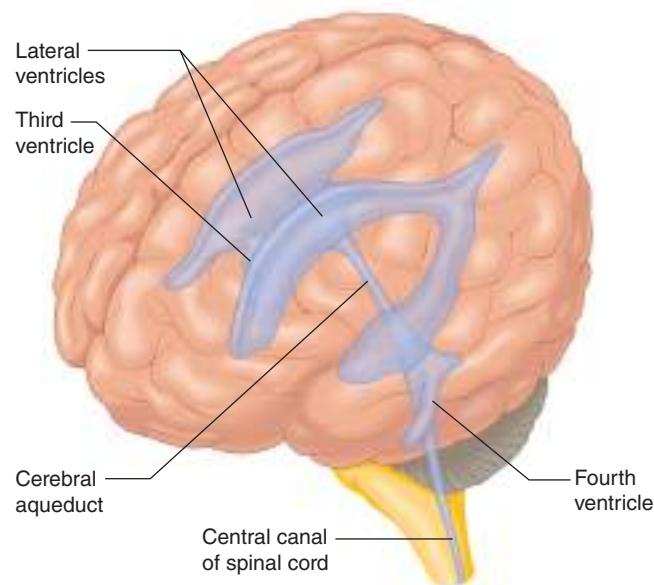

FIGURE 13.7

size may not be a problem, but the dilation (enlargement) of the ventricles indicates that adjacent parts of the brain either have not developed fully or have atrophied, thus allowing the ventricles to become larger.

Ventricle enlargement is not seen in everyone who has schizophrenia. Several factors seem to be associated with this finding. For example, enlarged ventricles are observed more often in men than in women (Abel, Drake, & Goldstein, 2010). Also, ventricles seem to enlarge in proportion to age and to the duration of the schizophrenia. One study found that individuals with schizophrenia who were exposed to influenza prenatally may be more likely to have enlarged ventricles (Takei, Lewis, Jones, Harvey, & Murray, 1996). (The possible role of prenatal exposure to influenza in the development of schizophrenia is described in the next section.)

In a study of ventricle size, researchers investigated the possible role of genetics (van Haren et al., 2012). Using a brain-imaging technique, magnetic resonance imaging (MRI), investigators pooled data to compare brain structure among twin pairs (both identical and fraternal) from several European countries for a total of 684 people. They compared twin pairs in which both twins had schizophrenia, twin pairs in which only one twin had schizophrenia, as well as healthy twin pairs. The results showed that lower white matter volume and larger third ventricular volume were associated with the risk for schizophrenia, and these differences appeared to be influenced by genetic factors.

We touched on the concept of unshared environments in the section on genetics (Jang, 2005; Plomin, 1990). Although twins are identical genetically, they can experience a number of environmental differences, even before they are born. For instance, in the intrauterine environment, twins must compete for nutrients,

and they may not be equally successful. In addition, birth complications, such as the loss of oxygen (anoxia), could affect only one of the twins (Murray & Castle, 2012). Obstetrical complications appear often in one of a pair of twins who develops schizophrenia and among the more severely affected if both twins have schizophrenia (McNeil, 1987). Different experiences among twins already predisposed to the disorder could damage the brain and cause the types of symptoms we associate with schizophrenia.

The frontal lobes of the brain have also interested researchers looking for structural problems associated with schizophrenia (Williams et al., 2013). As we described in the section on neurotransmitters, this area may be less active in people with schizophrenia than in people without the disorder, a phenomenon sometimes known as *hypofrontality* (*hypo* means “less active,” or “deficient”). Research by Weinberger and other scientists at the National Institute of Mental Health refined this observation, suggesting that deficient activity in a particular area of the frontal lobes, the dorsolateral prefrontal cortex (DLPFC), may be implicated in schizophrenia (Berman & Weinberger, 1990; Rasetti et al., 2011). When people with and without schizophrenia are given tasks that involve the DLPFC, less activity (measured by cerebral blood flow) is recorded in the brains of those with schizophrenia. Also, it has been shown that there is less connectivity between this region and other brain regions, meaning the DLPFC is “communicating” less with other brain regions (Rasetti et al., 2011). Follow-up studies show that some individuals with schizophrenia show *hyperfrontality* (that is, too much activity), indicating that the dysfunction is reliable, but hyperfrontality displays itself differently in different people (Callicott et al., 2003; Garrity et al., 2007).

It appears that several brain sites are implicated in the cognitive dysfunction observed among people with schizophrenia, especially the prefrontal cortex, various related cortical regions, and subcortical circuits, including the thalamus and the striatum (Shenton & Kubicki, 2009). Remember that this dysfunction seems to occur *before the onset* of schizophrenia. In other words, brain variations may develop progressively, beginning before the symptoms of the disorder are apparent, perhaps prenatally (Harrison, 2012).

Prenatal and Perinatal Influences

There is evidence that the prenatal (before birth) and perinatal (around the time of birth) environment are correlated with the development of schizophrenia (Murray & Castle, 2012). Fetal exposure to viral infection, pregnancy complications, and delivery complications are among the environmental influences that seem to affect whether or not someone develops schizophrenia.

Several studies have shown that schizophrenia may be associated with prenatal exposure to influenza, viruses, or infections. For example, Sarnoff Mednick and colleagues followed a large number of people after a severe Type A2 influenza epidemic in Helsinki, Finland, and found that those whose mothers were exposed to influenza during the second trimester of pregnancy were more likely to have schizophrenia than others (Cannon, Barr, & Mednick, 1991). This observation has been confirmed by some researchers (see, for example, O’Callaghan, Sham, Takei, Glover, & Murray, 1991; Venables, 1996) but not by others (Buchanan &

Carpenter, 2005; Seltén, Frissen, Lensvelt-Mulders, & Morgan, 2009). The indications that viruslike diseases may cause damage to the fetal brain, which later may cause the symptoms of schizophrenia, are suggestive and may help explain why some people with schizophrenia behave the way they do (Murray & Castle, 2012).

The evidence of pregnancy complications (for example, bleeding) and delivery complications (for example, asphyxia or lack of oxygen) and their relationship to later schizophrenia suggest, on the surface, that this type of environmental stress combined with genetic and other variables may trigger the expression of the disorder (Kotlicka-Antczak, Pawelczyk, Rabe-Jabłońska, Śmigielski, & Pawelczyk, 2014; Suvisaari et al., 2013). It is possible, however, that the genes carried by the fetus that make it vulnerable to schizophrenia may themselves contribute to the birth complications (van Os & Allardye, 2009).

The chronic and early use of marijuana (cannabis) is also being studied as a potential influence on the onset of schizophrenia (Murray & Castle, 2012). Some research suggests that people who use marijuana in high doses have an increased likelihood of developing schizophrenia for those with CNR1 genotypes (Ho, Wassink, Ziebell, & Andreasen, 2011) and that people with schizophrenia are more likely to have a cannabis use disorder than individuals without schizophrenia (Corcoran et al., 2008; Martins & Gorelick, 2011). The link between these two problems is not yet clearly understood, and there are conflicting findings about whether or not other factors may be responsible for this correlation (Murray & Castle, 2012).

Psychological and Social Influences

That one identical twin may develop schizophrenia and the other may not suggests that schizophrenia involves something in addition to genes. We know that early brain trauma, perhaps resulting from a second-trimester viruslike attack or obstetrical complications, may generate physical stress that contributes to schizophrenia. All these observations show clearly that schizophrenia does not fall neatly into a few simple causal packages. For instance, not all people with schizophrenia have enlarged ventricles, nor do they all have a hypofrontality or disrupted activity in their dopamine systems. The causal picture may be further complicated by psychological and social factors. We next look at research into psychosocial factors. Do emotional stressors or family interaction patterns *initiate* the symptoms of schizophrenia? If so, how might those factors cause people to relapse after a period of improvement?

Stress

It is important to learn how much and what kind of stress makes a person with a predisposition for schizophrenia develop the disorder. Think back to the two cases we presented at the beginning of this chapter. Did you notice any precipitating events? Arthur's father had died several years earlier, and Arthur was laid off from his job around the time his symptoms first appeared. David's uncle had died the same year he began acting strangely. Were these stressful events just coincidences, or did they contribute to the men's later problems?

Researchers have studied the effects of a variety of stressors on schizophrenia. Living in a large city, for example, is associated with an increased risk of developing schizophrenia—suggesting the stress of urban living may precipitate its onset (Boydell & Allardye, 2012). Dohrenwend and Egri (1981) observed that otherwise healthy people who engage in combat during a war often display temporary symptoms that resemble those of schizophrenia. In a classic study, Brown and Birley (1968; Birley & Brown, 1970) examined people whose onset of schizophrenia could be dated within a week. These individuals had experienced a high number of stressful life events in the 3 weeks before they started showing signs of the disorder. In a large-scale study sponsored by the World Health Organization, researchers also looked at the role of life events in the onset of schizophrenia (Day et al., 1987). This cross-national study confirmed the findings of Brown and Birley across eight research centers.

The *retrospective* nature of such research creates problems. Each study relies on after-the-fact reports, collected after the person showed signs of schizophrenia. One always wonders whether such reports are biased in some way and therefore misleading. At the same time, there are strong individual differences in how people experience the same life events, and people with schizophrenia may experience events differently than those without the disorder (Murray & Castle, 2012).

Do the symptoms of schizophrenia become worse as a result of stressful life experiences? This vulnerability–stress model of schizophrenia suggests that this is the case, and it may be helpful in predicting problems. One research study used a natural disaster—the 1994 Northridge, California, earthquake—to assess how people with schizophrenia would react to this stress when compared with those with bipolar disorder and healthy controls (Horan et al., 2007). Both patient groups reported more stress-related symptoms compared with the controls; however, the people with schizophrenia reported lower levels of self-esteem after the disaster and were more likely to engage in avoidance coping (not thinking about the problem or becoming resigned to difficulties) than the other two groups. Research on sociocultural stress, such as poverty, homelessness, early life adversity, growing up in an urban environment, minority group position, and the stress of being in a new country (van Os, Kenis, & Rutten, 2010; Lataster, Myin-Germeys, Lieb, Wittchen, & Van Os, 2012), suggests that these psychosocial stressors influence onset and possibly development of schizophrenia. Onset of symptoms usually happens as a result of environmental stressors, showing that these stressors may have their impact during sensitive periods in development. For example, stressors in early life may influence development of psychosis, possibly by increasing stressors later in life, making individuals more sensitive to later stressors, or both (Lataster et al., 2012).

A simple vulnerability can develop into a severe disorder from the interchange between gene–environment. Important research will isolate the gene–environment interactions in this area. For example, some studies now show that particular gene variances may predict which individuals with schizophrenia will be more likely to react negatively (such as relapse) with increased stress (Ascher-Svanum et al., 2010). These types of studies point to how stress can impact people with schizophrenia and may suggest useful

communication was used to portray a communication style that produced conflicting messages, which, in turn, caused schizophrenia to develop (Bateson, 1959). Here, the parent presumably communicates messages that have two conflicting meanings; for example, a mother responds coolly to her child's embrace but says, "Don't you love me anymore?" when the child withdraws. Although these theories are no longer supported, they have been—and in some cases continue to be—destructive, producing guilt in parents who are persuaded that their early mistakes caused devastating consequences.

Recent work has focused more on how family interactions contribute not to the onset of schizophrenia but to relapse after initial symptoms are observed. You will see that this research is similar to the work on vulnerability to stress in general that was just discussed. Research has focused on a particular emotional communication style known as **expressed emotion** (EE). This concept was formulated by George W. Brown and his colleagues in London. Following a sample of people who had been discharged from the hospital after an episode of schizophrenic symptoms, the researchers found that former patients who had limited contact with their relatives did better than the patients who spent longer periods with their families (Brown, 1959). Additional research results indicated that if the levels of criticism (disapproval), hostility (animosity), and emotional overinvolvement (intrusiveness) expressed by the families were high, patients tended to relapse (Brown, Monck, Carstairs, & Wing, 1962).

Other researchers have since found that ratings of high expressed emotion in a family are a good predictor of relapse among people with chronic schizophrenia (Cechnicki, Bielańska, Hanuszkiewicz, & Daren, 2013). If you have schizophrenia and live in a family with high expressed emotion, you are 3.7 times more likely to relapse than if you lived in a family with low expressed emotion (Kavanagh, 1992; Parker & Hadzi-Pavlovic, 1990). Here are examples of interviews that show how families of people with schizophrenia might communicate expressed emotion:

High Expressed Emotion

- I always say, "Why don't you pick up a book, do a crossword or something like that to keep your mind off it." That's even too much trouble.
- I've tried to jolly him out of it and pestered him into doing things. Maybe I've overdone it, I don't know.

treatments (such as cognitive-behavioral therapy to help them cope more appropriately) (Ascher-Svanum et al., 2010).

Families and Relapse

A great deal of research has studied how interactions within the family affect people who have schizophrenia. For example, the term **schizophrenogenic mother** was used for a time to describe a mother whose cold, dominant, and rejecting nature was thought to cause schizophrenia in her children (Fromm-Reichmann, 1948). In addition, the term **double bind**

Low Expressed Emotion

- I know it's better for her to be on her own, to get away from me and try to do things on her own.
- Whatever she does suits me.
- I just tend to let it go because I know that when she wants to speak she will speak. (Hooley, 1985, p. 134)

This style suggests that families with high expressed emotion view the symptoms of schizophrenia as controllable and that the hostility arises when family members think that patients just do not want to help themselves (Hooley & Campbell, 2002; McNab, Haslam, & Burnett, 2007). The literature on expressed emotion is valuable to our understanding of why symptoms of schizophrenia recur and may show us how to treat people with this disorder and their families so that they do not experience further psychotic episodes (Cechnicki et al., 2013).

An interesting issue that arises when studying family influences is whether what we see is unique to our culture or universal. Looking at expressed emotion across different cultures may help us learn whether expressed emotion is a *cause* of schizophrenia (Breitborde, López, & Kopelowicz, 2010; Kymäläinen & Weisman de Mamani, 2008). Remember that the rate of schizophrenia is observed to be about the same worldwide, with a prevalence of about 1% in the global population. If a factor like high expressed emotion in families is a causal agent, we should see the same rates in families across cultures; however, they differ, as you can see in Figure 13.8. These data come from an analysis of the concept of expressed emotion in several studies from India, Mexico, United

Kingdom, and the United States (Jenkins & Karno, 1992). The differences suggest that there are cultural variations in how families react to someone with schizophrenia and their reactions do not cause the disorder (Singh, Harley, & Suhail, 2013). In addition, what may appear to be over-involvement in one culture may be viewed as supportive in other cultures.

Treatment of Schizophrenia

If you remember our descriptions of Arthur and David, you will recall their families' concern for them. Arthur's mother spoke of the "living nightmare," and David's aunt expressed concern for both her safety and David's. In each case, the family was desperate to help, but what do you do for someone who has delusions, hears his dead uncle's voice, or can't communicate complete thoughts? The search for help has taken many paths, sometimes down some disturbing roads; for example, in the 1500s, primitive surgery was conducted to remove the "stone of madness," which was thought to cause disturbed behavior. As barbaric as this practice may seem today, it is not different from the prefrontal lobotomies performed on people with schizophrenia as late as the 1950s. This procedure severed the frontal lobes from the lower portion of the brain, which sometimes calmed the patient but also caused cognitive and emotional deficits. Even today, some societies use crude surgical procedures to eliminate the symptoms of schizophrenia. In Kenya, for instance, Kisii tribal doctors listen to their patients to find the location of the noises in their heads (hallucinations), then get them drunk, cut out a piece of scalp, and scrape the skull in the area of the voices (Mustafa, 1990).

In the Western world today, treatment usually begins with one of the neuroleptic drugs invaluable in reducing the symptoms of schizophrenia for many people. They are typically used with a variety of psychosocial treatments to reduce relapse, compensate for skills deficits, and improve cooperation for taking the medications (Cunningham Owens & Johnstone, 2012).

Biological Interventions

Researchers have assumed for more than 100 years that schizophrenia requires some form of biological intervention. Kraepelin,

who so eloquently described dementia praecox in the late 19th century, saw the disorder as a brain disease. Lacking a biological treatment, he routinely recommended that the physician use "good patience, kindly disposition, and self-control" to calm excited patients (Nagel, 1991). This approach was seen as only a temporary way of helping the person through disturbing times and was not thought to be an actual treatment.

During the 1930s, several novel biological treatments were tried. One approach was to inject massive doses of insulin—the drug that given in smaller doses is used to treat diabetes—to induce comas in people suffering from schizophrenia. Insulin coma therapy was thought for a time to be helpful, but closer examination showed it carried great risk of serious illness and death. During this time, *psychosurgery*, including prefrontal lobotomies, was introduced, and in the late 1930s, electroconvulsive therapy (ECT) was advanced as a treatment for schizophrenia. As with earlier drastic treatments, initial enthusiasm for ECT faded because it was found not to be beneficial for most people with schizophrenia—although it is still used with a limited number of people today, sometimes in combination with antipsychotic medications (Zervas, Theleritis, & Soldatos, 2012). As we explained in Chapter 7, ECT is sometimes recommended for people who experience severe episodes of depression.

Antipsychotic Medications

A breakthrough in the treatment of schizophrenia came during the 1950s with the introduction of several drugs that relieved symptoms in many people (Cunningham Owens & Johnstone, 2012). Called *neuroleptics* (meaning "taking hold of the nerves"), these medications provided the first real hope that help was available for

people with schizophrenia. When they are effective, neuroleptics help people think more clearly and reduce hallucinations and delusions. They work by affecting the positive symptoms (delusions, hallucinations, and agitation) and to a lesser extent the negative and disorganized ones, such as social deficits. Table 13.2 shows the classes of these drugs (based on their chemical structure) and their trade names.

Recall from our discussion of the dopamine theory of schizophrenia that the neuroleptics are dopamine antagonists. One of their major actions in the brain is to interfere with the dopamine neurotransmitter system. They can also affect other systems, however, such as the serotonergic and glutamate system. We are just beginning to understand the mechanisms by which these drugs work.

In general, each drug is effective with some people and not with others. Clinicians and patients often must go through a trial-and-error process to find the medication that works best, and some individuals do not benefit significantly from any of them. The earliest neuroleptic drugs, called conventional or first-generation antipsychotics (such as Haldol and Thorazine), are effective for approximately 60% to 70% of people who try them (Cunningham Owens & Johnstone, 2012). Many people are not helped by antipsychotics, however, or they experience unpleasant side effects. Fortunately, some people respond well to newer medications—sometimes called atypical or second-generation antipsychotics; the most common are risperidone and olanzapine. These newer drugs were in part developed to help patients who were previously unresponsive to medications. A comparison of multiple clinical trials shows better efficacy, though small, in preventing symptoms reemergence for these newer drugs over the previous ones.

(Kishimoto et al., 2013). Initially, it was thought that the newer drugs had fewer serious side effects than the conventional antipsychotics. However, two large-scale studies—one conducted in the United States (called the “Clinical Antipsychotic Trials of Intervention Effectiveness” or CATIE) (Stroup & Lieberman, 2010) and one in the United Kingdom (called the “Cost Utility of the Latest Antipsychotic Drugs in Schizophrenia Study” or CuTASS) (Jones et al., 2006)—found that the second-generation drugs were no more effective or better tolerated than the older drugs (Lieberman & Stroup, 2011). These results point out how important it is to carefully study the outcomes of all new treatments.

Noncompliance with Medication: Why?

Despite the optimism generated by the effectiveness of antipsychotics, they work only when they are taken properly, and many people with schizophrenia do not routinely take their medication. David frequently “cheeked” the Haldol pills that were helpful in reducing his hallucinations, holding them in his mouth until he was alone, then spitting them out. In the large-scale study we just mentioned, 74% of those studied had stopped taking their medications 18 months after initial use (Lieberman & Stroup, 2011).

A number of factors seem to be related to patients’ noncompliance with a medication regimen, including negative doctor-patient relationships, cost of the medication, stigma, and poor social support (Haddad, Brain, & Scott, 2014). Not surprisingly, negative side effects are a major factor in patient refusal. Antipsychotics can produce a number of unwanted physical symptoms, such as grogginess, blurred vision, and dryness of the mouth. Because the drugs affect neurotransmitter systems, more serious side effects, called *extrapyramidal symptoms*, can also result (Cunningham Owens & Johnstone, 2012). These symptoms include the motor difficulties similar to those experienced by people with Parkinson’s disease, sometimes called Parkinsonian symptoms. *Akinesia* is one of the most common; it includes an expressionless face, slow motor activity, and monotonous speech. Another extrapyramidal symptom is *tardive dyskinesia*, which involves involuntary movements of the tongue, face, mouth, or jaw and can include protrusions of the tongue, puffing of the cheeks, puckering of the mouth, and chewing movements. Tardive dyskinesia seems to result from long-term use of high doses of antipsychotic medication and is often irreversible. Studies have shown that up to 20% to 50% of all patients treated with antipsychotics develop tardive dyskinesia with lower risk for younger people (only 3% to 5% of younger people taking this medication display tardive dyskinesia, with the risk increasing over time) (Waln & Jankovic, 2013). These serious negative side effects have justifiably concerned people who otherwise benefit from the drugs.

To learn what patients themselves say, Windgassen (1992) questioned 61 people who had had recent onsets of schizophrenia. About half reported the feeling of sedation or grogginess as an unpleasant side effect: “I always have to fight to keep my eyes open,” “I felt as though I was on drugs . . . drowsy, and yet really wound up” (p. 407). Other complaints included deterioration in the ability to think or concentrate (18%), problems with salivation (16%), and blurred vision (16%). Although a third of the patients felt the medications were beneficial, about 25% had a negative

Radius Images/Jupiter Images

One of the major obstacles to drug treatment for schizophrenia is compliance. Patients discontinue their medication for a variety of reasons, including the negative side effects.

attitude toward them. A significant number of people who could benefit from antipsychotic medications find them unacceptable as a treatment, which may explain the relatively high rates of refusal and noncompliance (Sendt, Tracy, & Bhattacharyya, 2015; Yamada et al., 2006).

Researchers have made this a major treatment issue in schizophrenia, realizing that medications can't be successful if they aren't taken regularly. Researchers hoped compliance rates would improve with the introduction of injectable medications. Instead of taking an oral antipsychotic every day, patients can have their medications injected every few weeks. Unfortunately, noncompliance remains an issue, primarily because patients do not return to the hospital or clinic for repeated doses (Kane et al., 2009; Kishimoto et al., 2012). Psychosocial interventions are now used not only to treat schizophrenia but also to increase medication-taking compliance by helping patients communicate better with professionals about their concerns.

Additional Biological Treatments

An interesting treatment for the hallucinations experienced by many people with schizophrenia involves exposing the individual to magnetic fields. Called *transcranial magnetic stimulation*, this technique uses wire coils to repeatedly generate magnetic fields—up to 50 times per second—that pass through the skull to the brain. This input seems to interrupt temporarily the normal communication to that part of the brain. Hoffman and colleagues (2000, 2003) used this technique to stimulate the area of the brain involved in hallucinations for individuals with schizophrenia who experienced auditory hallucinations. They found that many of the individuals experienced improvement following transcranial magnetic stimulation. Subsequent studies have also shown promising results (Dougall, Maayan, Soares-Weiser, McDermott, & McIntosh, 2015) but more stringent clinical trials are needed to demonstrate that this treatment works. Additionally, follow-up

data is needed to test whether the improvements last. Preliminary research has shown that though this intervention may modestly improve auditory hallucinations, its effects last less than a month (Slotema, Aleman, Daskalakis, & Sommer, 2012).

Lastly, recent research has explored the added effect of the medication modafinil when taken in addition to antipsychotic medications. Modafinil is a cognitive enhancer with low abuse potential. In schizophrenia, this drug may improve cognitive functions, such as memory and problem solving. Some limited research also suggests that the drug may improve emotion processing in schizophrenia (Scorielis, Jones, & Sahakian, 2013).

Psychosocial Interventions

Historically, a number of psychosocial treatments have been tried for schizophrenia, reflecting the belief that the disorder results from problems in adapting to the world because of early experiences (Cunningham Owens & Johnstone, 2012). Many

therapists have thought that individuals who could achieve insight into the presumed role of their personal histories could be safely led to deal with their current situations. Although clinicians who take a traditional psychodynamic or psychoanalytic approach to therapy continue to use this type of treatment, research suggests that their efforts at best may not be beneficial and at worst may be harmful (Mueser & Berenbaum, 1990; Scott & Dixon, 1995).

Today, few believe that psychological factors cause people to have schizophrenia or that traditional psychotherapeutic approaches will cure them. Nevertheless, you will see that psychological methods have an important role. Despite the great promise of drug treatment, the problems with ineffectiveness, inconsistent use, and relapse suggest that by themselves drugs may not be effective with many people. As with a number of the disorders discussed in this text, recent work in the area of psychosocial intervention has suggested the value of an approach that uses both kinds of treatment (Mueser & Marcello, 2011).

Until relatively recently, most people with severe and chronic cases of schizophrenia were treated in hospital settings. During the 19th century, inpatient care involved “moral treatment,” which emphasized improving patients’ socialization, helping them establish routines for self-control, and showing them the value of work and religion (Tehula et al., 2009). Various types of such “milieu” treatments (changing the physical and social environment—usually to make institutional settings more homelike) have been popular, but, with one important exception: None seems to have helped people with schizophrenia.

Gordon Paul and Robert Lentz conducted pioneering work in the 1970s at a mental health center in Illinois (Paul & Lentz, 1977). Borrowing from the behavioral approaches used by Ted Aylon and Nate Azrin (1968), Paul and Lentz designed an environment for inpatients that encouraged appropriate socialization, participation in group sessions, and self-care such as bed making while discouraging violent outbursts. They set up an elaborate

token economy, in which residents could earn access to meals and small luxuries by behaving appropriately. A patient could, for example, buy cigarettes with the tokens he earned for keeping his room neat. On the other hand, a patient would be fined (lose tokens) for being disruptive or otherwise acting inappropriately. This incentive system was combined with a full schedule of daily activities. Paul and Lentz compared the effectiveness of applied behavioral (or social learning) principles with traditional inpatient environments. In general, they found that patients who went through their program did better than others on social, self-care, and vocational skills, and more of them could be discharged from the hospital. This study was one of the first to show that people suffering from the debilitating effects of schizophrenia can learn to perform some skills they need to live more independently.

During the years since 1955, many efforts have combined to halt the routine institutionalization of people with schizophrenia in the United States (Fakhoury & Priebe, 2007). This trend has occurred partly because of court rulings that limit involuntary hospitalization (as we saw in Arthur's case) and partly because of the relative success of antipsychotic medication. The bad news is that policies of deinstitutionalization have often been ill conceived, with the result that many people who have schizophrenia or other serious psychological disorders are homeless—the number is estimated at between 150,000 and 200,000 people in the United States alone (Foster, Gable, & Buckley, 2012; Pearson, Montgomery, & Locke, 2009). The good news is that more attention is being focused on supporting these people in their communities, among their friends and families. The trend is away from creating better hospital environments and toward the perhaps more difficult task of addressing complex problems in the less predictable and insecure world outside. So far, only a small fraction of the growing number of homeless individuals with mental disorders is being helped.

One of the more insidious effects of schizophrenia is its negative impact on a person's ability to relate to other people. Although not as dramatic as hallucinations and delusions, problems with social skills can be the most visible impairment displayed by people with schizophrenia and can prevent them from getting and keeping jobs and making friends. Clinicians attempt to reteach social skills such as basic conversation, assertiveness, and relationship building to people with schizophrenia (Mueser & Marcello, 2011).

Therapists divide complex social skills into their component parts, which they model. Then the clients do role-playing and ultimately practice their new skills in the "real world," all the while receiving feedback and encouragement at signs of progress. This isn't as easy as it may sound. For example, how would you teach someone to make a friend? Many skills are involved, such as maintaining eye contact when you talk to

someone and providing the prospective friend with some (but not too much) positive feedback on her own behavior ("I really enjoy talking to you"). Such individual skills are practiced and then combined until they can be used naturally (Kurtz & Richardson, 2012). The challenge of teaching social skills, as with all therapies, is to maintain the effects over a long period.

In addition to social skills, programs often teach a range of ways people can adapt to their disorder yet live in the community. At the Independent Living Skills Program at the University of California, Los Angeles, for example, the focus is on helping people take charge of their own care by such methods as identifying signs that warn of a relapse and learning how to manage their medication (see Table 13.3) (Liberman, 2007). Preliminary evidence indicates that this type of training may help prevent relapses by people with schizophrenia, although longer-term outcome research is needed to see how long the effects last (Cunningham Owens & Johnstone, 2012). To address some obstacles to this much-desired maintenance, such programs combine skills training with the support of a multidisciplinary team that provides services directly in the community, which seems to reduce hospitalization (Cunningham Owens & Johnstone, 2012). The more time and effort given to these services, the more likely the improvement.

Is there a role for new technologies in the diagnosis and treatment of schizophrenia? Creative researchers are answering this question in a number of exciting developments for the field. One study looked to improve the understanding of schizophrenia by using virtual reality technology to simulate multiple cognitive tasks (Macedo, Marques & Queirós, 2015; Sorkin, Weinshall, Modai, & Peled, 2006). Researchers created a gamelike task to test aspects of working memory and perseveration (focusing on the same things repeatedly) and found not only that this approach could create real-life simulations that revealed deficits but also that the tasks could be fun. A study carried out at King's College in London tested the nature of paranoia in a virtual reality environment among groups with low paranoia, nonclinical paranoia, and those with persecutory delusions (Freeman, Pugh, Vorontsova, Antley, & Slater, 2010). Researchers constructed a virtual scene that depicts a London subway and created avatars as passengers that at times would look at the study participant (see accompanying photos).

Across the groups, there were meaningful differences in levels of anxiety, worry, interpersonal sensitivity, and depression according to their previous levels of paranoia. This type of assessment provided a safe environment in which to assess and study persecutory paranoia in the groups. Other research is using this technology to assist older persons with schizophrenia improve their cognitive and general motor skills (for example, by having them push away colorful balls that are floating toward them in a virtual world) (Chan, Ngai, Leung, & Wong, 2010). Again, these virtual assessments and treatments provide clinicians with controllable and safer environments in which to study and treat persons with schizophrenia.

Another psychosocial intervention for schizophrenia is cognitive remediation aimed at improving cognitive processes, such as attention, executive functioning, and memory, all of which are associated with impairments over the course of schizophrenia. Impairment in these cognitive areas predicts patients' overall

functioning and poor response to other treatments (e.g., psychological rehabilitation or social skills training) (Mueser, Deavers, Penn, & Cassisi, 2013). Thus, a primary goal of cognitive remediation is to improve cognitive processes for those suffering from schizophrenia in order to increase these individuals' functioning in the community. The intervention consists of cognitive practice exercises and learning cognitive strategies. This intervention seems to improve cognitive abilities and overall functioning, especially when combined with other treatments, such as psychological rehabilitation (Mueser et al., 2013). Also, studies suggest that patients' functioning improves more when a strategy-based approach is taken (Wykes, Huddy, Cellard, McGurk, & Czobor, 2011).

In our discussion of the psychosocial influences on schizophrenia, we reviewed some work linking the person's social and emotional environments to the recurrence of schizophrenic episodes (McNab et al., 2007). It is logical to ask whether families could be helped by learning to reduce their level of expressed emotion and whether this would result in fewer relapses and better overall functioning for people with schizophrenia. Several studies have addressed these issues in a variety of ways (Falloon et al., 1985; Hogarty et al., 1986, 1991), and behavioral family therapy has been used to teach the families of people with schizophrenia to be more supportive (Dixon & Lehman, 1995; Mueser, Liberman, & Glynn, 1990). Research on professionals who provide care for people who have schizophrenia, and who may display high levels of expressed emotion, is also an active area of study (Cunningham Owens & Johnstone, 2012).

In contrast to traditional therapy, behavioral family therapy resembles classroom education (Falloon, 2015; Lefley, 2009). Family members are informed about schizophrenia and its treatment, relieved of the myth that they caused the disorder, and taught practical facts about antipsychotic medications and their side effects. They are also helped with communication skills so that they can become more empathetic listeners, and they learn constructive ways of expressing negative feelings to replace the harsh criticism that characterizes some family interactions. In addition, they learn problem-solving skills to help them resolve conflicts that arise. Like the research on social skills training, outcome research suggests that the effects of behavioral family therapy are significant during the first year but less robust 2 years after intervention (Cunningham Owens & Johnstone, 2012). This type of therapy, therefore, must be ongoing if patients and their families are to benefit from it.

Adults with schizophrenia face great obstacles to maintaining gainful employment. Their social skills deficits make reliable job performance and adequate employee relationships a struggle. To address these difficulties, some programs focus on vocational rehabilitation, such as supportive employment. Supportive employment involves providing coaches who give on-the-job training, and these efforts can help some people with schizophrenia maintain meaningful jobs (Mueser & Marcello, 2010).

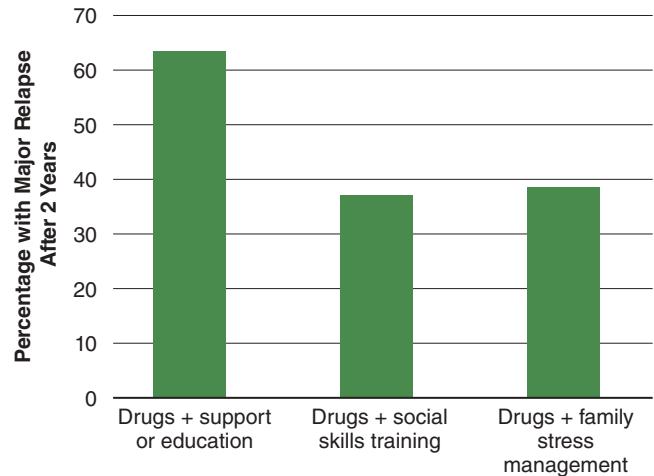

Research suggests that individual social skills training, family intervention, and vocational rehabilitation may be helpful additions to biological (drug) treatment for schizophrenia. Significant

relapses may be avoided or delayed by such psychosocial interventions. ● Figure 13.9 illustrates the studies reviewed by one group (Falloon, Brooker, & Graham-Hole, 1992), which show that multilevel treatments reduce the number of relapses among people receiving drug therapy in comparison with simple social support or educational efforts.

Where treatment occurs, it has expanded over the years from locked wards in large mental hospitals, to family homes, to local communities. In addition, the services have expanded to include self-advocacy and self-help groups. Former patients have organized programs such as Fountain House in New York City to provide mutual support. Psychosocial clubs have differing

models, but all are “person centered” and focus on obtaining positive experiences through employment opportunities, friendship, and empowerment. Many see this consumer-run self-help model as an added component to more specific interventions such as social skills training, family intervention, and medical management of symptoms. Some research indicates that participation may help reduce relapses, but as it is also possible that those who participate may be a special group of individuals, it is difficult to interpret improvements (Davidson, Chinman, Sells, & Rowe, 2006; Goering et al., 2006).

Because schizophrenia is a complex disorder that affects multiple areas of functioning, effective treatment is carried out at several levels. Table 13.4 lists six approaches to treatment that have proved effective in assisting these individuals to achieve higher quality lives. Probably the most extensively studied program is the assertive community treatment (ACT) program that grew out of work by researchers in Madison, Wisconsin (Swartz et al., 2006). ACT involves using a multidisciplinary team of professionals to provide broad-ranging treatment across all domains, including medication management, psychosocial treatment, and vocational training and support. As you can see, one approach alone is not sufficient to address the many needs of people with schizophrenia and their families (Cunningham Owens & Johnstone, 2012; Mueser & Marcello, 2011).

Treatment across Cultures

Treatment of schizophrenia and its delivery differ from one country to another and across cultures within countries. For example, the vast majority of the Xhosa people of South Africa who have schizophrenia report using traditional healers who sometimes recommend the use of oral treatments to induce vomiting, enemas, and the slaughter of cattle to appease the spirits (Koen, Niehaus, Muller, & Laurent, 2008). Latinos may be less likely than

Treatment	Description
Collaborative psychopharmacology	Using antipsychotic medications to treat the main symptoms of the disorder (hallucinations, delusions), as well as using other medications for secondary symptoms (for example, antidepressant medication for people with secondary depression)
Assertive community treatment	Providing support in the community, with emphasis on small caseloads for care providers, services in the community setting rather than a clinic, and 24-hour coverage
Family psychoeducation	Assisting family members, including educating them about the disorder and its management, helping them reduce stress and tension in the home, and providing social support
Supportive employment	Providing sufficient support before and during employment so that the person can find and keep a meaningful job
Illness management and recovery	Helping the individual become an active participant in treatment, including providing education about the disorder, teaching effective use of medication strategies for collaborating with clinicians, and coping with symptoms when they reoccur

other groups to seek help in institutional settings, relying instead on family support (Hernandez, Barrio, & Yamada, 2013; Liberman & Kopelowicz, 2009). Adapting treatments to make them culturally relevant—in this case, adding important relatives to the social skills training of Latinos with schizophrenia—is essential for effectiveness (Kopelowicz et al., 2012). In one interesting study, beliefs about symptoms and treatments were compared between British and Chinese populations (Furnham & Wong, 2007). Native Chinese hold more religious beliefs about both the causes and the

treatments of schizophrenia than those living in England—for example, endorsing statements such as “Schizophrenia is due to evil done in a previous life” and “Ancestor worship (burning candles and joss sticks) will help treat schizophrenia.” These different beliefs translate into practice—with the British using more biological, psychological, and community treatments, and the Chinese relying more on alternative medicine (Furnham & Wong, 2007). Supernatural beliefs about the cause of schizophrenia among family members in Bali lead to limited use of antipsychotic medication in treatment (Kurihara, Kato, Reverger, & Gusti Rai Tirta, 2006). In many countries in Africa, people with schizophrenia are kept in prisons, primarily because of the lack of adequate alternatives (Mustafa, 1990). In general, the movement from housing people in large institutional settings to community care is ongoing in most Western countries.

Prevention

One strategy for preventing a disorder such as schizophrenia—which typically first shows itself in early adulthood—is to identify and treat children who may be at risk for getting the disorder later in life. In our discussion of genetics, we noted that approximately 17% of the children born to parents who have schizophrenia are likely themselves to develop the disorder. These high-risk children have been the focus of several studies.

A classic at-risk study was initiated in the 1960s by Sarnoff A. Mednick and Fini Schulsinger (1965, 1968). They identified 207 Danish children of mothers who had severe cases of schizophrenia and 104 control children born to mothers who had no history of the disorder. The average age of these children was about 15 when they were first identified, and the researchers followed them for 10 more years to determine whether any factors had predicted who would and would not develop schizophrenia. We have already discussed pregnancy and delivery-related complications. Mednick and Schulsinger also identified *instability of early family rearing environment*, which suggests that environmental influences may trigger the onset of schizophrenia (Cannon et al.,

Paula Bronstein/Getty Images

Treatment for the symptoms of schizophrenia vary widely by culture—from humane approaches using empirically validated interventions to simply removing the person from society.

1991). Poor parenting may place additional strain on a vulnerable person who is already at risk.

One approach to prevention of schizophrenia receiving increased attention is the treatment of persons in the prodromal stages of the disorder. Here the individual is beginning to show early mild signs of schizophrenia (e.g., hallucinations, delusions) but is aware of these changes. Efforts to intervene with these individuals are being investigated as a means of either stopping progression of the disorder or preventing relapses (Cunningham Owens & Johnstone, 2012).

DSM-5 Controversies: Attenuated Psychosis Syndrome

One of the most discussed changes in DSM-5 related to schizophrenia spectrum and other psychotic disorders was the possible inclusion of a new diagnosis, Attenuated Psychosis Syndrome. Recall that this diagnosis would be given to a person who is beginning to experience one or more of the symptoms of schizophrenia such as hallucinations or delusions but is aware that these are unusual experiences and are not typical for a healthy person (i.e., relatively intact reality testing). They are at high risk for having more severe symptoms as

displayed in schizophrenia spectrum disorder. The argument for including this set of symptoms as a new disorder is that catching the person in these early stages might prove helpful for early intervention efforts (Pagsberg, 2013). It is possible that getting the symptoms under control before they become severe might save the person from years of suffering (Woods, Walsh, Saksa, & McGlashan, 2010).

On the other hand, some argued against focusing attention on this select group of individuals. From a public health perspective,

some suggest that rather than limit prevention efforts to this group, that broader attention should be paid to the mental health status of the general population to screen for and provide services for any person showing signs of these disturbances (van Os, 2011). DSM-5 “cut the baby in half” by including the disorder in its section “condition for further study.” It remains to be seen if this set of criteria will eventually make its way into the DSM and what impact that will have on treatment and outcomes for those affected.

Perspectives on Schizophrenia

- Schizophrenia is a complex syndrome that has been recognized for many years. Perhaps the earliest and best description of this disorder was published in 1809 by John Haslam in his book *Observations on Madness and Melancholy*.
- A number of historic figures during the 19th and early 20th century contributed to the evolving definitions and possible causes of this spectrum of disorders.

Clinical Description, Symptoms, and Subtypes

- Schizophrenia is characterized by a broad spectrum of cognitive and emotional dysfunctions that include delusions and hallucinations, disorganized speech and behavior, and inappropriate emotions.
- The symptoms of schizophrenia can be divided into positive, negative, and disorganized. Positive symptoms are active manifestations of abnormal behavior, or an excess or distortion of normal behavior, and include delusions and hallucinations. Negative symptoms involve deficits in normal behavior on such dimensions as affect, speech, and motivation. Disorganized symptoms include rambling speech, erratic behavior, and inappropriate affect.
- Psychotic behaviors, such as hallucinations and delusions, characterize several other disorders; these include schizopreniform disorder (which includes people who experience the symptoms of schizophrenia for less than 6 months); schizoaffective disorder (which includes people who have symptoms of schizophrenia and who exhibit the characteristics of mood disorders, such as depression and bipolar affective disorder); delusional disorder (which includes people with a persistent belief that is contrary to reality, in the absence of the other characteristics of schizophrenia); and

brief psychotic disorder (which includes people with one or more positive symptoms, such as delusions, hallucinations, or disorganized speech or behavior over the course of less than a month).

- A proposed new disorder—attenuated psychosis syndrome—which includes one or more of the symptoms of schizophrenia such as hallucinations or delusions, but the individual is aware that these are unusual experiences and are not typical for a healthy person. This is included in the Appendix of *DSM-5* as a disorder in need of further study.

Prevalence and Causes of Schizophrenia

- A number of causative factors have been implicated for schizophrenia, including genetic influences, neurotransmitter imbalances, structural damage to the brain caused by a prenatal viral infection or birth injury, and psychological stressors.
- Relapse appears to be triggered by hostile and critical family environments characterized by high expressed emotion.

Treatment of Schizophrenia

- Successful treatment for people with schizophrenia rarely includes complete recovery. The quality of life for these individuals can be meaningfully affected, however, by combining antipsychotic medications with psychosocial approaches, employment support, and community-based and family interventions.
- Treatment typically involves antipsychotic drugs that are usually administered with a variety of psychosocial treatments, with the goal of reducing relapse and improving skills in deficits and compliance in taking the medications. The effectiveness of treatment is limited, because schizophrenia is typically a chronic disorder.

TREATMENT OF SCHIZOPHRENIA

Treatment

Individual, Group, and Family Therapy

- Can help patient and family understand the disease and symptom triggers.
- Teaches families communication skills.
- Provides resources for dealing with emotional and practical challenges.

Social Skills Training

- Can occur in hospital or community settings.
- Teaches the person with schizophrenia social, self-care, and vocational skills.

Medications

- Taking neuroleptic medications may help people with schizophrenia to:
 - Clarify thinking and perceptions of reality
 - Reduce hallucinations and delusions
- Drug treatment must be consistent to be effective. Inconsistent dosage may aggravate existing symptoms or create new ones.

SYMPTOMS OF SCHIZOPHRENIA

People with schizophrenia do not all show the same kinds of symptoms.

Symptoms vary from person to person and may be cyclical. Common symptoms include:

Overview of Neurodevelopmental Disorders

Almost all disorders described in this book are developmental disorders in the sense that they change over time. Most disorders originate in childhood, although the full presentation of the problem may not manifest itself until much later. Disorders that show themselves early in life often persist as the person grows older, so the term *childhood disorder* may be misleading. Because the developmental disorders in this group are all believed to be neurologically based, *DSM-5* categorizes them as **neurodevelopmental disorders** (American Psychiatric Association, 2013). In this chapter, we cover those disorders that are revealed in a clinically significant way during a child's developing years and are of concern to families and educators. Remember, however, that these difficulties often persist through adulthood and are typically lifelong problems, not problems unique to children.

Again, a number of difficulties and, indeed, distinct disorders begin in childhood. In certain disorders, some children are fine except for difficulties with talking. Others have problems relating to their peers. Still other children have a combination of conditions that significantly hinder their development, as illustrated by the case of Timmy.

Timmy...

The Boy Who Looked Right Through You

Timmy, a beautiful blond baby, was born with the umbilical cord wrapped around his neck, so he had been without oxygen for an unknown period. Nonetheless, he appeared to be a healthy little boy. His mother later related that he was a good baby who rarely cried, although she was concerned he didn't like to be picked up and cuddled. His family became worried about his development when he was 2 years old and didn't talk (his older sister had at that age). They also noticed that he didn't play with other children; he spent most of his time alone, spinning plates on the floor, waving his hands in front of his face, and lining up blocks in a certain order.

The family's pediatrician assured them that Timmy was just developing at a different rate and would grow out of it. When, at age 3, Timmy's behavior persisted, his parents consulted a second pediatrician. Neurological examinations revealed nothing unusual but suggested, on the basis of Timmy's delay in learning such basic skills as talking and feeding himself, that he had severe intellectual disability.

Timmy's mother did not accept this diagnosis, and over the next few years she consulted numerous other professionals and received numerous diagnoses (including childhood schizophrenia, childhood psychosis, and developmental delay). By age 7, Timmy still didn't speak or play with other children, and he was developing aggressive and self-injurious behaviors. His parents brought him to a clinic for children with severe disabilities. Here, Timmy was diagnosed as having autism.

The clinic specialists recommended a comprehensive educational program of intensive behavioral intervention to help Timmy with language and socialization and to counter his increasing tendency to engage in tantrums. The work continued daily for approximately 10 years, both at the clinic and at home. During this time, Timmy learned to say only three words: "soda," "cookie," and "Mama." Socially, he appeared to like other people (especially adults), but his interest seemed to center on their ability to get him something he wanted, such as a favorite food or drink. If his surroundings were changed in even a minor way, Timmy became disruptive and violent to the point of hurting himself; to minimize his self-injurious behavior, the family took care to ensure that his surroundings stayed the same as much as possible. No real progress was made toward eliminating his violent behavior, however, and as he grew bigger and stronger, he became increasingly difficult to work with; he hurt his mother physically on several occasions. With great reluctance, she institutionalized Timmy when he was 17. •

As clinicians have grown to appreciate the far-reaching effects of childhood problems and the importance of early intervention in treating most disorders, they have become more interested in understanding the diversity of severe problems experienced in early life. Timmy was diagnosed with “autism” (now referred to as *autism spectrum disorder*) in the early 1970s. More than four decades later, we know more—although still not enough—about how to help children who have autism spectrum disorder. Who can say what the prognosis for Timmy might be today, especially if he were diagnosed and treated at age 2 instead of at age 7?

What Is Normal? What Is Abnormal?

Before we discuss specific disorders, we need to address the broad topic of development in relation to disorders usually first diagnosed in infancy, childhood, or adolescence. What can we learn from children like Timmy, and what effect do the early disruptions in their skills have on their later lives? Does it matter when in the developmental period certain problems arise? Are disruptions in development permanent, thus making any hope for treatment doubtful?

Recall that in Chapter 2 we described developmental psychopathology as the study of how disorders arise and how they change with time (Nigg, 2015). Childhood is considered particularly important, because the brain changes significantly for several years after birth; this is also when critical developments occur in social, emotional, cognitive, and other important competency areas. These changes mostly follow a pattern: The child develops one skill before acquiring the next, and subsequent skills often build upon one another. Although this pattern of change is only one aspect of development, it is an important concept at this point because it implies that any disruption in the development of early skills will, by the very nature of this sequential process, disrupt the development of later skills. For example, some researchers believe that people with autism spectrum disorder suffer from a disruption in early social development, which prevents them from developing important social relationships, even with their parents (Durand, 2014). From a developmental perspective, the absence of early and meaningful social relationships has serious consequences. Children whose motivation to interact with others is disrupted may have a more difficult time learning to communicate; that is, they may not want to learn to speak if other people are not important to them. Researchers don’t know whether a disruption in communication skills is a direct outcome of the disorder or a by-product of disrupted early social development.

Understanding this type of developmental relationship is important for several reasons. Knowing what processes are disrupted will help us understand the disorder better and may lead to more appropriate intervention strategies. It may be important to identify children with attention-deficit/hyperactivity disorder, for example, because their problems with impulsivity may interfere with their ability to create and maintain

friendships, an important developmental consideration. Similarly, identifying a disorder such as autism spectrum disorder at an early age is important for these children so that their social deficits can be addressed before they affect other skill domains, such as social communication. Too often, people see early and pervasive disruptions in developmental skills (such as you saw with Timmy) and expect a negative prognosis, with the problems predetermined and permanent. Remember, however, that biological and psychosocial influences continuously interact with each other. Therefore, even for disorders such as attention-deficit/hyperactivity disorder and autism spectrum disorder that have clear biological bases, the presentation of the disorder is different for each individual. Changes at the biological or the psychosocial level may reduce the impact of the disorder.

One note of caution is appropriate here. There is real concern in the profession, especially among developmental psychologists, that some workers in the field may view aspects of normal development as symptoms of abnormality. For example, *echolalia*, which involves repeating the speech of others, was once thought to be a sign of autism spectrum disorder. When we study the development of speech in children without disorders, however, we find that repeating what someone else says is an intermediate step in language development. In children with autism spectrum disorder, therefore, echolalia is just a sign of relatively delayed language skills and not a symptom of their disorder (Roberts, 2014). Knowledge of development is important for understanding the nature of psychological disorders.

With that caveat in mind, we now examine several disorders usually diagnosed first in infancy, childhood, or adolescence, including *attention-deficit/hyperactivity disorder*, which involves characteristics of inattention or hyperactivity and impulsivity, and *specific learning disorder*, which is characterized by one or more difficulties in areas such as reading and writing. We then focus on *autism spectrum disorder*, a more severe disability, in which the child shows significant impairment in social communication and has restricted patterns of behavior, interest, and activities. Finally, we examine *intellectual disability*, which involves considerable deficits in cognitive abilities. Communication and motor disabilities, which are also considered neurodevelopmental disorders, are described in Table 14.1.

Attention-Deficit/Hyperactivity Disorder

Do you know people who flit from activity to activity, who start many tasks but seldom finish one, who have trouble concentrating, and who don’t seem to pay attention when others speak? These people may have **attention-deficit/hyperactivity disorder (ADHD)**, one of the most common reasons children are referred for mental health services in the United States. The primary characteristics of such people include a pattern of inattention, such as being disorganized or forgetful about school or work-related tasks, or of hyperactivity and impulsivity. These deficits can significantly

TABLE 14.1 Common Communication and Motor Disorders.

Childhood-Onset Fluency Disorder			
Clinical Description	Statistics	Etiology	Treatment
A disturbance in speech fluency that includes a number of problems with speech, such as repeating syllables or words, prolonging certain sounds, making obvious pauses, or substituting words to replace ones that are difficult to articulate.	Occurs twice as often among boys as among girls. Begins most often in children by the age of 6, and 98% of cases occur before the age of 10 (Maguire, Yeh, & Ito, 2012). Approximately 80% of children who stutter before they enter school will no longer stutter after they have been in school a year or so (Kroll & Beitchman, 2005).	Rather than anxiety causing childhood-onset fluency disorder, this problem makes people socially anxious (Ezrati-Vinacour & Levin, 2004). Multiple brain pathways appear to be involved, and genetic influences may be a factor (Maguire et al., 2012).	Parents are counseled about how to talk to their children. <i>Regulated-breathing method</i> is a promising behavioral treatment in which the person is instructed to stop speaking when a stuttering episode occurs and then to take a deep breath (exhale, then inhale) before proceeding (Onslow, Jones, O'Brian, Packman, & Menzies, 2012). Altered auditory feedback (electronically changing speech feedback to people who stutter) can improve speech, as can using forms of self-monitoring, in which people modify their own speech for the words they stutter (Onslow et al., 2012).
Language Disorder			
Clinical Description	Statistics	Etiology	Treatment
Limited speech in <i>all</i> situations. <i>Expressive language</i> (what is said) is significantly below <i>receptive language</i> (what is understood); the latter is usually average.	Occurs in 10% to 15% of children younger than 3 years of age (Johnson & Beitchman, 2005) and is almost five times as likely to affect boys as girls (Whitehurst et al., 1988).	An unfounded psychological explanation is that the children's parents may not speak to them enough. A biological theory is that middle ear infection is a contributory cause.	May be self-correcting and may not require special intervention (Whitehurst et al., 1988).
Social (Pragmatic) Communication Disorder			
Clinical Description	Statistics	Etiology	Treatment
Difficulties with the social aspects of verbal and nonverbal communication, including verbosity, prosody, excessive switching of topics, and dominating conversations (Adams et al., 2012). Does not have the restricted and repetitive behaviors found in ASD.	Exact estimates not yet available, but the number of cases identified appears to be rising with increasing awareness (Baird et al., 2006; Bishop, 2000).	Limited information.	Individualized social skills training (e.g., modeling, role playing) with an emphasis on teaching important rules necessary for carrying on conversations with others (e.g., what is too much and too little information) (Adams et al., 2012).
Tourette's Disorder			
Clinical Description	Statistics	Etiology	Treatment
Involuntary motor movements (<i>tics</i>), such as head twitching, or vocalizations, such as grunts, that often occur in rapid succession, come on suddenly, and happen in idiosyncratic or stereotyped ways. Vocal tics often include the involuntary repetition of obscenities.	Of all children, up to 20% show some tics during their growing years, and 1 to 10 children out of every 1,000 have Tourette's disorder (Jummani & Coffey, 2009). Usually develops before the age of 14. High comorbidity between tics and ADHD, as well as obsessive-compulsive disorder (Jummani & Coffey, 2009).	There are likely multiple vulnerability genes that influence the form and severity of tics (Jummani & Coffey, 2009).	<i>Psychological:</i> Self-monitoring, relaxation training, and habit reversal.

disrupt academic efforts, as well as social relationships. Consider the case of Danny.

Danny...

The Boy Who Couldn't Sit Still

Danny, a handsome 9-year-old boy, was referred to us because of his difficulties at school and at home. Danny had a great deal of energy and loved playing most sports, especially baseball. Academically, his work was adequate, although his teacher reported that his performance was diminishing and she believed he would do better if he paid more attention in class. Danny rarely spent more than a few minutes on a task without some interruption: He would get up out of his seat, rifle through his desk, or constantly ask questions. His peers were frustrated with him because he was equally impulsive during their interactions. He never finished a game, and in sports he tried to play all positions simultaneously.

At home, Danny was considered a handful. His room was in a constant mess because he became engaged in a game or activity only to drop it and initiate something else. Danny's parents reported that they often scolded him for not carrying out some task, although the reason seemed to be that he forgot what he was doing rather than that he deliberately tried to defy them. They also said that, out of their own frustration, they sometimes grabbed him by the shoulders and yelled, "Slow down!" because his hyperactivity drove them crazy. •

Clinical Description

Danny has many characteristics of ADHD. Like Danny, people with this disorder have a great deal of difficulty sustaining their attention on a task or activity (Barkley, 2015c). As a result, their tasks are often unfinished, and they often seem not to be listening when someone else is speaking. In addition to this serious disruption in attention, some people with ADHD display motor hyperactivity. Children with this disorder are often described as fidgety in school, unable to sit still for more than a few minutes. Danny's restlessness in his classroom was a considerable source of concern for his teacher and peers, who were frustrated by his impatience and excessive activity. In addition to hyperactivity and problems sustaining attention, impulsivity—acting apparently without thinking—is a common complaint made about people with ADHD. For instance, during meetings at baseball practice, Danny often shouted responses to the coach's questions even before the coach had a chance to finish his sentence.

For ADHD, *DSM-5* differentiates two categories of symptoms. The first includes problems of *inattention*. People may appear not to listen to others; they may lose necessary school assignments, books, or tools; and they may not pay enough attention to details, making careless mistakes. The second category of symptoms includes *hyperactivity and impulsivity*. Hyperactivity includes fidgeting, having trouble sitting for any length of time, and always

being on the go. Impulsivity includes blurting out answers before questions have been completed and having trouble waiting turns. Either the first (inattention) or the second and third (hyperactivity and impulsivity) set of symptoms must be present for someone to be diagnosed with ADHD (American Psychiatric Association, 2013). These different presentations are called *subtypes*, and they include the inattentive subtype (what some may call *ADD*, noting the absence of hyperactivity, although this is not an official diagnostic label), and the hyperactive/impulsive subtype. Other individuals meet criteria for both inattention and hyperactivity/impulsivity, and these individuals are labeled with the *combined* subtype.

Inattention, hyperactivity, and impulsivity often cause other problems that appear secondary to ADHD. Academic performance often suffers, especially as the child progresses in school. The cause of this poor performance is not known. It could be a result of inattention and impulsivity, and in some children this can be made worse by factors such as concurrent learning disabilities. Genetic research on both ADHD and learning disabilities suggests that they may share a common biological cause (DuPaul, Gormley, & Laracy, 2013). Children with ADHD are likely to be unpopular and rejected by their peers (McQuade & Hoza, 2015). This, too, may be the result of genetic factors as well as environmental influences such as a hostile home environment and gene-environment interactions. For example, some research shows that having a specific genotype (i.e., a dopamine transporter—DAT1; and a serotonin transporter) and psychosocial distress can predict ADHD in children (Barkley, 2015a; Nigg, Nikolas, & Burt, 2010).

Statistics

An important analysis of prevalence of ADHD suggests that the disorder is found in about 5.2% of the child populations across all regions of the world (Polanczyk, de Lima, Horta, Biederman, & Rohde, 2007). This finding of comparable rates of ADHD worldwide is important because debates continue to rage about the validity of ADHD as a real disorder. Some people believe that children who are just normally "active" are being misdiagnosed with ADHD. Previously, geographic differences were noted in the number of people diagnosed with this disorder. Children were more likely to receive the label of ADHD in the United States than anywhere else. For example, an analysis of data from surveying parents over the phone suggests that 11% of children in the United States aged 4 to 17 were labeled with ADHD between 2011 and 2012 (Centers for Disease Control and Prevention, 2013). This higher number may suggest that it is being over-diagnosed in the United States.

Based on these different rates of diagnosis, some have argued that ADHD in children is simply a cultural construct—meaning that the behavior of these children is typical from a developmental perspective, and it is Western society's intolerance (due to the loss of extended family support, pressure to succeed academically, and busy family life) that causes labeling ADHD as a disorder (Timimi & Taylor, 2004). The best data suggest, however, that from 5% to 7% of the worldwide population of children currently meet the criteria for ADHD and 3% to 5% have symptoms that significantly interfere with their quality of life (Roberts, Milich, & Barkley, 2015).

Boys are 2 to 3 times more likely to be diagnosed with ADHD than girls, and this discrepancy increases for children being seen in clinics (Owens, Cardoos, & Hinshaw, 2015; Spencer, Biederman, & Mick, 2007). The reason for this gender difference is largely unknown. It may be that adults are more tolerant of hyperactivity among girls, who tend to be less active than boys with ADHD. Boys tend to be more aggressive, which will more likely result in attention by mental health professionals (Rucklidge, 2010). Girls with ADHD, on the other hand, tend to display more behaviors referred to as “internalizing”—specifically, anxiety and depression (Owens et al., 2015).

The higher prevalence of boys identified as having ADHD has led some to question whether the *DSM-5* diagnostic criteria for this disorder are applicable to girls. Here is the quandary: Most research over the past several decades has used young boys as participants. This focus on boys may have been the result of their active and disruptive behaviors, which caused concern among families and school personnel and therefore prompted research into the nature, causes, and treatment of these problems. More boys displayed these behaviors, which made it easier to find participants to study. But did this almost singular focus on boys result in ignoring how young girls experience this disorder?

This concern is being raised by some psychologists, including Kathleen Nadeau (a clinical psychologist who specializes in girls with ADHD), who argues that more research is needed on ADHD in girls: “Girls experience significant struggles that are often overlooked because their ADHD symptoms bear little resemblance to those of boys” (Crawford, 2003, p. 28). She says that girls with ADHD were neglected because their symptoms differ so dramatically from boys’ symptoms, although to date there is little firm evidence for these differences (Owens et al., 2015). Just as researchers are now exploring ADHD among adults, in addition to children, more research is now addressing the relative lack of research on girls and women. This expansion of research across age and gender bodes well for a fuller understanding of the disorder.

Children with ADHD are first identified as different from their peers around age 3 or 4; their parents describe them as active, mischievous, slow to toilet train, and oppositional (Taylor, 2012). The symptoms of inattention, impulsivity, and hyperactivity become increasingly obvious during the school years. Despite the perception that children grow out of ADHD, their problems usually continue: it is estimated that about half of the children with ADHD have ongoing difficulties through adulthood (McGough, 2005). Over time, children with ADHD seem to be less impulsive, although inattention persists. During adolescence, the impulsivity manifests itself in different areas; for example, teens with ADHD are at greater risk for pregnancy and contracting sexually transmitted

infections. They are also more likely to have driving difficulties, such as crashes; to be cited for speeding; and to have their licenses suspended (Barkley, 2015b; Fabiano & Schatz, 2015).

What happens to children and adolescents with ADHD as they become adults? Rachel Klein and her colleagues followed up on more than 200 boys with this disorder and reported on their status 33 years later (Klein et al., 2012). When compared with a group without ADHD, the majority of these men (84%) were employed but in jobs with significantly lower positions than the comparison group. They also had 2.5 fewer years of education and were much less likely to hold higher degrees. These men were also more likely to be divorced and to have substance use problems and antisocial personality disorder (Klein et al., 2012). In addition, the effects of their tendency to be impulsive may account for their increased risk of displaying risky driving, having a sexually transmitted disease, increased chance

of having a head injury, and more emergency department admissions (Ramos Olazagasti et al., 2013). In short, although the manifestations of ADHD change as people grow older, many of their problems persist.

Diagnosing children with ADHD is complicated. Several other *DSM-5* disorders, also found in children, appear to overlap significantly with this disorder. Specifically, oppositional defiant disorder (ODD), conduct disorder, and bipolar disorder all have characteristics seen in children with ADHD. ODD is a *DSM-5* disorder that includes behaviors such as “often loses temper,” “argues with adults,” “often deliberately annoys people,” “touchy and easily annoyed by others,” and “often spiteful and vindictive” (Toth, de Lacy, & King, 2016). The impulsivity and hyperactivity observed in children with ADHD can manifest themselves in some of these symptoms. Similarly, conduct disorder—which, as you saw in Chapter 12, can be a precursor to antisocial personality disorder—is also observed in many children with ADHD (Toth et al., 2016). Bipolar disorder—which, you will recall from Chapter 7, is one of the mood disorders—also overlaps significantly with ADHD (Pliszka, 2015). This overlap can complicate diagnosis in these children.

Causes

Important information about the genetics of ADHD is beginning to be uncovered (Barkley, 2015a). Researchers have known for some time that ADHD is more common in families in which one person has the disorder. For example, the relatives of children with ADHD have been found to be more likely to have ADHD themselves than would be expected in the general population (Fliers et al., 2009). It is important to note that these families display an

TABLE 14.1

Diagnostic Criteria for Attention Deficit/Hyperactivity Disorder

- A.** A persistent pattern of inattention and/or hyperactivity-impulsivity that interferes with functioning or development, as characterized by (1) and/or (2):
- 1. Inattention:** Six (or more) of the following symptoms have persisted for at least 6 months to a degree that is inconsistent with developmental level and that negatively impacts directly on social and academic/occupational activities:

Note: The symptoms are not solely a manifestation of oppositional behavior, defiance, hostility, or failure to understand tasks or instructions. For older adolescents and adults (aged 17 and older), at least five symptoms are required.

 - a. Often fails to give close attention to details or makes careless mistakes in schoolwork, at work, or during other activities (e.g., overlooks or misses details, work is inaccurate).
 - b. Often has difficulty sustaining attention in tasks or play activities (e.g., has difficulty remaining focused during lectures, conversations, or lengthy reading).
 - c. Often does not seem to listen when spoken to directly (e.g., mind seems elsewhere, even in the absence of any obvious distraction).
 - d. Often does not follow through on instructions and fails to finish schoolwork, chores, or duties in the workplace (e.g., starts tasks but quickly loses focus and is easily sidetracked).
 - e. Often has difficulty organizing tasks and activities (e.g., difficulty managing sequential tasks; difficulty keeping materials and belongings in order; messy, disorganized work; has poor time management; fails to meet deadlines).
 - f. Often avoids, dislikes, or is reluctant to engage in tasks that require sustained mental effort (e.g., schoolwork or homework; for older adolescents and adults, preparing reports, completing forms, reviewing lengthy papers).
 - g. Often loses things necessary for tasks or activities (e.g., school materials, pencils, books, tools, wallets, keys, paperwork, eyeglasses, or mobile telephones).
 - h. Is often easily distracted by extraneous stimuli (for older adolescents and adults, may include unrelated thoughts).
 - i. Is often forgetful in daily activities (e.g., chores, running errands; for older adolescents and adults, returning calls, paying bills, keeping appointments).
 - 2. Hyperactivity and impulsivity:** Six (or more) of the following symptoms have persisted for at least 6 months to a degree that is inconsistent with developmental level and that negatively impacts directly on social and academic/occupational activities:

Note: The symptoms are not solely a manifestation of oppositional behavior, defiance, hostility, or failure to understand tasks or instructions. For older adolescents and adults (age 17 and older), at least five symptoms are required.

 - a. Often fidgets with or taps hands or feet or squirms in seat.
 - b. Often leaves seat in situations when remaining seated is expected (e.g., leaves his or her place in the classroom, in the office or other workplace, or in other situations that require remaining in place).
 - c. Often runs about or climbs in situations where it is inappropriate. (**Note:** In adolescents or adults, may be limited to feeling restless.)
 - d. Often unable to play or engage in leisure activities quietly.
 - e. Is often "on the go," acting as if "driven by a motor" (e.g., is unable to be or uncomfortable being still for an extended time, as in restaurants, meetings; may be experienced by others as being restless or difficult to keep up with).
 - f. Often talks excessively.
 - g. Often blurts out an answer before a question has been completed (e.g., completes people's sentences; cannot wait for turn in conversation).
 - h. Often has difficulty waiting his or her turn (e.g., while waiting in line).
 - i. Often interrupts or intrudes on others (e.g., butts into conversations, games, or activities; may start using other people's things without asking or receiving permission; for adolescents or adults, may intrude into or take over what others are doing).
- B.** Several inattentive or hyperactive-impulsive symptoms were present prior to age 12 years.
- C.** Several inattentive or hyperactive-impulsive symptoms are present in two or more settings (e.g., at home, school, or work; with friends or relatives; in other activities).
- D.** There is clear evidence that the symptoms interfere with, or reduce the quality of, social, academic, or occupational functioning.
- E.** The symptoms do not occur exclusively during the course of schizophrenia or another psychotic disorder and are not better explained by another mental disorder (e.g., mood disorder, anxiety disorder, dissociative disorder, personality disorder, substance intoxication or withdrawal).

Specify whether:

Combined presentation: If both Criterion A1 (inattention) and Criterion A2 (hyperactivity-impulsivity) are met for the past 6 months.

Predominantly inattentive presentation: If Criterion A1 (inattention) is met but Criterion A2 (hyperactivity-impulsivity) is not met for the past 6 months.

Predominantly hyperactive/impulsive presentation: If Criterion A2 (hyperactivity-impulsivity) is met and Criterion A1 (inattention) is not met for the past 6 months.

increase in psychopathology in general, including conduct disorder, mood disorders, anxiety disorders, and substance abuse (Barkley, 2015a). This research and the comorbidity in the children themselves suggest that some shared genetic deficits may contribute to the problems experienced by individuals with these disorders (Brown, 2009).

ADHD is considered to be highly influenced by genetics. Environmental influences play a relatively small role in the cause of the disorder when compared with many other disorders we discuss in this book. As with other disorders, researchers are finding that multiple genes are responsible for ADHD (Nikolas & Burt, 2010). In its simplest form, we tend to think of genetic “problems” in terms of having genes turned off (not making proteins) when they should be turned on and vice versa. Research on ADHD (and on other disorders) is finding that in many cases, however, mutations occur that either create extra copies of a gene on one chromosome or result in the deletion of genes (called **copy number variants**—CNVs) (Martin, O’Donovan, Thapar, Langley, & Williams, 2015). Because our DNA is structured to function with corresponding or matching pairs of genes on each chromosome, the additions or deletions of one or more genes result in disrupted development.

Most attention to date focuses on genes associated with the neurochemical dopamine, although norepinephrine, serotonin, and gamma-aminobutyric acid (GABA) are also implicated in the cause of ADHD. More specifically, there is strong evidence that ADHD is associated with the dopamine D₄ receptor gene, the dopamine transporter gene (DAT1), and the dopamine D₅ receptor gene. DAT1 is of particular interest because methylphenidate (Ritalin)—one of the most common medical treatments for ADHD—inhibits this gene and increases the amount of dopamine available (Davis et al., 2007; de Azeredo et al., 2014). Such research helps us understand at a microlevel what might be going wrong and how to design new interventions.

As with several other disorders we’ve discussed, researchers are looking for endophenotypes, those basic deficits—such as specific attentional problems—characteristic of ADHD. The goal is to link these deficits to specific brain dysfunctions. Not surprisingly, specific areas of current interest for ADHD are the brain’s attention system, working memory functions, inattentiveness, and impulsivity. Researchers are now trying to tie specific genetic defects to these cognitive processes to make the link between genes and behavior. Some research indicates that poor “inhibitory control” (the ability to stop responding to a task when signaled) may be common among both children with ADHD and their unaffected family members (siblings and parents) and may be one genetic marker (an endophenotype) for this disorder (Goos, Crosbie, Payne, & Schachar, 2009; Nikolas & Nigg, 2015).

The strong genetic influence in ADHD does not rule out any role for the environment (Ficks & Waldman, 2009). In one of a growing number of gene–environment interaction studies of ADHD, for example, researchers found that children with a specific mutation involving the dopamine system (called the DAT1 genotype) were more likely to exhibit the symptoms of ADHD if their mothers smoked during pregnancy (Kahn, Khoury, Nichols, & Lanphear, 2003; Russell, Ford, Williams, & Russell, in press). Prenatal smoking seemed to interact with this genetic predisposition to increase the risk for hyperactive and impulsive behavior.

Other research is now pointing to additional environmental factors, such as maternal stress and alcohol use, and parental marital instability and discord, as involved in these gene–environment interactions (Barkley, 2015a; Ficks & Waldman, 2009).

The association between ADHD and maternal smoking is one of the more consistent findings in this area. In addition, a variety of other pregnancy complications (for example, maternal alcohol consumption and low birth weight) may play a role in increasing the chance that a child with a genetic predisposition for ADHD will display the symptoms characteristic of this disorder (Barkley, 2006c). Unfortunately, many of the studies in this area confound socioeconomic and genetic factors (for example, there is an increased likelihood of smoking among women who also have low socioeconomic status or are under other stressors) (Russell et al., in press).

For several decades, ADHD has been thought to involve brain damage, and this notion is reflected in the previous use of labels such as “minimal brain damage” or “minimal brain dysfunction” (Ross & Pelham, 1981). The rapid advances in scanning technology now permit us to see just how the brain may be involved in this disorder. A great deal of research on the structure and the function of the brain for children with this disorder has been conducted over the past few years. In general, researchers now know that the overall volume of the brain in those with this disorder is slightly smaller (3% to 4%) than in children without this disorder (Barkley, 2015a). A number of areas in the brains of those with ADHD appear affected, especially those involved in self-organizational abilities (Valera, Faraone, Murray, & Seidman, 2007). These changes seem less pronounced in persons who received medication (Taylor, 2012). In fact, a number of studies now point to a “growth enhancing effect” of stimulant medication, suggesting that brain development progresses in a more typical fashion in children receiving medication for ADHD versus those who do not (Frodl & Skokauskas, 2012; Rubia et al., 2014).

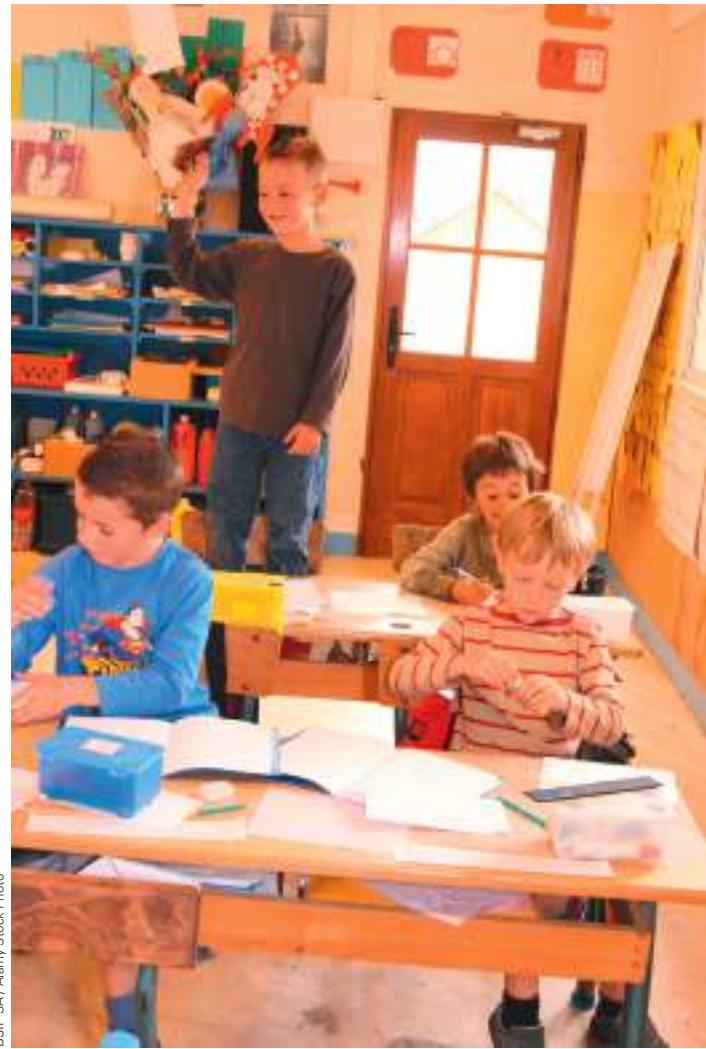

A variety of toxins such as allergens and food additives have been considered as possible causes of ADHD over the years, although little evidence supports the association. The theory that food additives such as artificial colors, flavorings, and preservatives are responsible for the symptoms of ADHD has been highly controversial. Feingold (1975) presented this view, along with recommendations for eliminating these substances as a treatment for ADHD. As a result, hundreds of thousands of families put their children on the Feingold diet, despite arguments by some that the diet has little or no effect on the symptoms of ADHD (Barkley, 1990; Kavale & Forness, 1983). Some large-scale research now suggests that there may be a small but measurable impact of artificial food colors and additives on the behavior of young children (Hurt & Arnold, 2015). One study found that 3-year-old and 8- to 9-year-old children who consumed typical amounts of preservatives (sodium benzoate) and food colorings had increased levels of hyperactive behaviors (inattention, impulsivity, and overactivity) (McCann et al., 2007). Other research now points to the possible role of toxins such as the pesticides found in foods as contributing to an increased risk of ADHD (Barkley, 2015a; Bouchard, Bellinger, Wright, & Weisskopf, 2010).

Psychological and social dimensions of ADHD may further influence the disorder itself—especially how the child fares over

time. Negative responses by parents, teachers, and peers to the affected child's impulsivity and hyperactivity may contribute to feelings of low self-esteem, especially in children who are also depressed (Anastopoulos, Sommer, & Schatz, 2009). Years of constant reminders by teachers and parents to behave, sit quietly, and pay attention may create a negative self-image in these children, which, in turn, can negatively affect their ability to make friends, and these effects can last into adulthood (Murphy, 2015). Thus, the possible biological influences on impulsivity, hyperactivity, and attention, combined with attempts to control these children, may lead to rejection and consequent poor self-image. An integration of the biological and psychological influences on ADHD suggests that both need to be addressed when designing effective treatments (Barkley, 2015c).

Treatment of ADHD

Treatment for ADHD has proceeded on two fronts: psychosocial and biological interventions (Smith & Shapiro, 2015). Psychosocial treatments generally focus on broader issues such as improving academic performance, decreasing disruptive behavior, and improving

social skills. Typically, the goal of biological treatments is to reduce the children's impulsivity and hyperactivity and to improve their attention skills. Current thinking in this area points to using parent- and/or teacher-delivered behavioral interventions for young children before attempting medication (Subcommittee on Attention-Deficit/Hyperactivity Disorder & Management, 2011).

Psychosocial Interventions

Researchers recommend various behavioral interventions to help these children at home and in school (Pfiffner & DuPaul, 2015; Robin, 2015). In general, the programs set such goals as increasing the amount of time the child remains seated, the number of math papers completed, or appropriate play with peers. Reinforcement programs reward the child for improvements and, at times, punish misbehavior with loss of rewards. Other parent education programs teach families how to respond constructively to their child's behaviors and how to structure the child's day to help prevent difficulties (e.g., Loren et al., 2015). Social skills training for these children, which includes teaching them how to interact appropriately with their peers, also seems to be an important treatment component (Watson, Richels, Michalek, & Raymer, 2015). For adults with ADHD, cognitive-behavioral intervention to reduce distractibility and improve organizational skills appears quite helpful (Knouse, 2015). Most clinicians typically recommend a combination of approaches designed to individualize treatments for those with ADHD, targeting both short-term management issues (decreasing hyperactivity and impulsivity) and long-term concerns (preventing and reversing academic decline and improving social skills).

Biological Interventions

The first types of medication used for children with ADHD were stimulants. Since the use of stimulant medication for children with ADHD was first described (Bradley, 1937), hundreds of studies have documented the effectiveness of this kind of medication in reducing the core symptoms (hyperactivity, impulsiveness) of the disorder. It is estimated that 3.5% of the children living in the United States are being treated with medication for symptoms of ADHD (Zuvekas & Vitiello, 2012). Drugs such as methylphenidate (Ritalin, Adderall) and several nonstimulant medications such as atomoxetine (Strattera), guanfacine (Tenex), and clonidine have proved helpful in reducing the core symptoms of hyperactivity and impulsivity and in improving concentration on tasks (Connor, 2015).

Originally, it seemed paradoxical or contrary to expect that children would calm down after taking a stimulant. However, on the same low doses, children and adults with and without ADHD react in the same way. It appears that stimulant medications reinforce the brain's ability to focus attention during problem-solving tasks (Connor, 2006). Although the use of stimulant medications remains controversial, especially for children, most clinicians recommend them temporarily, in combination with psychosocial interventions, to help improve children's social and academic skills.

The concerns over the use of stimulant medications now include their potential for abuse. In Chapter 11, we discussed that drugs such as Ritalin and Adderall are sometimes abused for their ability to create elation and reduce fatigue (Varga, 2012). And, the widespread misperception that use of these prescription medications to improve academic performance (they are frequently used for this purpose on college campuses) and that they are harmless is also of great concern (Watson, Arcona, & Antonuccio, 2015). This is particularly worrisome for children with ADHD because they are at increased risk for later substance abuse (Wagner & Pliszka, 2009). As mentioned previously, other nonstimulant drugs such as atomoxetine (Strattera) also appear effective for some children with ADHD. This drug is a selective norepinephrine-reuptake inhibitor and therefore does not produce the same “highs” when used in larger doses. Research suggests that other drugs, such as some antidepressants (imipramine) and a drug used for treating high blood pressure (clonidine) may have similar effects as atomoxetine on people with ADHD (Connor, 2015). Not all children with ADHD have depression or high blood pressure (although depression can be a problem in some of these children), but these drugs work on the same neurotransmitter systems (norepinephrine and dopamine) involved in ADHD (Subcommittee on Attention-Deficit/Hyperactivity Disorder & Management, 2011). All these drugs seem to improve compliance and decrease negative behaviors in many children, and their effects do not usually last when the drugs are discontinued.

Psychopharmacogenetics is the study of how your genetic makeup influences your response to certain drugs. The hope for this field is that medications can be matched or even “designed” for individuals to better complement their specific needs (Jain, 2015). For example, one study looked at the use of methylphenidate (Ritalin) for children and adolescents with ADHD (Polanczyk, Zeni, et al., 2007). For those who had a specific gene defect—the adrenergic alpha-2A receptor gene (ADRA2A)—methylphenidate had a strong positive effect, especially on their problems with inattention. This was not the case for those with ADHD who did not have the ADRA2A gene defect. Currently, the use of drug treatments tends to be by trial and error: A medication is attempted at a particular dose; if it is not effective, the dose is changed. If that does not work, a different medication is tried. This new study holds the promise of potentially eliminating this guesswork by tailoring the treatment to the individual.

This exciting new approach to medical treatment for mental illness brings with it some weighty concerns. Central to these concerns are issues of privacy and confidentiality. Genetic screening to identify defects is likely to identify any number of potential genetic problems in each of us. How will schools, employment sites, and insurance companies view this information if they have access? The concern is that people will be discriminated against based on this information (for example, having the genes that may or may not lead to having ADHD or another disorder). Will the desire to better target drug treatments outweigh these types of ethical and privacy concerns? Most new technical advances, like those promised with psychopharmacogenetics, also uncover new problems, and it is essential that ethical issues be part of the discussion as researchers move forward in this area.

Some portion of children with ADHD do not respond to medications, and most children who do respond show improvement in

ability to focus their attention but do not show gains in the important areas of academics and social skills. In addition, the medications often result in unpleasant side effects, such as insomnia, drowsiness, or irritability (Connor, 2015).

Combined Approach to Treatment

To determine whether or not a combined approach to treatment is the most effective, a large-scale study initiated by the National Institute of Mental Health was conducted by six teams of researchers (Jensen et al., 2001). Labeled the Multimodal Treatment of Attention-Deficit/Hyperactivity Disorder (MTA) study, this 14-month study included 579 children who were randomly assigned to one of four groups. One group of the children received routine care without medication or specific behavioral interventions (community care). The three treatment groups consisted of medication management (usually methylphenidate), intensive behavioral treatment, and a combination of the two treatments. Initial reports from the study suggested that the combination of behavioral treatments and medication and medication alone were superior to behavioral treatment alone and community intervention for ADHD symptoms. For problems that went beyond the specific symptoms of ADHD, such as social skills, academics, parent-child relations, oppositional behavior, and anxiety or depression, results suggested slight advantages of combination over single treatments (medication management, behavioral treatment) and community care.

Some controversy surrounds the interpretation of these findings—specifically, whether or not the combination of behavioral and medical treatments is superior to medication alone (Biederman, Spencer, Wilens, & Greene, 2001; Pelham, 1999). One of the concerns surrounding the study was that although medication continued to be dispensed, the behavioral treatment was faded over time, which may account for the observed differences.

Practically, if there is no difference between these two treatments, most parents and therapists would opt for simply providing medication for these children because of its ease of use and lower time commitment (Connor, 2015). Behavioral interventions have the added benefit, however, of improving aspects of the child and family that are not directly affected by medication. Reinterpretations of the data from this large-scale study continue, and more research likely will be needed to clarify the combined and separate effects of these two approaches to treatment (Connor, 2015; Ollendick & Shirk, 2010). Despite these advances, however, children with ADHD continue to pose a considerable challenge to their families and to the educational system.

Specific Learning Disorder

Academic achievement is highly valued in our society. We often compare the performance of our schoolchildren with that of children in other cultures to estimate whether we are succeeding or failing as a world leader and economic force. On a personal level, because parents often invest a great deal of time, resources, and emotional energy to ensure their children’s academic success, it can be extremely upsetting when a child with no obvious intellectual

deficits does not achieve as expected. In this section, we describe **specific learning disorder**—which is characterized by performance that is substantially below what would be expected given the person’s age, intelligence quotient (IQ) score, and education (Pierce, 2016). We also look briefly at disorders that involve how we communicate. Consider the case of Alice.

Alice...

Taking a Learning Disorder to College

Alice, a 20-year-old college student, sought help because of her difficulty in several of her classes. She reported that she had enjoyed school and had been a good student until about the sixth grade, when her grades suffered significantly. Her teacher informed her parents that she wasn’t working up to her potential and she needed to be better motivated. Alice had always worked hard in school but promised to try harder. However, with each report card, her mediocre grades made her feel worse about herself. She managed to graduate from high school, but by that time she felt she was not as bright as her friends.

Alice enrolled in the local community college and again found herself struggling with the work. Over the years, she had learned several tricks that seemed to help her study and at least get passing grades. She read the material in her textbooks aloud to herself; she had earlier discovered that she could recall the material much better this way than if she just read silently to herself. In fact, reading silently, she could barely remember any of the details just minutes later.

After her sophomore year, Alice transferred to the university, which she found even more demanding and where she failed most of her classes. After our first meeting, I suggested that she be formally assessed to identify the source of her difficulty. As suspected, Alice had a specific learning disorder.

Scores from an IQ test placed her slightly above average, but she was assessed to have significant difficulties with reading. Her comprehension was poor, and she could not remember most of the content of what she read. We recommended that she continue with her trick of reading aloud, because her comprehension for what she heard was adequate. In addition, Alice was taught how to analyze her reading—that is, how to outline and take notes. She was even encouraged to audiotape her lectures and play them back to herself as she drove around in her car. Although Alice did not become an A student, she was able to graduate from the university, and she now works with young children who themselves have learning disabilities. •

Clinical Description

According to *DSM-5* criteria, Alice would be diagnosed as having a specific learning disorder (in her case especially in the area of reading), which is defined as a significant discrepancy between a person’s academic achievement and what would be expected for someone of the same age—referred to by some as “unexpected

underachievement” (Miciak, Fletcher, & Stuebing, 2016; Scanlon, 2013). More specifically, the criteria require that the person perform academically at a level significantly below that of a typical person of the same age, cognitive ability (as measured on an IQ test), and educational background. In addition, a diagnosis of specific learning disorder requires that the person’s disability not be caused by a sensory difficulty, such as trouble with sight or hearing, and should not be the result of poor or absent instruction. *DSM-IV-TR* listed specific disorders in reading, mathematics, and written expression as separate disorders, but because of the significant overlap in these disabilities, they are now combined to assist clinicians in taking a broader view of the individual’s learning styles (Pierce, 2016). Clinicians can use the specifiers for *disorders of reading, written expression, or mathematics* to highlight specific problems for remediation. As with other disorders, clinicians rate the disorder on levels of severity.

Historically, a specific learning disorder would be defined as a discrepancy of more than 2 standard deviations between achievement and IQ. There was considerable controversy, however, over using the discrepancy between IQ and achievement as part of the process of identifying children with learning disorders (Cavendish, 2013). Part of the criticism involves the delay between when learning problems occur and when they finally result in a large enough difference between IQ scores and achievement scores—which may not be measurable until later in a child’s academic life. An alternative approach—called *response to intervention*—is now being used by many clinicians (Miciak et al., 2016). It involves identifying a child as having a specific learning disorder when the response to a known effective intervention (for example, an early reading program) is significantly inferior to the performance by peers (Cavendish, 2013; Sadler & Sugai, 2009; VanDerHeyden & Harvey, 2012). This provides an early warning system and focuses on providing effective instruction.

Statistics

The prevalence of specific learning disorders has been estimated between 5% and 15% across youth of various ages and cultures (American Psychological Association, 2013). A study of more than 1,600 German elementary schoolers found that approximately 7% showed significant deficits in reading, 9% in spelling (i.e., written expression), and 5% in arithmetic (Moll, Kunze, Neuhoff, Bruder, & Schulte-Körne, 2014). Another study of Brazilian children in second through sixth grades estimated the prevalence of specific learning disorders to be between 5% and 8% across categories of written expression, reading, arithmetic and global impairment (Fortes et al., 2015). In the United States, approximately 6.5 million students between the ages of 3 and 21 were receiving services for specific learning disorder between 2009 and 2010 (U.S. Department of Education, 2012). The frequency of this diagnosis appears to increase in wealthier regions of the country, suggesting that with better access to diagnostic services, more children are identified (see ● Figure 14.1). There do appear to be racial differences in the diagnosis of specific learning disorder (referred to as “disproportionality”) (Bruce & Venkatesh, 2014; Cortiella & Horowitz, 2014). Approximately 1% of Caucasian children and 2.6% of black children were receiving services for problems with learning in 2001 (Bradley, Danielson, & Hallahan, 2002). It

appears that societal views of disability, racism, and inequitable assessment are among the factors that contribute to disproportionality (Bruce & Venkatesh, 2014). Difficulties with reading are the most common of the learning disorders and occur in some form in 7% of the general population (Pennington & Bishop, 2009; Peterson & Pennington, 2012). Mathematics disorder appears in approximately 5% to 6% of the population (Pierce, 2016), but there is limited information about the prevalence of disorder of written expression among children and adults. Early studies suggested that boys were more likely to have a reading disorder than

girls, although other research indicates that boys and girls may be equally affected by this disorder (Feinstein & Phillips, 2006). Students with learning disorders are more likely to drop out of school (Vogel & Reder, 1998; Kearney, 2008), more likely to be unemployed (Gerber, 2012), and more likely to have suicidal thoughts and attempt suicide (Daniel et al., 2006). However, the negative outcomes for adults may be mitigated by providing the proper supports, such as having a positive relationship with caring adults and providing accommodations in postsecondary educational and employment settings (Gregg, 2013).

Diagnostic Criteria for Specific Learning Disorder

5

- A.** Difficulty learning and using academic skills, as indicated by the presence of at least one of the following symptoms that have persisted for at least 6 months, despite the provision of interventions that target those difficulties:
- 1.** Inaccurate or slow and effortful word reading (e.g., reads single words aloud incorrectly or slowly and hesitantly, frequently guesses words, has difficulty sounding out words).
 - 2.** Difficulty understanding the meaning of what is read (e.g., may read text accurately but not understand the sequence, relationships, inferences, or deeper meanings of what is read).
 - 3.** Difficulties with spelling (e.g., may add, omit, or substitute vowels or consonants).
 - 4.** Difficulties with written expression (e.g., makes multiple grammatical or punctuation errors within sentences; employs poor paragraph organization, written expression of ideas lacks clarity).
 - 5.** Difficulties mastering number sense, number facts, or calculation (e.g., has poor understanding of numbers, their magnitude, and relationships; counts on fingers to add single-digit numbers instead of recalling the math fact as peers do; gets lost in the midst of arithmetic computation and may switch procedures).
 - 6.** Difficulties with mathematical reasoning (e.g., has severe difficulty applying mathematical concepts, facts, or procedures to solve quantitative problems).
- B.** The affected academic skills are substantially and quantifiably below those expected for the individual's chronological age and cause significant interference with academic or occupational performance, or with activities of daily living, as confirmed by individually administered standardized achievement measures and comprehensive clinical assessment. For individuals aged 17 years and older, a documented history of impairing learning difficulties may be substituted for the standardized assessment.
- C.** The learning difficulties begin during school-age years but may not become fully manifest until the demands for those affected academic skills exceed the individual's limited capacities (e.g., as in timed tests, reading or writing lengthy, complex reports for a tight deadline, excessively heavy academic loads).
- D.** The learning difficulties are not better accounted for by intellectual disabilities, uncorrected visual or auditory acuity, other mental or neurological disorders, psychosocial adversity, lack of proficiency in the language of academic instruction, or inadequate educational instruction.

Note: The four diagnostic criteria are to be met based on clinical synthesis of the individual's history (developmental, medical, family, educational), school reports, and psychoeducational assessment.

Uneven distribution. The highest percentages of schoolchildren diagnosed with learning disabilities are in the wealthiest states.

Interviews with adults who have specific learning disorder reveal that their school experiences were generally negative, and the effects often lasted beyond graduation. One man who did not have special assistance during school reports the following:

I faked my way through school because I was very bright. I resent most that no one picked up my weaknesses. Essentially I judge myself on my failures. . . . [I] have always had low self-esteem. In hindsight, I feel that I had low self-esteem in college. . . . I was afraid to know myself. A blow to my self-esteem when I was in school was that I could not write a poem or a story. . . . I could not write with a pen or pencil. The computer has changed my life. I do everything on my computer. It acts as my memory. I use it to structure my life and for all of my writing since my handwriting and written expression has always been so poor. (Polloway, Schewel, & Patton, 1992, p. 521)

A group of disorders loosely identified as *communication disorders* seems closely related to specific learning disorder (American Psychiatric Association, 2013). These disorders can appear deceptively benign, yet their presence early in life can cause wide-ranging problems later. For a brief overview of these disorders, which include **childhood-onset fluency disorder** (previously called **stuttering**) and **language disorder** (which combines DSM-IV-TR expressive and mixed receptive-expressive language disorders), see Table 14.1.

Causes

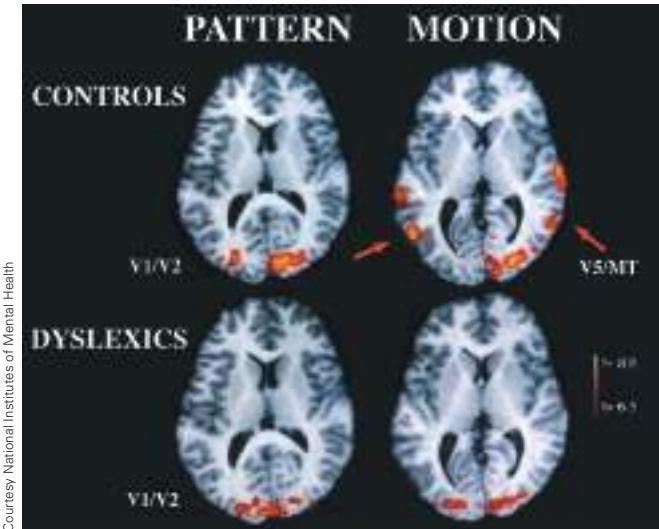

Theories about the causes of specific learning disorder include genetic, neurobiological, and environmental factors (Peterson & Pennington, 2012). The genetic research in this area is particularly complex. It is clear that learning disorders run in families, and sophisticated family and twin studies bear this out (e.g., Christopher et al., 2013). Yet, analyses of the genes involved suggest that many effects are not specific—meaning that there are not different genes responsible for reading disorders and mathematics disorders. Instead, there are genes that affect learning, and they may contribute to problems across domains (reading, mathematics, writing) (Petrill, 2013; Plomin & Kovas, 2005).

The different problems associated with learning themselves have different origins. For example, children (and adults) often have very different problems associated with reading. Reading disorders are sometimes broken into problems with word recognition (difficulty decoding single words—sometimes called *dyslexia*), fluency (problems being able to read words and sentences smoothly and automatically), and comprehension (difficulty getting meaning from what is read) (Siegel & Mazabell, 2013; Tannock, 2009b). Most research to date focuses on problems with word recognition,

and there is evidence that some develop these problems primarily through their genes, whereas others develop problems as a result of environmental factors (Siegel & Mazabell, 2013). Genes located on chromosomes 1, 2, 3, 6, 11, 12, 15, and 18 have all been repeatedly linked to these difficulties (Cope et al., 2012; Zou et al., 2012). At the same time, environmental influences such as the home reading habits of families can significantly affect outcomes—especially with skills such as word recognition—suggesting that reading to children at risk for reading disorders can lessen the impact of the genetic influence (Siegel & Mazabell, 2013).

Various forms of subtle brain impairment have also been thought responsible for learning disabilities; some of the earliest theories involve a neurological explanation (Hinshelwood, 1896). Research suggests structural, as well as functional, differences in the brains of people with learning disabilities. Specifically, three areas of the left hemisphere appear to be involved in problems with dyslexia (word recognition)—Broca's area (which affects articulation and word analysis), an area in the left parietotemporal area (which affects word analysis), and an area in the left occipitotemporal area (which affects recognizing word form) (Peterson & Pennington, 2012). A different area in the left hemisphere—the intraparietal sulcus—seems to be critical for the development of a sense of numbers and is implicated in mathematics disorder (Ashkenazi, Black, Abrams, Hoeft, & Menon, 2013). In contrast, there is no current evidence for specific deficits responsible for disorders of written expression.

Disorders of reading have been diagnosed more often in English-speaking countries. Although some have thought that this may simply be a difference in diagnostic practices, biological

These functional MRI scans of composite data from six dyslexic adults and eight controls show a horizontal slice through the brain, with the face at the top. Imaging shows atypical brain activity associated with dyslexia. The scans were performed while subjects tracked a pattern of moving dots on a computer screen. research now suggests it may involve the relative complexity of the written word in English. Researchers tested individuals who displayed reading disorders and who spoke English, French, or Italian (Paulesu et al., 2001). Although those who spoke Italian did better on tests of reading, brain imaging (positron emission tomography) while participants were reading indicated that all of these people with reading disorders experienced the same reduced activity in the left temporal lobe. It was hypothesized that characteristics of the English and French languages may make them more difficult languages to read, thus accounting for these cultural differences in rates of diagnosis for reading disorders.

You saw that Alice persisted despite the obstacles caused by her specific learning disorder, as well as by the reactions of teachers and others. What helped her continue toward her goal when others choose, instead, to drop out of school? Psychological and motivational factors that have been reinforced by others seem to play an important role in the eventual outcome of people with learning disorders. Factors such as socioeconomic status, cultural expectations, parental interactions and expectations, and child management practices, together with existing neurological deficits and the types of support provided in the school, seem to determine outcome (Gregg, 2013).

Treatment of Learning Disorders

As you will see in the case of intellectual disability, learning disorders primarily require educational intervention. Biological (drug) treatment is typically restricted to those individuals who may also have comorbid ADHD, which, as we discussed, involves impulsivity and an inability to sustain attention and can be helped with

certain stimulant medications, such as methylphenidate (Ritalin or Adderall). Educational efforts can be broadly categorized into (1) specific skills instruction, including instruction on vocabulary, finding the main idea, and finding facts in readings, and (2) strategy instruction, which includes efforts to improve cognitive skills through decision making and critical thinking (Fletcher, Lyon, Fuchs, & Barnes, 2006; Pierce, 2016).

Many programs are used to assist children with their problems related to learning. One approach that has received considerable research support is called Direct Instruction (Kame'enui, Fien, & Korgesaar, 2013). This program includes several components; among them are systematic instruction (using highly scripted lesson plans that place students together in small groups based on their progress) and teaching for mastery (teaching students until they understand all concepts). In addition, children are constantly assessed, and plans are modified based on progress or lack of progress. Direct Instruction and several related training programs appear to significantly improve academic skills in children with specific learning disorder (Kame'enui et al., 2013).

How do these behavioral and educational approaches help children with reading difficulties? Are they just tricks or adaptations to learning, or do these treatments have a more profound effect on the way these children process information? Exciting research using brain-imaging technology is allowing us to answer these important questions. One study used functional magnetic resonance imaging scanning (fMRI) to compare how children with and without reading disorders processed simple tasks (Temple et al., 2003). The children with reading difficulties were then exposed to 8 weeks of intensive training on a computer program that helped them work on their auditory and language-processing skills. Not only did the children improve their reading skills, but also their brains started functioning in a way similar to the brains

of their peers who were good readers. This and similar studies (Peterson & Pennington, 2012) mirror results seen with other disorders—namely, that behavioral interventions can change the way the brain works and that we can use such interventions to help individuals with significant problems.

Concept Check 14.1

Assign a label to each of the following cases: (a) ADHD, (b) social (pragmatic) communication disorder, (c) Tourette's disorder, or (d) specific learning disorder.

1. Trent's developmental disorder is characterized by uncontrollable yelps, sniffs, and grunting noises.
2. Ten-year-old Cole can be frustrating to his parents, teachers, and friends. He has trouble waiting his turn during games and does things seemingly without thinking. He often calls out answers in school, sometimes before the complete question is asked.
3. In school, 6-year-old Miley appears extremely awkward. She doesn't understand when other children are being sarcastic and misses many social communication cues.
4. Kelly was a good student until the sixth grade. Her grades slowly began to drop, despite her increased studying. Now, as a high school senior concerned about graduation, and with hopes of going to college, Kelly has sought help. She places above average on an IQ test but shows significant problems with reading and comprehension.
5. Eight-year-old Chandra is described by everyone as a "handful." She fidgets constantly in class, drumming her fingers on the desk, squirming in her chair, and getting up and down. She has trouble waiting her turn at work or at play, and she sometimes has violent outbursts.

Autism Spectrum Disorder

Autism spectrum disorder (ASD) is a neurodevelopmental disorder that, at its core, affects how one perceives and socializes with others (Durand, 2014). *DSM-5* combined most of the disorders previously included under the umbrella term “pervasive developmental disorders” (e.g., autistic disorder, Asperger’s disorder, and **childhood disintegrative disorder**) and included them into this one category (American Psychiatric Association, 2013). Moreover, **Rett disorder**, a genetic condition that affects mostly females and is characterized by hand wringing and poor coordination, is diagnosed as ASD with the qualifier “associated with Rett syndrome” or “associated with MeCP2 mutation” (the gene involved in Rett syndrome). And the

designation “not otherwise specified,” which was applied to other disorders prior to *DSM-5*, was deleted. A disorder new to *DSM-5*—social (pragmatic) communication disorder—includes the difficulties in social communication seen in ASD, but without restricted, repetitive patterns of behavior. These individuals do not easily learn the social rules when communicating with others (e.g., interrupting, talking too loud, not listening to others). Certain individuals previously diagnosed with pervasive developmental disorder—not otherwise specified may fall into this category.

Clinical Description

Two major characteristics of ASD are expressed in *DSM-5*: 1) impairments in social communication and social interaction, and 2) restricted, repetitive patterns of behavior, interests, or activities (American Psychiatric Association, 2013). In addition, *DSM-5* recognizes that the impairments are present in early childhood and that they limit daily functioning. It is the degree of impairment in each of these characteristics that presumably distinguish individuals previously diagnosed with the separate disorders of autistic disorder, Asperger’s disorder, and **pervasive developmental disorder—not otherwise specified**.

To accommodate the range of difficulties in the two symptom clusters (social/communication interaction and restricted, repetitive patterns of behavior, interests, or activities), *DSM-5* introduced three levels of severity: Level 1—“Requiring support,” Level 2—“Requiring substantial support,” and “Level 3—“Requiring very substantial support.” Separate ratings are provided for social/communication interaction and for restricted interests and repetitive behaviors. Each level of support is described qualitatively and, as yet, has no quantitative equivalent. This subjectivity makes assigning the appropriate level of support needed somewhat problematic if the person with ASD does not perform at the extreme ends of these categories (Durand, 2014). Consider the case of Amy.

Amy . . .

In Her Own World

Amy, 3 years old, spends much of her day picking up pieces of lint. She drops the lint in the air and then watches intently as it falls to the floor. She also licks the back of her hands and stares at the saliva. She hasn’t spoken yet and can’t feed or dress herself. Several times a day, she screams so loudly that the neighbors at first thought she was being abused. She doesn’t seem to be interested in her mother’s love and affection but will take her mother’s hand to lead her to the refrigerator. Amy likes to eat butter—whole pats of it, several at a time. Her mother uses the pats of butter that you get at some restaurants to help Amy learn and to keep her well-behaved. If Amy helps with dressing herself, or if she sits quietly for several minutes, her mother gives her some butter. Amy’s mother knows that the butter isn’t good for her, but it is the only thing that seems to get through to the child. The family’s pediatrician has been concerned about Amy’s developmental delays for some time and has recently suggested that she be evaluated by specialists. The pediatrician thinks Amy may have autism spectrum disorder, and the child and her family will probably need extensive support. •

Impairment in Social Communication and Social Interaction

One of the defining characteristics of people with ASD is that they fail to develop age-appropriate social relationships (Davis & Carter, 2014). Amy never made friends among her peers and often limited her contact with adults to using them as tools—for example, taking the adult's hand to reach for something she wanted. Research on the symptoms of ASD including communication difficulties and social difficulties (which were listed independently as part of *DSM-IV-TR*) revealed the considerable overlap of these symptoms (Frazier et al., 2012; Skuse, 2012). *DSM-5* combines these two areas into one general symptom cluster (social communication and social interaction). Difficulties with social communication and interaction are further defined by the inclusion of three aspects—problems with social reciprocity (a failure to engage in back-and-forth social interactions), nonverbal communication, and initiating and maintaining social relationships—all three of which must be present to be diagnosed with ASD.

Social reciprocity for individuals with more severe symptoms of ASD (previously diagnosed with autistic disorder) involves the inability to engage in **joint attention** (Gillespie-Lynch et al., 2012; Schietecatte et al., 2012). If a toddler without ASD sees a toy she likes, she might look at her mother, smile, look at the toy, and look at her mother again. This social act communicates not only interest

in the toy but also the desire to share this interest with another person. This action is limited in persons with ASD. Among persons with milder symptoms of ASD (previously diagnosed with Asperger's disorder), this lack of social reciprocity might present itself as appearing self-focused and not showing interest in things other people care about.

Research using sophisticated eye-tracking technology shows how social deficits evolve as the person develops. In one classic study, scientists showed an adult man with ASD some scenes from movies and compared how he looked at social scenes with how a man without ASD did so (Klin, Jones, Schultz, Volkmar, & Cohen, 2002). You can see from the photo that the man with ASD (indicated by the red lines) scanned nonsocial aspects of the scene (the actors' mouth and jacket), while the man without ASD looked at the socially meaningful sections (looking from eye to eye of the people conversing). This research suggests that people with ASD—for reasons not yet fully understood—may not be interested in social situations.

Deficits in nonverbal communication can involve problems with a range of actions in persons with severe forms of ASD (e.g., not pointing to things you want) and among those with milder forms of ASD (e.g., standing too close to someone). Individuals with the less severe form of ASD may also lack appropriate facial expressions or tone of voice (also known as "**prosody**"; Durand,

Diagnostic Criteria for Autism Spectrum Disorder

5

- A.** Persistent deficits in social communication and social interaction across multiple contexts, as manifested by the following, currently or by history (examples are illustrative, not exhaustive; see text):
- 1.** Deficits in social-emotional reciprocity; ranging, for example, from abnormal social approach and failure of normal back-and-forth conversation; to reduced sharing of interests, emotions, and affect; to failure to initiate or respond to social interactions.
 - 2.** Deficits in nonverbal communicative behaviors used for social interaction, ranging, for example, from poorly integrated verbal and nonverbal communication; to abnormalities in eye contact and body language or deficits in understanding and use of gestures; to a total lack of facial expressions and nonverbal communication.
 - 3.** Deficits in developing, maintaining, and understanding relationships, ranging, for example, from difficulties adjusting behavior to suit various social contexts; to difficulties in sharing imaginative play and in making friends; to absence of interest in peers.
- B.** Restricted, repetitive patterns of behavior, interests, or activities, as manifested by at least two of the following, currently or by history (examples are illustrative, not exhaustive; see text):
- 1.** Stereotyped or repetitive motor movements, use of objects, or speech; (e.g., simple motor stereotypies, lining up toys or flipping objects, echolalia, idiosyncratic phrases).
 - 2.** Insistence on sameness, inflexible adherence to routines, or ritualized patterns of verbal or nonverbal behavior (e.g., extreme distress at small changes, difficulties with transitions, rigid thinking patterns, greeting rituals, need to take same route or eat same food every day).
 - 3.** Highly restricted, fixated interests that are abnormal in intensity or focus (e.g., strong attachment to or preoccupation with unusual objects, excessively circumscribed or perseverative interests).
 - 4.** Hyper- or hyporeactivity to sensory input or unusual interest in sensory aspects of the environment (e.g., apparent indifference to pain/temperature, adverse response to specific sounds or textures, excessive smelling or touching of objects, visual fascination with lights or movement).
- C.** Symptoms must be present in the early developmental period (but may not become fully manifest until social demands exceed limited capacities, or may be masked by learned strategies in later life).
- D.** Symptoms cause clinically significant impairment in social, occupational, or other important areas of current functioning.
- E.** The disturbances are not better explained by intellectual disability (intellectual developmental disorder) or global developmental delay. Intellectual disability and autism spectrum disorder frequently co-occur; to make comorbid diagnoses of autism spectrum disorder and intellectual disability, social communication should be below that expected for general developmental level.

2014) when speaking or just give the appearance of general nonverbal awkwardness. Finally, the deficits in social reciprocity and nonverbal communication can combine to influence the third symptom—problems maintaining social relationships.

Approximately 25% of individuals with ASD do not develop speech proficiency sufficient to communicate their needs effectively (Anderson et al., 2007). In those with some speech, sometimes their communication is unusual. Some repeat the speech of others, a pattern called echolalia, which we referred to earlier as a sign of delayed speech development. If you say, “My name is Eileen, what’s yours?” they will repeat all or part of what you said: “Eileen, what’s yours?” And often, not only are your words repeated, but so is your intonation. On the other end of the autism spectrum, these individuals can be very verbal, but because of the social deficits and their tendency to have restricted interests, they often have one-sided conversations about the topics they want to discuss.

Restricted, Repetitive Patterns of Behavior, Interests, or Activities

The more striking characteristics of ASD include *restricted, repetitive patterns of behavior, interests, or activities*. Amy appeared to like things to stay the same: She became extremely upset if even a small change was introduced (such as moving her toys in her room). This intense preference for the status quo has been called *maintenance of sameness*. Often, people with ASD spend countless hours in *stereotyped and ritualistic behaviors*, making such stereotyped movements as spinning around in circles, waving their hands in front of their eyes with their heads cocked to one side, or biting their hands (Durand, 2014). For individuals with less severe ASD, these behaviors can take the form of an almost obsessive interest in certain, very specific subjects (such as following airline schedules or memorizing ZIP codes). This tendency to be much

more interested in esoteric facts than in people further helps to interfere with social relationships.

Statistics

Current estimates of the rates of ASD are based on the previous *DSM-IV-TR* and *ICD-10* criteria (Lord & Bishop, 2010). ASD was once thought to be a rare disorder (e.g., 1 in 10,000 births), although more recent estimates of its occurrence show an increase in its prevalence. For example, estimates as reported by the Centers for Disease Control and Prevention suggest that an average of 1 in 68 8-year-old children in the United States had a diagnosis under the category of ASD (Centers for Disease Control and Prevention, 2014). The majority of the rise in the rates may be the result of changes between versions of the *DSM* (Miller et al., 2013) as well as increased awareness on the part of professionals and the general public. The reasons behind these changes are complex, however, and other environmental factors (e.g., prenatal exposure to toxins) cannot yet be ruled out as partially contributing to the rise in rates (Frombonne et al., 2011; Liu & Bearman, 2012).

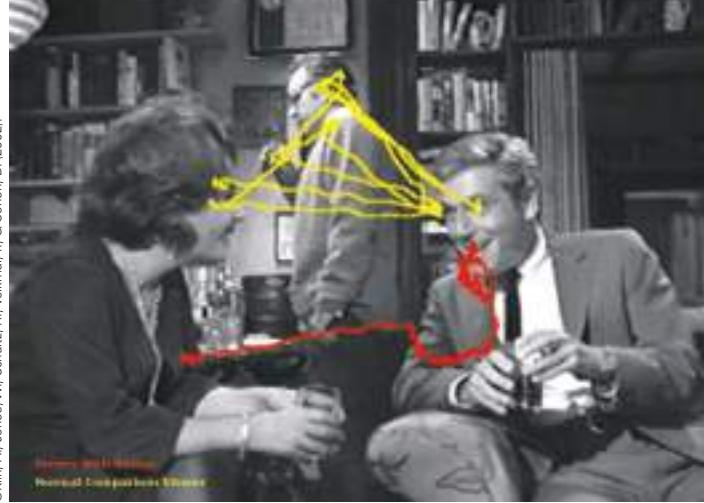

Gender differences are apparent in ASD, with the average reported male to female estimate being 4.5 to 1 (Centers for Disease Control and Prevention, 2014). ASD appears to be a universal phenomenon, identified in every part of the world, including Sweden (Gillberg, 1984), Japan (Sugiyama & Abe, 1989), Russia (Lebedinskaya & Nikolskaya, 1993), and Hong Kong (Chung, Luk, & Lee, 1990).

People with ASD have a range of IQ scores. It is estimated that approximately 31% of individuals with ASD have intellectual disabilities (defined as an IQ score less than 70, comparable deficits in adaptive functioning, and present before the age of 18) (Centers for Disease Control and Prevention, 2014). IQ measures are used to determine prognosis: The higher children score on IQ tests, the less likely they are to need extensive support by family members or people in the helping professions. Conversely, young children with ASD who score lower on IQ tests are more likely to be severely delayed in acquiring communication skills and to need a great deal of educational and social support as they grow older. Usually, language abilities and IQ scores are reliable predictors of how children with ASD will fare later in life: The better the language skills and IQ test performance, the better the prognosis (Ben Itzhak, Lahat, Burgin, & Zachor, 2008).

Causes: Psychological and Social Dimensions

ASD is a complex condition that does not appear to have a single cause (Durand, 2014). Instead, a number of biological contributions may combine with psychosocial influences. Because historical context is important to research, it is helpful to examine past, as well as more recent, theories of ASD. (In doing this, we are departing from this book’s usual format of providing biological dimensions first.)

Historically, ASD was wrongly seen as the result of failed parenting (Bettelheim, 1967; Ferster, 1961; Tinbergen & Tinbergen, 1972). Mothers and fathers of children with the more severe form of ASD were characterized as perfectionistic, cold, and aloof (Kanner, 1949), with relatively high socioeconomic status (Allen, DeMyer,

©Klin, A., Jones, W., Schultz, R., Volkmar, F., & Cohen, D. (2002).

Researchers are exploring how people with autism view social interactions among other people. (From Klin, A., Jones, W., Schultz, R., Volkmar, F., & Cohen, D. (2002). Defining and quantifying the social phenotype in autism. *American Journal of Psychiatry*, 159, 895–908.)

Norton, Pontius, & Yang, 1971; Cox, Rutter, Newman, & Bartak, 1975) and higher IQs than the general population (Kanner, 1943). Descriptions such as these inspired theories that held parents responsible for their children's unusual behaviors. These views were devastating to a generation of parents, who felt guilty and responsible for their children's problems. Imagine being accused of such coldness toward your own child as to cause serious and permanent disabilities! More sophisticated research using larger samples of children and families suggests that the parents of individuals with autism may not differ substantially from parents of children without disabilities (Bhasin & Schendel, 2007).

Other theories about the origins of ASD were based on the unusual speech patterns of some individuals—namely, their tendency to avoid first-person pronouns such as *I* and *me* and to use *he* and *she* instead. For example, if you ask a child with ASD, “Do you want something to drink?” he might say, “He wants something to drink” (meaning “I want something to drink”). This observation led some theorists to wonder whether ASD involves a lack of self-awareness (Goldfarb, 1963; Mahler, 1952). Imagine, if you can, not understanding that your existence is distinct. There is no “you,” only “them.” Such a debilitating view of the world was used to explain the unusual ways people with ASD behaved. Theorists suggested that the withdrawal seen among people with ASD reflected a lack of awareness of their own existence.

Later research has shown, however, that some people with ASD do seem to have self-awareness (Lind & Bowler, 2009) and that it follows a developmental progression. Just like children without a disability, those with cognitive abilities below the level expected for a child of 18 to 24 months show little or no self-recognition, but people with more advanced abilities do demonstrate self-awareness. Self-concept may be lacking when people with ASD also have cognitive disabilities or delays, not because of the disorder itself.

Myths about people with ASD are perpetuated when the idiosyncrasies of the disorder are highlighted. These perceptions are furthered by portrayals such as Dustin Hoffman's in the movie *Rain Man*—his character could, for instance, instantaneously and accurately count hundreds of toothpicks falling to the floor. This type of exceptional mental ability—referred to as savant skills—does not occur in all individuals with ASD. It is estimated that approximately one third of individuals with ASD have these unusual skills, although no persons with the more severe form of ASD appear to have savant abilities (Howlin, Goode, Hutton, & Rutter, 2010; Rutter & Pickles, 2015). These exceptional skills appear to be the result of possessing superior working memory and highly focused attention (Bennett & Heaton, 2012). It is important always to separate myth from reality and to be aware that such portrayals do not accurately represent the full range of manifestations of this complex disorder.

The phenomenon of echolalia, repeating a word or phrase spoken by another person, was once believed to be an unusual

characteristic of this disorder. Subsequent work in developmental psychopathology, however, has demonstrated that repeating the speech of others is part of the typically developing language skills observed in most young children (Dawson, Mottron, & Gernsbacher, 2008). Even a behavior as disturbing as the self-injurious behavior (such as head banging) sometimes seen in people with ASD is observed in milder forms among typically developing infants (de Lissovoy, 1961). This type of research has helped clinicians isolate the facts from the myths about ASD and clarify the role of development in the disorder. One generally accepted conclusion is that social deficiencies are the primary distinguishing characteristic of people with ASD.

Causes: Biological Dimensions

Deficits in such skills as social communication and the characteristic restricted and repetitive behaviors and interests appear to be biological in origin. The role of biological influences on the origins of ASD, examined next, has received much empirical support.

Genetic Influences

It is now clear that ASD has a significant genetic component. What is also evident is that the genetics of ASD are highly complex (Wang et al., 2015) with a moderate genetic heritability (Hallmayer et al., 2011; Rutter, 2011a). Numerous genes on a number of our chromosomes have already been implicated in some way in the presentation of ASD (Li, Zou, & Brown, 2012). And as with other psychological disorders such as schizophrenia, many genes are involved, but each one has only a relatively small effect.

Families that have one child with ASD have about a 20% chance of having another child with the disorder (Ozonoff et al., 2011). This rate is more than 100 times the risk in the general population, providing strong evidence of a genetic component in the disorder. The exact genes involved in the development of ASD remain elusive. One area that is receiving attention involves the genes responsible for the brain chemical oxytocin. Because oxytocin is shown to have a role in how we bond with others and in our social memory, researchers are looking at whether genes responsible for this neurochemical are involved with the disorder. Preliminary work identifies an association between ASD and an oxytocin receptor gene (Wermter et al., 2010).

There appears to be an increased risk of having a child with ASD among older parents. One group of researchers in Israel, for example, found that fathers 40 years old and up were more than five times more likely to have a child with ASD than fathers under the age of 30 (Reichenberg et al., 2006). The same correlation does seem to hold up for maternal age (Croen, Najjar, Fireman, & Grether, 2007; Durkin et al., 2008; Parner et al., 2012). These findings suggest that mutations may occur in the sperm of fathers or

the eggs of mothers (called *de novo* mutations) that influence the development of ASD.

Neurobiological Influences

As in the area of genetics, many neurobiological influences are being studied to help explain the social communication and behavior problems observed in ASD (Fein, 2011). One intriguing theory involves research on the amygdala—the area of the brain that, as you saw in Chapter 5, is involved in emotions such as anxiety and fear. Researchers studying the brains of people with ASD after they died note that adults with and without the disorder have an amygdala of about the same size but that those with ASD have fewer neurons in this structure (Schumann & Amaral, 2006). Earlier research showed that young children with ASD actually have a larger amygdala. The theory being proposed is that the amygdala in children with ASD is enlarged early in life—causing excessive anxiety and fear (perhaps contributing to their social withdrawal). With continued stress, the release of the stress hormone cortisol damages the amygdala, causing the relative absence of these neurons in adulthood. The damaged amygdala may account for the different way people with ASD respond to social situations (Lombardo, Chakrabarti, & Baron-Cohen, 2009).

An additional neurobiological influence we mentioned in the section on genetics involves the neuropeptide oxytocin. Remember that this is an important social neurochemical that influences bonding and is found to increase trust and reduce fear. Some research on children with ASD found lower levels of oxytocin in their blood (Modahl et al., 1998), and giving oxytocin to people with ASD improved their ability to remember and process information with emotion content (such as remembering happy faces), a problem that is symptomatic of ASD (Guastella et al., 2010). This is one of a number of theories being explored as possible contributors to this puzzling disorder.

One highly controversial theory is that mercury—specifically, the mercury previously used as a preservative in childhood vaccines (thimerosal)—is responsible for the increases seen in ASD. Large epidemiological studies conducted in Denmark show that there is no increased risk of ASD in children who are vaccinated (Madsen et al., 2002; Parker, Schwartz, Todd, & Pickering, 2004). Additional research shows that the number of vaccinations—also a cause of concern by some families—also does not contribute to an increased risk of ASD (DeStefano, Price, & Weintraub, 2013). Despite this and other convincing evidence, the correlation between when a child is vaccinated for measles, mumps, and rubella (12–15 months) and when the symptoms of ASD first become evident (before 3 years), continues to fuel the belief by many families that there must be some connection. The negative consequence of this concern is that some parents are not vaccinating their children, and this is thought to contribute to a significant increase in cases of measles and mumps in the United States and other countries (Centers for Disease Control and Prevention, 2011).

The study of ASD is a relatively young field and still awaits an integrative theory of how biological, psychological, and social factors work together to put an individual at risk for developing autism. It is likely, however, that further research will identify

the biological mechanisms that may explain the social aversion experienced by many people with the disorder. Also to be outlined are the psychological and social factors that interact early with the biological influences, producing deficits in socialization and communication, as well as the characteristic unusual behaviors.

Treatment of Autism Spectrum Disorder

Most treatment research has focused on children with the more severe form of ASD, so we primarily discuss treatment research for these individuals. There are a growing number of studies aimed at persons displaying less severe forms of ASD—typically focused on teaching social skills—and we describe this research as well. One generalization that can be made about ASD is that no completely effective treatment exists. Attempts to eliminate the social communication problems experienced by these individuals have not been successful to date. Rather, most efforts at treating people with ASD focus on enhancing their communication and daily living skills and on reducing problem behaviors, such as tantrums and self-injury (Durand, 2014). We describe some of these approaches next, including important work on early intervention for young children with ASD.

Psychosocial Treatments

Early psychodynamic treatments were based on the belief that ASD is the result of improper parenting, and they encouraged ego development (the creation of a self-image) (Bettelheim, 1967). Given our current understanding about the nature of the disorder, we should not be surprised to learn that treatments based solely on ego development have not had a positive impact on the lives of people with ASD (Kanner & Eisenberg, 1955). Greater success has been achieved with behavioral approaches that focus on skill building and behavioral treatment of problem behaviors. This approach is based on the early work of Charles Ferster (1961) and Ivar Lovaas. Although the work of Ferster and Lovaas has been greatly refined over the past few decades, the basic premise—that people with ASD can learn and that they can be taught some

skills they lack—remains central. There is a great deal of overlap between the treatment of ASD and the treatment of intellectual disability. With that in mind, we highlight several treatment areas that are particularly important for people with ASD, including communication and socialization.

Problems with communication and language are among the defining characteristics of this disorder. A significant portion of people with ASD often do not acquire meaningful speech; they tend either to have limited speech or to use unusual speech, such as echolalia. Teaching people to speak in a useful way is difficult. Think about how we teach languages: It mostly involves imitation. Imagine how you would teach a young girl to say the word *spaghetti*. You could wait for several days until she said a word that sounded something like *spaghetti* (maybe *confetti*) and then reinforce her. You could then spend several days or weeks trying to shape *confetti* into something closer to *spaghetti*. Or you could just prompt, “Say ‘spaghetti.’” Fortunately, most children can imitate and learn to communicate efficiently. But a child who has ASD can’t or won’t imitate.

In the mid-1960s, the late Ivar Lovaas and his colleagues took a monumental first step toward addressing the difficulty of getting children with the more severe forms of ASD to respond. They used the basic behavioral procedures of shaping and discrimination training to teach these nonspeaking children to imitate others verbally (Lovaas, Berberich, Perloff, & Schaeffer, 1966). The first skill the researchers taught the children was to imitate other people’s speech. They began by reinforcing a child with food and praise for making any sound while watching the teacher. After the child mastered that step, they reinforced the child only if she made a sound after the teacher made a request—such as the phrase, “Say ‘ball’” (a procedure known as *discrimination training*). Once the child reliably made some sound after the teacher’s request, the teacher used *shaping* to reinforce only approximations of the requested sound, such as the sound of the letter “b.” Sometimes the teacher helped the child with physical prompting—in this case, by gently holding the lips together to help the child make the sound of “b.” Once the child responded successfully, a second word was introduced—such as “mama”—and the procedure was repeated. This continued until the child could correctly respond to multiple requests, demonstrating imitation by copying the words or phrases made by the teacher. Once the children could imitate, speech was easier, and progress was made in teaching some of them to use labels, plurals, sentences, and other more complex forms of language (Lovaas, 1977).

More recently, several different approaches have “normalized” this type of teaching, bringing the instruction away from a desk with one child and one teacher to regular settings at home, in school, and in the community and attempting to use more child-directed versus adult-directed techniques (**naturalistic teaching strategies**) (Durand, 2014). These teaching strategies include arranging the environment so that the child initiates an interest (e.g., placing a favorite toy just out of reach), and this is used as a teaching opportunity (e.g., Say, “I want truck.”). Various evidence-based treatment packages use aspects of this approach, including incidental teaching (McGee, Morrier, & Daly, 1999), pivotal response training (Koegel & Koegel, 2012), and milieu teaching (Hancock & Kaiser, 2012). These techniques

seem to increase a variety of social communication skills (e.g., making requests, interactions with peers, joint-attention skills, play skills) among some children with more severe forms of ASD (Goldstein, 2002). Despite the success of some children in learning speech, other children do not respond to this training, and workers sometimes use alternatives to vocal speech, such as pointing to pictures or using devices that have vocal output and can literally “speak” for the child (e.g., tablet computers) (Schlosser & Koul, 2015; van der Meer, Sutherland, O'Reilly, Lancioni, & Sigafoos, 2012).

One of the most striking features of people with ASD is their unusual reactions to other people. Although social deficits are among the more obvious problems experienced by people with autism, they can also be the most difficult to teach. A number of approaches are now used to teach social skills (for example, how to carry on a conversation and ask questions of other people), including the use of peers who do not have ASD as trainers, and there is evidence that those with ASD can improve their socialization skills (Durand, 2014).

Lovaas and his colleagues at the University of California, Los Angeles, reported on their early intervention efforts with young children (Lovaas, 1987). They used intensive behavioral treatment for communication and social skills problems for 40 hours or more per week, which seemed to improve intellectual and educational functioning. Follow up suggests that these improvements are long lasting (Smith & Iadarola, 2015). Subsequent research on early intervention for toddlers with ASD include programs specifically targeting joint attention and play skills—the absence of which are some of the earliest signs of problematic social development. Focusing on these skills in the early years is important for helping the child develop more sophisticated social repertoires (Poon, Watson, Baranek, & Poe, 2012). A growing research base suggests that these skills can be facilitated among very young children with ASD (Lawton & Kasari, 2012; Wong & Kasari, 2012) and preliminary follow-up data suggest this approach may facilitate later development of language (Kasari, Gulsrud, Freeman, Paparella, & Hellemann, 2012). Some exciting research suggests that intensive early behavioral intervention may “normalize” the functioning of the developing brain in these children compared with children with ASD who do not receive this treatment (Dawson et al., 2012; Voos et al., 2013).

Individuals with less severe forms of ASD do not have the cognitive delays often found in persons with more severe forms, and can—with support—do well academically in school. However, their social difficulties and common comorbid problems (e.g., ADHD, anxiety) complicate their interactions with peers and teachers and can lead to disruptive behavior problems. A number of different programs exist to help school-aged children improve skills such as appropriate social interaction, problem-solving, self-control, recognizing emotions in others, expanding their often narrow range of interests, and improving their understanding of non-literal idioms (e.g., understanding that the phrase “get off my back” means something very different from its literal meaning) (e.g., Karkhaneh et al., 2010; Koning, Magill-Evans, Volden, & Dick, 2011). This work is in its infancy, and future research should tell us how best to improve these abilities in persons with ASD.

Biological Treatments

Medical intervention has had little positive impact on the core symptoms of social and language difficulties (Durand, 2014). A variety of pharmacological treatments are used to decrease agitation, with the major tranquilizers and serotonin-specific reuptake inhibitors being most helpful (Greydanus, Kaplan, & Patel, 2015). Because ASD may result from a variety of deficits, it is unlikely that one drug will work for everyone with this disorder. Much current work is focused on finding pharmacological treatments for specific behaviors or symptoms.

Integrating Treatments

Early intervention for very young children with ASD holds the most hope for significant changes in the core symptoms of this disorder. The treatment of choice for older children and those not responsive to early intervention combines various approaches to the many facets of this disorder. For children, most therapy consists of school education with special psychological supports for problems with communication and socialization. Behavioral approaches have been most clearly documented as benefiting children in this area. Pharmacological treatments can help some of them temporarily. Parents also need support because of the great demands and stressors involved in living with and caring for such children. As children with ASD grow older, intervention focuses on efforts to integrate them into the community, often with supported living arrangements and work settings. Because the range of abilities of people with ASD is so great, however, these efforts differ dramatically. Some people are able to live in their own apartments with only minimal support from family members. Others, with more severe forms of cognitive impairment, require more extensive efforts to support them in their communities.

Concept Check 14.2

Determine how well you are able to diagnose the disorder in each of the following situations by labeling them (a) ASD requiring very substantial support, (b) ASD requiring support, (c) Rett disorder, (d) social (pragmatic) communication disorder.

1. At an early age, Dwight became preoccupied with geography and could name all of the state capitals. His speech development was not delayed, but he does not like to play with other children or to be touched or held. _____
2. Six-year-old Tangelique has a low IQ and enjoys sitting in the corner by herself, where she arranges her toys or spins around in circles. She is unable to communicate verbally. She throws temper tantrums when her routine is changed even in the slightest way or when her parents

try to get her to do something she doesn't want to do.

3. Six-year-old Megan experiences many problems in communicating and does not seem to understand the "rules" when speaking with other children.
4. Five-year-old Alicia has increasingly severe intellectual disability and is beginning to have trouble walking on her own. One of the characteristics of her disorder is constant hand-wringing. _____

Intellectual Disability (Intellectual Developmental Disorder)

Intellectual disability (ID) is a disorder evident in childhood as significantly below-average intellectual and adaptive functioning (Toth et al., 2016). People with ID experience difficulties with day-to-day activities to an extent that reflects both the severity of their cognitive deficits and the type and amount of assistance they receive. *DSM-5* identifies difficulties in three domains: conceptual (e.g., skill deficits in areas such as language, reasoning, knowledge, and memory), social (e.g., problems with social judgment and the ability to make and retain friendships), and practical (e.g., difficulties managing personal care or job responsibilities) (American Psychiatric Association, 2013). Perhaps more than any other group you have studied in this text, people with ID have throughout history received treatment that can best be described as shameful (Scheerenberger, 1983). With notable exceptions, societies throughout the ages have devalued individuals whose intellectual abilities are deemed less than adequate. *DSM-IV-TR* previously used the term "mental retardation," but

this was changed in *DSM-5* to "intellectual disability" (or intellectual developmental disorder) to be consistent with changes in terminology in this field (American Psychiatric Association, 2013).

The field of ID has undergone dramatic and fundamental changes during the past few decades. What it means to have an ID, how to define it, how to label it, and how people with this disorder are treated have been scrutinized, debated, and fought over by a variety of concerned groups. We describe the disorder in the context of these important changes, explaining both the status of people who have ID and our current understanding of its causes and treatment.

Lauren Potter (an actress with Down syndrome) played Becky Jackson in the popular television show *Glee*.

The manifestations of ID are varied. Some individuals function quite well, even independently, in our complex society. For example, Lauren Potter (an actor with Down syndrome) played a cheerleader in the television show *Glee*. Others with ID have significant cognitive and physical impairments and require considerable assistance to carry on day-to-day activities. Consider the case of James.

James... Up to the Challenge

James's mother contacted us because he was disruptive at school and at work. James was 17 and attended the local high school. He had Down syndrome and was described as likable and, at times, mischievous. He enjoyed skiing, bike riding, and many other activities common among teenage boys. His desire to participate was a source of some conflict between him and his mother: He wanted to take the driver's education course at school, which his mother felt would set him up for failure, and he had a girlfriend he wanted to date, a prospect that also caused his mother concern.

School administrators complained because James didn't participate in activities such as physical education, and at the work site that was part of his school program, he was often sullen, sometimes lashing out at the supervisors. They were considering moving him to a program with more supervision and less independence.

James's family had moved often during his youth, and they experienced striking differences in the way each community responded to James and his intellectual disability. In some school districts, he was immediately placed in classes with other children his age, and his teachers were provided with additional assistance and consultation. In others, it was just as quickly recommended that he be taught separately. Sometimes the school district had a special classroom in the local school for children with intellectual disabilities. Other districts had programs in other towns, and James would have to travel an hour to and from school each day. Every time he was assessed in a new school, the evaluation was similar to earlier ones. He received scores on his IQ tests in the range of 40 to 50, which placed him in the moderate range of intellectual disability. Each school gave him the same diagnosis: Down syndrome with moderate intellectual disability. At each school, the teachers and other professionals were competent and caring individuals who wanted the best for James and his mother. Yet some believed that to learn skills James needed a separate program with specialized staff. Others felt they could not provide a program with specialized staff. Still others felt they could provide a comparable education in a regular classroom and that to have peers without disabilities would be an added benefit.

In high school, James had several academic classes in a separate classroom for children with learning problems, but he participated in some classes, such as gym, with students who did not have intellectual disability. His current difficulties in gym (not participating) and at work (being

oppositional) were jeopardizing his placement in both programs. When I spoke with James's mother, she expressed frustration that the work program was beneath him because he was asked to do boring, repetitious work such as folding paper. James expressed a similar frustration, saying that he was treated like a baby. He could communicate fairly well when he wanted to, although he sometimes would become confused about what he wanted to say and it was difficult to understand everything he tried to articulate. On observing him at school and at work, and after speaking with his teachers, we realized that a common paradox had developed. James resisted work he thought was too easy. His teachers interpreted his resistance to mean that the work was too hard for him, and they gave him even simpler tasks. He resisted or protested more vigorously, and they responded with even more supervision and structure. •

Clinical Description

People with ID display a broad range of abilities and personalities. Individuals like James, who have mild or moderate impairments, can, with proper preparation, carry out most of the day-to-day activities expected of any of us. Many can learn to use mass transportation, purchase groceries, and hold a variety of jobs. Those with more severe impairments may need help to eat, bathe, and dress themselves, although with proper training and support, they can achieve a degree of independence. These individuals experience impairments that affect most areas of functioning. Language and communication skills are often the most obvious. James was only mildly impaired in this area, needing help with articulation. In contrast, people with more severe forms of ID may never learn to use speech as a form of communication, requiring alternatives such as sign language or special communication devices to express even their most basic needs. Because many cognitive processes are adversely affected, individuals with intellectual disability have difficulty learning, the level of challenge depending on how extensive the cognitive disability is.

Before examining the specific criteria for ID, note that, like the personality disorders we described in Chapter 12, ID was previously included on Axis II of *DSM-IV-TR*. The rationale for placing these disorders on a separate axis was that they tend to be more chronic and less amenable to treatment, and second, it was to remind clinicians to consider whether these disorders, if present, were affecting an Axis I disorder. People could be diagnosed on both Axis I (for example, generalized anxiety disorder) and Axis II (for example, mild intellectual disability). *DSM-5* no longer has a separate axis for these disorders.

The *DSM-5* criteria for ID no longer include numeric cut-offs for IQ scores, which were present in previous versions. They are still included in the narrative of the broader description, but the goal was to de-emphasize these numbers in favor of a comprehensive assessment of functioning. To be diagnosed with ID, a person must have significantly subaverage intellectual functioning, a determination made with one of several IQ tests with a cutoff score set by *DSM-5* of approximately 70.

Diagnostic Criteria for Intellectual Disability (Intellectual Developmental Disorder)

Intellectual disability (intellectual developmental disorder) is a disorder with onset during the developmental period that includes both intellectual and adaptive functioning deficits in conceptual, social, and practical domains. The following three criteria must be met:

- A.** Deficits in intellectual functions, such as reasoning, problem solving, planning, abstract thinking, judgment, academic learning, and learning from experience, confirmed by both clinical assessment and individualized, standardized intelligence testing.
- B.** Deficits in adaptive functioning that result in failure to meet developmental and sociocultural standards for personal independence and social responsibility. Without ongoing support, the adaptive deficits limit functioning in one or more activities of daily life, such as communication, social participation, and independent living, across multiple environments such as home, school, work, and community.
- C.** Onset of intellectual and adaptive deficits during the developmental period.

From American Psychiatric Association. (2013). *Diagnostic and statistical manual of mental disorders* (5th ed.). Washington, DC.

The American Association on Intellectual and Developmental Disabilities (AAIDD), which has its own, similar definition of intellectual disability, has a cutoff score of approximately 70 to 75 (Toth et al., 2016).

The second criterion calls for concurrent deficits or impairments in adaptive functioning. In other words, scoring “approximately 70 or below” on an IQ test is not sufficient for a diagnosis of ID; a person must also have significant difficulty in areas such as communication, self-care, home living, social and interpersonal skills, use of community resources, self-direction, functional academic skills, work, leisure, health, and safety. To illustrate, although James had many strengths, such as his ability to communicate and his social and interpersonal skills (he had several good friends), he was not as proficient as other teenagers at caring for himself in areas such as home living, health, and safety or in academic areas. This aspect of the definition is important because it excludes people who can function quite well in society but for various reasons do poorly on IQ tests. For instance, someone whose primary language is not English may do poorly on an IQ test but may still function at a level comparable with those of peers. This person would not be considered to have ID even with a score of below 70 on the English-based IQ test.

The final criterion for ID is the age of onset. The characteristic below-average intellectual and adaptive abilities must be evident before the person is 18. This cutoff is designed to identify affected individuals when the brain is developing and therefore when any problems should become evident. The age criterion rules out the diagnosis of ID for adults who suffer from brain trauma or forms of dementia that impair their abilities. The age of 18 is somewhat arbitrary, but it is the age at which most children leave school, when our society considers a person an adult.

The imprecise definition of ID brings up an important issue: Intellectual disability, perhaps more than any of the other disorders, is defined by society. The cutoff score of 70 or 75 is based on a statistical concept (two or more standard deviations from the mean), not on qualities inherent in people who supposedly have ID. There is little disagreement about the diagnosis for people with the most severe disabilities; however, the majority of people diagnosed with ID are in the mild range of cognitive impairment. They need some support and assistance, but remember that the criteria for using the label of ID are based partly on a somewhat arbitrary cutoff score for IQ that can (and does) change with changing social expectations.

People with ID differ significantly in their degree of disability. Almost all classification systems have differentiated these individuals in terms of their ability or on the cause of the ID (Holland, 2012). Traditionally, classification systems have identified four levels of ID: *mild*, which is identified by an IQ score between 50–55 and 70; *moderate*, with a range of 35–40 to 50–55; *severe*, ranging from 20–25 to 35–40; and *profound*, which includes people with IQ scores below 20–25. It is difficult to categorize each level of ID according to “average” individual achievements by people at each level. A person with severe or profound ID tends to have extremely limited formal communication skills (no spoken speech or only one or two words) and may require great or even total assistance in dressing, bathing, and eating. Yet people with these diagnoses have a range of skills that depend on training and the availability of other supports. Similarly, people like James, who have mild or moderate ID, should be able to live independently or with minimal supervision; again, however, their achievement depends partly on their education and the community support available to them.

Perhaps the most controversial change introduced in the AAIDD definition of ID is its description of different levels of this disorder, which are based on the level of support or assistance people need: *intermittent*, *limited*, *extensive*, or *pervasive* (Papazoglou, Jacobson, McCabe, Kaufmann, & Zabel, 2014; Thompson et al., 2009). The important difference is that the AAIDD system identifies the role of “needed supports” in determining level of functioning,

Although this man cannot speak, he is learning to communicate with an eye-gaze board, pointing to or simply looking at the image that conveys his message.

whereas *DSM-5* implies that the ability of the person is the sole determining factor. The AAIDD system focuses on specific areas of assistance a person needs that can then be translated into training goals. Whereas James's *DSM-5* diagnosis might be "moderate intellectual disability," he might receive the following AAIDD diagnosis: "a person with intellectual disability who needs limited supports in home living, health and safety, and in academic skills." The AAIDD definition emphasizes the types of support that James and others require, and it highlights the need to identify what assistance is available when considering a person's abilities and potential.

Statistics

Approximately 90% of people with ID fall under the label of mild intellectual disability (IQ of 50 to 70). When you add individuals with moderate, severe, and profound ID (IQ below 50), the total population of people with this disorder represents approximately 1% to 3% of the general population (Toth et al., 2016).

The course of ID is chronic, meaning that people do not go through periods of remission, such as with substance use disorders or anxiety disorders. The prognosis for people with this disorder varies considerably, however. Given appropriate training and support, individuals with less severe forms of ID can live relatively independent and productive lives. People with more severe impairments require more assistance to participate in work and community life.

Over the past century, a curious thing has occurred—IQ scores have risen. This phenomenon is known as the Flynn effect (Flynn, 1984). As these scores rise, those who make up IQ tests adjust the assessments every decade or two to keep the average score around 100. For most people, these changes have no practical effect. However, for people hovering at the cutoff point for ID, this may mean the difference between receiving the diagnosis or not (Kanaya &

Ceci, 2012). In one study, the number of people scoring just below 70 (the cutoff for mild ID) tripled when they were administered one of the revised IQ tests (Kanaya, Scullin, & Ceci, 2003). These results emphasize the caution we need to take when interpreting who does or does not have ID.

Causes

There are literally hundreds of known causes of intellectual disability, including the following:

Environmental: For example, deprivation, abuse, and neglect

Prenatal: For instance, exposure to disease or drugs while still in the womb

Perinatal: Such as difficulties during labor and delivery

Postnatal: For example, infections and head injury

As we mentioned in Chapter 11, heavy use of alcohol among pregnant women can produce a disorder in their children called *fetal alcohol syndrome*, a condition that can lead to severe learning disabilities (Rangmar et al., 2015). Other prenatal factors that can produce ID include the pregnant woman's exposure to disease and chemicals and poor nutrition. In addition, lack of oxygen (anoxia) during birth and malnutrition and head injuries during the developmental period can lead to severe cognitive impairments (Toth et al., 2016).

Biological Dimensions

Most research on the causes of ID focuses on biological influences. We next look at biological dimensions that appear to be responsible for the more common forms of ID.

Genetic Influences

Multiple genetic influences appear to contribute to ID, including chromosomal disorders (e.g., having an extra 21st chromosome, as in Down syndrome), single-gene disorders, mitochondrial disorders (defects in mitochondria, which are compartments found in most human cells that generate the majority of energy needed by the cells to function) and multiple genetic mutations (Toth et al., 2016). A portion of the people with more severe ID have identifiable single-gene disorders, involving a *dominant gene* (which expresses itself when paired with a normal gene), a *recessive gene* (which expresses itself only when paired with another copy of itself), or an *X-linked gene* (present on the X or sex chromosome).

Before we discuss known genetic causes of ID, it is important to recognize that as many as 30% of cases of ID have no identified etiology (Toth et al., 2016).

Intellectual disability can be defined in terms of the level of support people need.

Important research using sophisticated genetic analysis techniques is pointing to genetic causes that went previously undetected. One study of children from Germany and Switzerland found that a variety of genetic mutations including *de novo* disorders (genetic mutations occurring in the sperm or egg or after fertilization) were present in those children with ID of unknown origin (Rauch et al., 2012). This work is important not only because it helps identify new causes of ID but also because it helps explain why a child could have a genetically based disorder without that mutation being present in either parent. Mutations in genetic material can occur at various points in development, and this helps explain the causes of previously puzzling cases of ID.

Only a few dominant genes result in ID, probably because of natural selection: Someone who carries a dominant gene that results in ID is less likely to have children and thus less likely to pass the gene to offspring. Therefore, this gene becomes less likely to continue in the population. Some people, however, especially those with mild ID, do marry and have children, thus passing on their genes. One example of a dominant gene disorder, *tuberous sclerosis*, is relatively rare, occurring in 1 of approximately every 30,000 births. About 60% of the people with this disorder have ID, and most have seizures (uncontrolled electrical discharges in the brain) and characteristic bumps on the skin that during their adolescence resemble acne (Samueli et al., 2015).

The next time you drink a diet soda, notice the warning, “Phenylketonurics: Contains Phenylalanine.” This is a caution for people with the recessive disorder called **phenylketonuria (PKU)**, which affects 1 of every 10,000 newborns and is characterized by an inability to break down a chemical in our diets called phenylalanine (Schuck et al., 2015; Toth et al., 2016). Until the mid-1960s, the majority of people with this disorder had ID, seizures, and behavior problems, resulting from high levels of this chemical. Researchers developed a screening technique, however, that identifies the

existence of PKU; infants are now routinely tested at birth, and any individuals identified with PKU can be successfully treated with a special diet that avoids the chemical phenylalanine. This is a rare example of the successful prevention of one form of ID.

Because untreated maternal PKU can harm the developing fetus, there is concern now that women with PKU who are of childbearing age may not stick to their diets and inadvertently cause PKU-related ID in their children before birth. Many physicians recommend dietary restriction through the person’s lifetime, especially during the childbearing period—thus the warnings on products with phenylalanine (Widaman, 2009).

Lesch-Nyhan syndrome, an X-linked disorder, is characterized by ID, signs of cerebral palsy (spasticity or tightening of the muscles), and self-injurious behavior, including finger and lip biting (Nyhan, 1978). Only males are affected, because a recessive gene is responsible; when it is on the X chromosome in males, it does not have a normal gene to balance it because males do not have a second X chromosome. Women with this gene are carriers and do not show any of the symptoms.

As our ability to detect genetic defects improves, more disorders will be identified genetically. The hope is that our increased knowledge will be accompanied by improvements in our ability to treat or, as in the case of PKU, prevent intellectual disability and other negative outcomes.

Chromosomal Influences

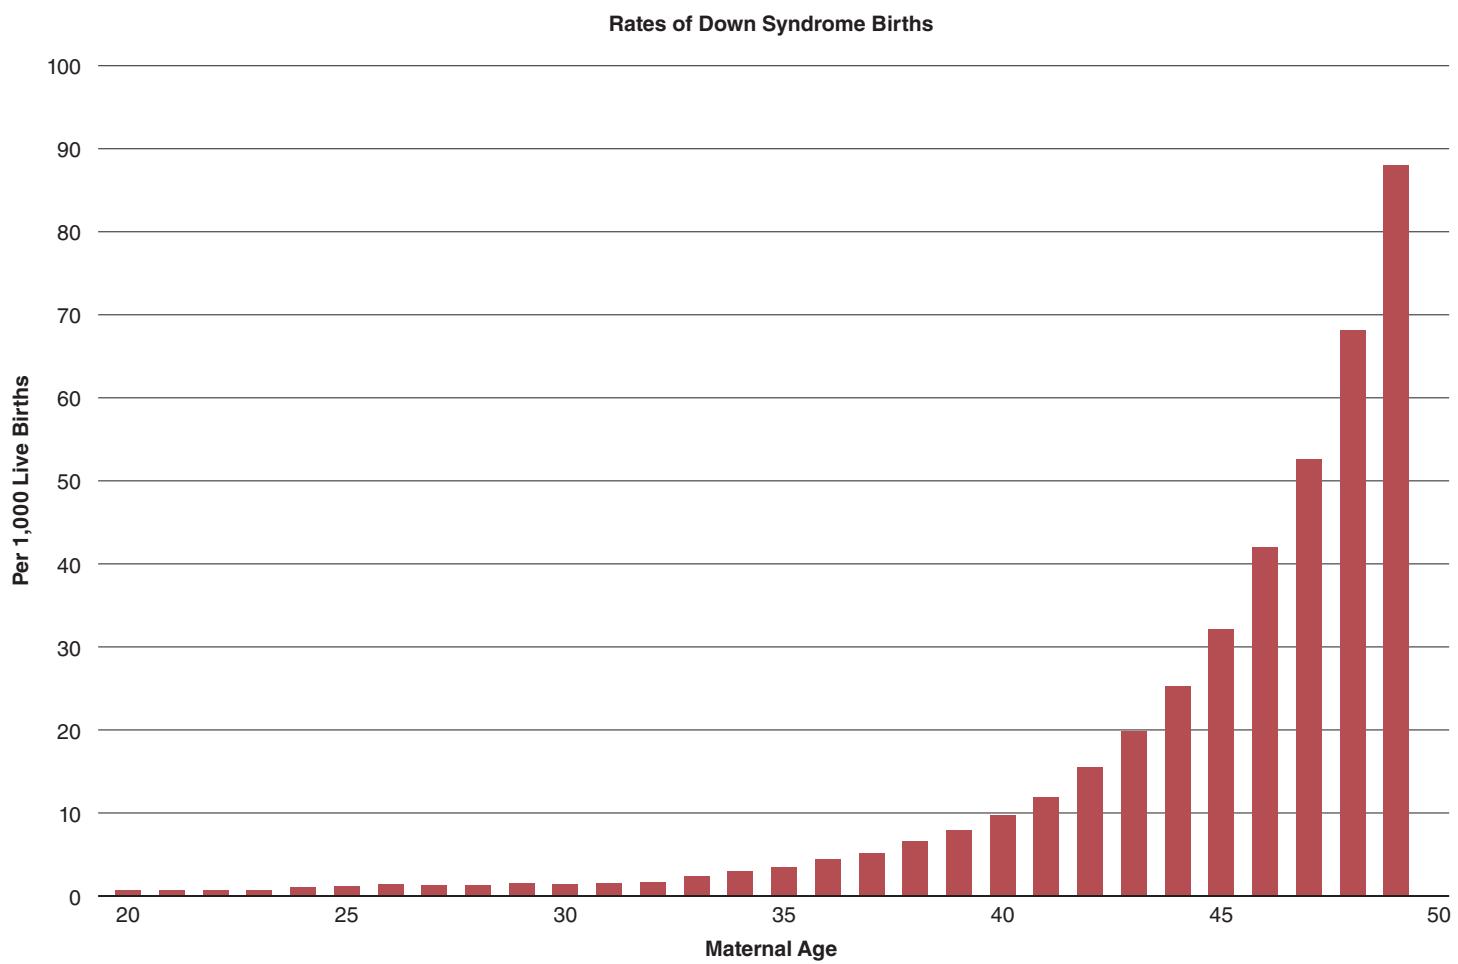

Approximately 60 years ago the number of chromosomes—46—was correctly identified in human cells (Tjio & Levan, 1956). Three years later, researchers found that people with Down syndrome (the disorder James displayed) had an additional small chromosome (Lejeune, Gauthier, & Turpin, 1959). Since that time, a number of other chromosomal aberrations that result in intellectual disability have been identified. We describe Down syndrome and fragile X syndrome in some detail, but there are hundreds of other ways in which abnormalities among the chromosomes can lead to ID (Toth et al., 2016).

Down syndrome, the most common chromosomal form of ID, was first identified by the British physician Langdon Down in 1866. Down had tried to develop a classification system for people with ID based on their resemblance to people of other races; he described individuals with this particular disorder as “mongoloid” because they resembled people from Mongolia (Scheerenberger, 1983). The term *mongoloidism* was used for some time but has been replaced with the term *Down syndrome*. The disorder is caused by the presence of an extra 21st chromosome and is therefore sometimes referred to as *trisomy 21*. For reasons not completely understood, during cell division, two of the 21st chromosomes stick

together (a condition called nondisjunction), creating one cell with one copy that dies and one cell with three copies that divide to create a person with Down syndrome.

People with Down syndrome have characteristic facial features, including folds in the corners of their upwardly slanting eyes, a flat nose, and a small mouth with a flat roof that makes the tongue protrude somewhat. Like James, they tend to have congenital heart malformations. Tragically, adults with Down syndrome have a greatly increased risk of dementia of the Alzheimer's type, a degenerative brain disorder that causes impairments in memory and other cognitive disorders (Wiseman et al., 2015). This disorder among people with Down syndrome occurs earlier than usual (sometimes in their early 20s) and has led to the finding that at least one form of Alzheimer's disease is attributable to a gene on the 21st chromosome.

The incidence of children born with Down syndrome has been tied to maternal age: As the age of the mother increases, so does her chance of having a child with this disorder (see ● Figure 14.2). A woman at age 20 has a 1 in 2,000 chance of having a child with Down syndrome; at the age of 35, this risk increases to 1 in 500; and at the age of 45, it increases again

to 1 in 18 births (Girirajan, 2009). Despite these numbers, many more children with Down syndrome are born to younger mothers simply because younger mothers have more children. The reason for the rise in incidence with maternal age is not clear. Some suggest that because a woman's ova (eggs) are all produced in youth, the older ones have been exposed to toxins, radiation, and other harmful substances over longer periods. This exposure may interfere with the normal meiosis (division) of the chromosomes, creating an extra 21st chromosome (Pueschel & Goldstein, 1991). It may also be that the hormonal changes that occur as women age contribute to this error in cell division (Pandya, Mevada, Patel, & Suthar, 2013).

For some time, it has been possible to detect the presence of Down syndrome—but not the degree of ID—through **amniocentesis**, a procedure that involves removing and testing a sample of the fluid that surrounds the fetus in the amniotic sac, and through **chorionic villus sampling (CVS)** in which a small piece of placenta tissue is removed and tested. These types of test are not always desirable because it is an invasive procedure (inserting a needle that could cause unwanted damage to the developing fetus). There are now more sophisticated tests of a mother's blood that can be

used to detect Down syndrome as early as the first trimester of pregnancy (Abele et al., 2015). The presence of this chromosomal abnormality does not convey information about the eventual severity of the disorder, however. Despite this lack of information, some estimate that a prenatal diagnosis of Down syndrome leads to a choice for an elective abortion more than 50% of the time (Natoli, Ackerman, McDermott, & Edwards, 2012). Prenatal testing for Down syndrome cannot assist parents with information about the outcomes.

Fragile X syndrome is a second common chromosomally related cause of ID (Clarke & Deb, 2012). As its name suggests, this disorder is caused by an abnormality on the X chromosome, a mutation that makes the tip of the chromosome look as though it were hanging from a thread, giving it the appearance of fragility (Lubs, Stevenson, & Schwartz, 2012). As with Lesch-Nyhan syndrome, which also involves the X chromosome, fragile X primarily affects males because they do not have a second X chromosome with a normal gene to balance out the mutation. Unlike Lesch-Nyhan carriers, however, women who carry fragile X syndrome commonly display mild-to-severe learning disabilities (Santoro, Bray, & Warren, 2012). Men with the disorder display moderate-to-severe levels of ID and have higher rates of hyperactivity, short attention spans, gaze avoidance, and perseverative speech (repeating the same words again and again). In addition, such physical characteristics as large ears, testicles, and head circumference are common. Estimates are that 1 of every 4,000 males and 1 of every 8,000 females are born with fragile X syndrome (Toth & King, 2010).

Psychological and Social Dimensions

Cultural influences that may contribute to ID can include abuse, neglect, and social deprivation. Sometimes referred to as **cultural-familial intellectual disability**, people with these

characteristics are thought to have cognitive impairments that result from a combination of psychosocial and biological influences, although the specific mechanisms that lead to this type of intellectual disability are not yet understood. Fortunately, because of better child care systems and early identification of potential family difficulties, these cases are rare today (Kaski, 2012).

Treatment of Intellectual Disability

Biological treatment of ID is currently not a viable option. Generally, the treatment of individuals with ID parallels that of people with more severe forms of autism spectrum disorder, attempting to teach them the skills they need to become more productive and independent. For individuals with mild ID, intervention is similar to that for people with learning disorders. Specific learning deficits are identified and addressed to help the student improve such skills as reading and writing. At the same time, these individuals often need additional support to live in the community. For people with more severe disabilities, the general goals are the same; however, the level of assistance they need is often more extensive. Remember that the expectation for all people with ID is that they will in some way participate in community life, attend school and later hold a job, and have the opportunity for meaningful social relationships. Advances in electronic and educational technologies have made this goal realistic even for people with profound intellectual disability.

Individuals with ID can acquire skills through the many behavioral innovations first introduced in the early 1960s to teach such basic self-care as dressing, bathing, feeding, and toileting to people with even the most severe disabilities (Durand, 2014). The skill is broken into its component parts (a procedure called a *task analysis*), and people are taught each part in succession until they can perform the whole skill. Performance on each step is encouraged by praise and by access to objects or activities the people desire (reinforcers). Success in teaching these skills is usually measured by the level of independence people can attain by using them. Typically, most individuals, regardless of their disability, can be taught to perform some skills.

Communication training is important for people with ID. Making their needs and wants known is essential for personal satisfaction and for participation in most social activities. The goals of communication training differ, depending on the existing skills. For people with mild levels of ID, the goals may be relatively minor (for example, improving articulation) or more extensive (for example, organizing a conversation) (Berney, 2012; Heath, Ganz, Parker, Burke, & Ninci, 2015). Some, like James, have communication skills that are already adequate for day-to-day needs.

For individuals with the most severe disabilities, communication skills training can be particularly challenging, because they may have multiple physical or cognitive deficits that make spoken communication difficult or impossible. Creative researchers, however, use alternative systems that may be easier for these individuals, including sign language, used primarily by people with hearing disabilities, and *augmentative communication strategies*. Augmentative strategies may use picture books, teaching the person to make a request by pointing to a picture—for instance, pointing to

Today, great efforts are made to keep people with intellectual disability and other mental disorders in their homes and communities.

a picture of a cup to request a drink (Heath et al., 2015). A variety of computer-assisted devices including tablet computers can be programmed so that the individual presses a button to produce complete spoken sentences (for example, “Would you come here? I need your help.”). People with limited communication skills can be taught to use these devices, which helps them reduce the frustration of not being able to relate their feelings and experiences to other people (Durand, 2011).

Concern is often expressed by parents, teachers, and employers that some people with ID can be physically or verbally aggressive or may hurt themselves. Considerable debate has ensued over the proper way to reduce these behavior problems; the most heated discussions involve whether to use painful punishers (Repp & Singh, 1990). Alternatives to punishment that may be equally effective in reducing behavior problems such as aggression and self-injury include teaching people how to communicate their need or desire for such things as attention that they seem to be getting with their problem behaviors (Durand, 2012). Important advances are being made in significantly reducing even severe behavior problems for some people.

In addition to ensuring that people with ID are taught specific skills, caretakers focus on the important task of supporting them in their communities. “Supported employment” involves helping an individual find and participate satisfactorily in a competitive job (Drake, Bond, & Becker, 2012). Research has shown not only that people with ID can be placed in meaningful jobs but also that, despite the costs associated with supported employment, it can be cost-effective (Cimera, 2012). The benefits to people who achieve the satisfaction of being a productive part of society are incalculable.

There is general agreement about *what* should be taught to people with ID. The controversy in recent years has been over *where* this teaching should take place. Should people with ID, especially the severe forms, be taught in specially designed separate classrooms or workshops, or should they attend their neighborhood public schools and work at local businesses? Increasingly, teaching strategies to help these students learn are being used in regular classrooms and in preparing them to work at jobs in the community (Foley, Dyke, Girdler, Bourke, & Leonard, 2012). The

current prevention and treatment efforts suggest that meaningful changes can be achieved in the lives of those with ID.

Prevention of Neurodevelopmental Disorders

Prevention efforts for the neurodevelopmental disorders outlined in this chapter are in their early stages. One such effort—early intervention—has been described for ASD and appears to hold considerable promise for some children. In addition, early intervention can target and assist children who, because of inadequate environments, are at risk for developing cultural-familial ID (Eldevik, Jahr, Eikeseth, Hastings, & Hughes, 2010). The national Head Start program is one such effort at early intervention; it combines educational, medical, and social supports for these children and their families. One project identified a group of children shortly after birth and provided them with an intensive preschool program, along with medical and nutritional supports. This intervention continued until the children began formal education in kindergarten (Martin, Ramey, & Ramey, 1990). The researchers of this study found that for all but one of the children in a control group who received medical and nutritional support but not the intensive educational experiences, each had IQ scores below 85 at age 3, but that 3-year-olds in the experimental group all tested above 85. Such findings are important because they show the potential for creating a lasting impact on the lives of children with developmental disorders and their families.

Although it appears that many children can make significant progress if interventions are initiated early in life (Eldevik et al., 2010), a number of important questions remain regarding early intervention efforts. Not all children, for example, benefit significantly from such efforts, and future research will need to resolve a number of lingering concerns. For example, researchers need to determine how best to identify children and families who will benefit from such programs, how early in the child’s development programs should begin, and how long to continue these early intervention programs to produce desirable outcomes.

Given recent advances in genetic screening and technology, it may someday be possible to detect and correct genetic and chromosomal abnormalities; related ongoing research could fundamentally change our approach to children with developmental disorders. For example, one study used mice that were genetically engineered to model fragile X syndrome found in many individuals with intellectual disability (Suvrathan, Hoeffer, Wong, Klann, & Chattarji, 2010). Researchers found that they could improve the functioning of certain glutamate receptors in the amygdala of the mice with a drug that blocks these receptors. The results were more normalized functioning between these neurons, a potential early medical intervention for children with fragile X disorder (Krueger & Bear, 2011; Suvrathan, Hoeffer, Wong, Klann, & Chattarji, 2010). Someday, it may be possible for similar research to be performed prenatally on children identified as having syndromes associated with ID. For example, it may soon be possible to conduct prenatal gene therapy, where a developing fetus that has been screened for a genetic disorder may be the target of intervention before birth. This prospect is not without its difficulties, however.

Advances in biomedical technology will need support from psychological researchers to make sure that any needed treatments are carried out properly. For example, biological risk factors for several developmental disorders include malnutrition and exposure to toxins such as lead and alcohol. Although medical researchers can identify the role of these biological events in cognitive development, psychologists will need to support these efforts. Behavioral intervention for safety training (for example, involving lead-based paints in older homes), substance-use treatment and prevention, and behavioral medicine (for example, “wellness” efforts) are examples of crucial roles played by psychologists in helping to prevent certain forms of developmental disorders.

Concept Check 14.3

In the following situations, label each level of intellectual disability as mild, moderate, severe, or profound. Also label the corresponding levels of necessary support: intermittent, limited, extensive, or pervasive.

1. Kevin received an IQ score of 20. He needs help with all his basic needs, including dressing, bathing, and eating. _____, _____
2. Adam received an IQ score of 45. He lives in a fully staffed group home and needs a great deal of help with many tasks. He is beginning to receive training for a job in the community. _____, _____
3. Jessica received an IQ score of 30. She lives in a fully staffed group home where she is trained in basic adaptive skills and communication. She is improving over time and can communicate by pointing or using her eye-gaze board. _____, _____
4. Ledel received an IQ score of 65. He lives at home, goes to school, and is preparing to work when he is through with school. _____, _____

DSM Controversies: Losing a Valued Label

One of the most talked about and debated changes in the *DSM-5* was the elimination of separate categories for “autistic disorder” and “Asperger’s disorder”—which were present in *DSM-IV*. The rationale behind this reorganization of the separate autism related disorders under one rubric was that ASDs could be reliably distinguished from other disorders, but within this category there were considerable inconsistencies (Frazier et al., 2012; Rutter, 2011b). In other words, it was not always clear if someone had a milder form of autistic disorder (e.g., with more speech) or whether it was Asperger’s disorder. They all share the pervasive deficits in social communication skills as well as the restricted patterns of behaviors. It was argued that the main differences among the disorders are ones involving the severity of the symptoms, language level, and levels of intellectual deficit and therefore could be grouped together as autism spectrum disorder—with varying degrees of severity.

One of the first concerns was that these new criteria might exclude some individuals who previously met *DSM-IV* criteria and, in turn, it might result in the denial of treatment services for those left out. This concern was precipitated by researchers who evaluated cases that received a *DSM-IV* diagnosis of autism or a related disorder and tried to see how many would now fall into the new ASD category (McPartland, Reichow, & Volkmar, 2012). Their initial findings caused considerable alarm since they concluded that almost 40% of individuals would not meet the *DSM-5* criteria. Although subsequent analyses found this number to be lower (e.g., approximately 9% in one study; Huerta, Bishop, Duncan, Hus, & Lord, 2012), there remains a concern that some individuals will no longer be eligible for needed services.

In addition to the concern about combining this disorder into the generic

autism spectrum disorder, many of those individuals who have been previously diagnosed with Asperger’s disorder feel that this decision takes away part of their identity (Pellicano & Stears, 2011). Rather than feeling shame or embarrassment about receiving this diagnosis, a good number of these individuals embrace their distinctiveness. Some advocate for seeing these differences in terms of “neurodiversity,” or viewing their “disorder” as just a different and not abnormal way to view the world (Armstrong, 2010; Singer, 1999). In fact, the word “Aspies” is sometimes used with pride by individuals with this label (e.g., Beardon & Worton, 2011) and those who do not have this disorder are often referred to as “neurotypical”—sometimes in a negative way. It is likely that despite the elimination of Asperger’s disorder from *DSM-5*, some in this community will continue to hold on to the label with pride.

Summary

Overview of Neurodevelopmental Disorders

- ▶ Developmental psychopathology is the study of how disorders arise and change with time. These changes usually follow a pattern, with the child mastering one skill before acquiring the next. This aspect of development is important because it implies that any disruption in the acquisition of early skills will, by the very nature of the developmental process, also disrupt the development of later skills.

Attention-Deficit/Hyperactivity Disorder

- ▶ The primary characteristics of people with attention-deficit/hyperactivity disorder are a pattern of inattention (such as not paying attention to school- or work-related tasks), impulsivity, and/or hyperactivity. These deficits can significantly disrupt academic efforts and social relationships.

Specific Learning Disorder

- ▶ DSM-5 describes specific learning disorder as academic performance that is substantially below what would be expected given the person's age, intelligence quotient (IQ) score, and education. These problems can be seen as difficulties with reading, mathematics, and/or written expression. All are defined by performance that falls far short of expectations based on intelligence and school preparation.
- ▶ Communication and motor disorders seem closely related to specific learning disorder. They include childhood speech fluency disorder (stuttering), a disturbance in speech fluency; language disorder, limited speech in all situations but without the types of cognitive deficits that lead to language problems in people with intellectual disability or one of the pervasive developmental disorders; and Tourette's disorder, which includes involuntary motor movements such as head twitching and vocalizations such as grunts that occur suddenly, in rapid succession, and in idiosyncratic or stereotyped ways.

Autism Spectrum Disorder

- ▶ People with ASD all experience trouble progressing in language, socialization, and cognition. This is not a relatively minor problem (like specific learning disorder) but is a condition that significantly affects how individuals live and interact with others.
- ▶ Autistic spectrum disorder is a childhood disorder characterized by significant impairment in social communication skills and restricted, repetitive patterns of behavior, interests, or activities. This disorder does not have a single cause; instead, a number of biological conditions may contribute, and these, in combination with psychosocial influences, result in the unusual behaviors displayed by people with ASD.
- ▶ Impressive advances have been made in improving outcomes for many young children with ASD using early intervention programs. Treatment for older children involves behavioral interventions focused on their social communication deficits and the restricted, repetitive patterns of behavior, interests, or activities.

Intellectual Disability

- ▶ The definition of intellectual disability has three parts: significantly subaverage intellectual functioning, concurrent deficits or impairments in present adaptive functioning, and an onset before the age of 18.
- ▶ Down syndrome is a type of intellectual disability caused by the presence of an extra 21st chromosome. It is possible to detect the presence of Down syndrome in a fetus through a process known as amniocentesis.
- ▶ Two other types of intellectual disability are common: fragile X syndrome, which is caused by a chromosomal abnormality of the tip of the X chromosome, and cultural–familial intellectual disability, a rare problem resulting from adverse environmental conditions.

Exploring Neurodevelopmental Disorders

Disorders that appear early in life disrupt the normal course of development.

- Interrupting or preventing the development of one skill impedes mastery of the skill that is normally acquired next.
- Knowing what skills are disrupted by a particular disorder is essential to developing appropriate intervention strategies.

Research on the brain and its role in psychopathology has increased at a rapid pace, and we have described many of the latest advances throughout this book. All the disorders we have reviewed are in some way influenced by the brain. You have seen, for example, that relatively subtle changes in neurotransmitter systems can significantly affect mood, cognition, and behavior. Unfortunately, the brain is sometimes affected profoundly and, when this happens, drastic changes occur. In earlier editions of this book, the tone of this chapter was quite dark given the lack of information on these cognitive disorders that impair all aspects of mental functioning. The typically poor prognosis of the people afflicted led to pessimistic conclusions. However, a great deal of new research is leading us to be more optimistic about the future. For example, we used to think that once neurons died, there was no hope of any replacement, yet we now know brain cells can regenerate even in the aging brain (Seib & Martin-Villalba, 2015; Stellos et al., 2010). In this chapter, we examine this exciting new work related to the brain disorders that affect cognitive processes such as learning, memory, and consciousness.

Perspectives on Neurocognitive Disorders

Most neurocognitive disorders develop much later in life, whereas intellectual disability and specific learning disorder are believed to be present from birth (see Chapter 14). In this chapter, we review two classes of cognitive disorders: *delirium*, an often temporary condition displayed as confusion and disorientation; and *mild or major neurocognitive disorder*, a progressive condition marked by gradual deterioration of a range of cognitive abilities.

The label “neurocognitive disorders” in *DSM-5* reflects a shift in the way these disorders are viewed (American Psychiatric Association, 2013). In early editions of the *DSM*, they were labeled “organic mental disorders,” along with mood, anxiety, personality, hallucination (an abnormal mental state involving hallucinations), and delusional disorders. The word *organic* indicated that brain damage or dysfunction was believed to be involved. The “organic mental

disorders” category, however, covered so many disorders that the distinction was meaningless. Consequently, the traditional organic disorders—delirium, dementia, and amnestic disorders—were kept together, and the others—organic mood, anxiety, personality, hallucinosis, and delusional disorders—were categorized with disorders that shared their symptoms (such as anxiety and mood disorders).

Once the term *organic* was dropped, attention moved to developing a better label for delirium, dementia, and the amnestic disorders. The label “cognitive disorders” was used in *DSM-IV* to signify that their predominant feature is the impairment of such cognitive abilities as memory, attention, perception, and thinking. Although disorders such as schizophrenia, autism spectrum disorder, and depression also involve cognitive problems, cognitive issues are not believed to be primary characteristics (Ganguli et al., 2011; Sachdev et al., 2014). Problems still existed with the “cognitive disorder” label, however, because although the cognitive disorders usually first appear in older adults, intellectual disability and specific learning disorder (which are apparent early) also have cognitive impairment as a predominant characteristic. Finally, in *DSM-5*, *neurocognitive disorders* is the new category name for the various forms of dementia and amnestic disorders, with “major” or “mild” subtypes; *DSM-5* retains the “delirium” label (American Psychiatric Association, 2013). This new categorization was created because of the overlap of the different types of dementia (e.g., Alzheimer’s disease) and amnestic disorder found in people such that one person may actually suffer from multiple types of neurocognitive problems (Ganguli et al., 2011; Sachdev et al., 2014).

As with certain other disorders, it may be useful to clarify why neurocognitive disorders are discussed in a textbook on abnormal psychology. Because they so clearly have organic causes, you could argue that they are purely medical concerns. You will see, however, that the consequences of a neurocognitive disorder often include profound changes in a person’s behavior and personality. Intense anxiety, depression, or both are common, especially among people with major neurocognitive disorder. In addition, paranoia is often reported, as are extreme agitation and aggression. Families and friends are also

profoundly affected by such changes. Imagine your emotional distress as a loved one is transformed into a different person, often one who no longer remembers who you are or your history together. The deterioration of cognitive ability, behavior, and personality and the effects on others are major concerns for mental health professionals.

Delirium

The disorder known as **delirium** is characterized by impaired consciousness and cognition during the course of several hours or days. Delirium is one of the earliest-recognized mental disorders: Descriptions of people with these symptoms were written more than 2,400 years ago (Solai, 2009). Consider the case of Mr. J.

Mr. J...

Sudden Distress

Mr. J., an older gentleman, was brought to the hospital emergency room. He didn't know his own name, and at times he didn't seem to recognize his daughter who was with him. Mr. J. appeared confused, disoriented, and a little agitated. He had difficulty speaking clearly and could not focus his attention to answer even the most basic questions. Mr. J.'s daughter reported that he had begun acting this way the night before, had been awake most of the time since then, was frightened, and seemed even more confused today. She told the nurse that this behavior was not normal for him, and she was worried that he was becoming "senile." She mentioned that his doctor had just changed his hypertension medication and wondered whether the new medication could be causing her father's distress. Mr. J. was ultimately diagnosed as having substance-induced delirium (a reaction to his new medication); once the medication was stopped, he improved significantly over the course of the next 2 days.

The preceding scenario is played out daily in most major metropolitan hospital emergency rooms.

Clinical Description and Statistics

People with delirium appear confused, disoriented, and out of touch with their surroundings. They cannot focus and sustain their attention on even the simplest tasks. There are marked impairments in memory and language (Meagher & Trzapacz, 2012). Mr. J. had trouble speaking; he was not only confused but also couldn't remember basic facts, such as his own name. As you saw, the symptoms of delirium do not come on gradually but develop over hours or a few days, and they can vary over the course of a day.

Delirium is estimated to be present in approximately 20% of older adults who are admitted into acute care facilities such as emergency rooms (Meagher & Trzapacz, 2012). It is most prevalent among older adults, people undergoing medical procedures, cancer patients, and people with acquired immune deficiency syndrome (AIDS). Delirium subsides relatively quickly. Once thought to be only a temporary problem, more recent work indicates that the effects of delirium may be more lasting (Cole, Ciampi, Belzile, & Zhong, 2009; Meagher, Adamis, Trzepacz, & Leonard, 2012).

Some individuals continue to have problems on and off; some even lapse into a coma and may die. Concern by medical professionals is increasing—perhaps because of the increased number of adults living longer—leading some to recommend that delirium be included as one of the "vital signs" (along with heartbeat, breathing rate, temperature, and blood pressure) that physicians routinely check when seeing older adults (Flaherty, 2011).

Many medical conditions that impair brain function have been linked to delirium, including intoxication by drugs and poisons; withdrawal from drugs such as alcohol and sedative, hypnotic, and anxiolytic drugs; infections; head injury; and various other types of brain trauma (Meagher & Trzapacz, 2012). *DSM-5* recognizes several causes of delirium among its subtypes. The diagnosis received by Mr. J.—substance-induced delirium—as well as delirium not otherwise specified all include disruptions in the person's ability to direct, focus, sustain, and shift attention. The rise in the use of designer drugs such as Ecstasy or "Molly" (methylene-dioxymethamphetamine) and more recently "bath salts" (methylenedioxypyrovalerone) is of particular concern because of such drugs' potential to produce delirium (Penders, Gestring, & Vilensky 2012; Solai, 2009). Substance-induced delirium indicates the often complex nature of this condition.

That delirium can be brought on by the improper use of medication is a particular problem for older adults, because they tend to use prescription medications more than any other age group. The risk of problems among the elderly is increased further because they tend to eliminate drugs from their systems less efficiently than younger individuals. It is not surprising, then, that adverse drug reactions resulting in hospitalization are almost 6 times higher among elderly people than in other age groups (Budnitz, Lovegrove, Shehab, & Richards, 2011; Olivier et al., 2009). And it is believed that delirium is responsible for many of the falls that cause debilitating hip fractures in the elderly (Seitz, Adunuri, Gill, & Rochon, 2011; Stenvall et al., 2006). Although there has been some improvement in the use of medication among older adults with physicians using more care with drug dosages and the use of multiple drugs, improper use continues to produce serious side effects, including symptoms of delirium (Budnitz et al., 2011; Olivier et al., 2009). Because possible combinations of illnesses and medications are so numerous, determining the cause of delirium is extremely difficult (Solai, 2009).

Delirium may be experienced by children who have high fevers or who are taking certain medications and is often mistaken as non-compliance (Kelly & Frosch, 2012). It often occurs during the course of dementia; as many as 50% of people with dementia suffer at least one episode of delirium (Fong, Davis, Growdon, Albuquerque, & Inouye, 2015; Kwok, Lee, Lam, & Woo, 2008). Because many of the primary medical conditions can be treated, delirium is often reversed within a relatively short time. Yet, those who develop delirium while in the hospital have a one-and-a-half times increased risk for death in the following year and this risk of mortality increases to two-to-four-times for those in critical care with delirium (Inouye, Westendorp, & Saczynski, 2014). However, factors other than medical conditions can trigger delirium. Age itself is an important factor; older adults are more susceptible to developing delirium as a result of mild infections or medication changes (Inouye et al., 2014). Sleep deprivation, immobility, and excessive stress can also cause delirium (Solai, 2009).

Researchers studying the brain functioning of persons with and without delirium are beginning to understand the mechanisms

- A.** A disturbance in attention (i.e., reduced ability to direct, focus, sustain, and shift attention) and awareness (reduced orientation to the environment).
- B.** The disturbance develops over a short period of time (usually hours to a few days), represents a change from baseline attention and awareness, and tends to fluctuate in severity during the course of a day.
- C.** An additional disturbance in cognition (e.g., memory deficit, disorientation, language, visuospatial ability, or perception).
- D.** The disturbances in Criteria A and C are not better explained by another preexisting, established, or evolving neurocognitive disorder and do not occur in the context of a severely reduced level of arousal, such as coma.
- E.** There is evidence from the history, physical examination, or laboratory findings that the disturbance is a direct physiological consequence of another medical condition, substance intoxication or withdrawal (i.e., due to a drug of abuse or to a medication), or exposure to a toxin, or is due to multiple etiologies.

underlying this disorder of attention. In one study, scientists assessed brain activity using fMRI scanning during active episodes of delirium as well as after these episodes and found both lasting disruption of connectivity (between the dorsolateral prefrontal cortex with the posterior cingulate cortex) as well as reversible disruptions (such as between the thalamus with the reticular activating system) (Choi et al., 2012; Slooter & de Groot, 2014). Although such research is potentially important for efforts to both prevent and treat delirium, there are potential ethical concerns. For example, a person experiencing delirium is not capable of providing informed consent for participating in such research and therefore someone else (e.g., a spouse or relative) must agree. In addition, fMRI testing can be anxiety-provoking for many people and was possibly very frightening for someone already so disoriented (Gaudreau, 2012). We discuss these issues in more detail in Chapter 16.

Treatment

The first step for the treatment of delirium is addressing underlying causes. For example, delirium brought on by withdrawal from alcohol or other drugs is usually treated with haloperidol or other antipsychotic medications, which help calm the individual. Infections, brain injury, and tumors are given the necessary and appropriate medical intervention, which often then resolves the accompanying delirium. The antipsychotic drugs haloperidol or olanzapine are also prescribed for individuals in acute delirium when the cause is unknown (Meagher & Trzapacz, 2012).

The recommended first line of treatment for a person experiencing delirium is psychosocial intervention. The goal of nonmedical treatment is to reassure the individual to help him or her deal with the agitation, anxiety, and hallucinations of delirium. The inclusion of a family member in the care for patients with delirium, such as

overnight stays with the patient may be a great comfort to the patient. Similarly, familiar personal belongings such as family photographs may also be an easy and comforting intervention (Fearing & Inouye, 2009; van Munster & de Rooij, 2014). Also, a patient who is included in all treatment decisions retains a sense of control that can aid in the patient's ability to cope with anxiety and agitation due to the delirium (Katz, 1993). This type of psychosocial treatment can help the person manage during this disruptive period until the medical causes are identified and addressed (Breitbart & Alici, 2012). Some evidence suggests that this type of support can also delay institutionalization for elderly patients (Rahkonen et al., 2001).

Richard Hutchings / PhotoEdit

Elderly patients with delirium in care facilities are often comforted by having their personal belongings nearby.

Prevention

Preventive efforts may be most successful in assisting people who are susceptible to delirium. Proper medical care for illnesses and therapeutic drug monitoring can play significant roles in preventing delirium (Breitbart & Alici, 2012). For example, the increased number of older adults involved in managed care and patient counseling on drug use appear to have led to more appropriate use of prescription drugs among the elderly (U.S. General Accounting Office, 1995). In addition, structured multidisciplinary interventions that target the prevention of delirium during hospital stays in older patients are very effective (for more information see Hospital Elder Life Program; Inouye et al., 2014). These types of programs are implemented by an interdisciplinary team of doctors, nurses, and volunteers and consist of all of the following: re-orientating the patient, providing vision and hearing aids as needed, increasing sleep and physical activity, maintaining proper hydration and nutrition, involving the patient in therapeutic activities, and reducing dosages of psychoactive drugs. One downside is that these programs require a lot of resources from hospitals to put it into place consistently with all those who are at risk for delirium.

Concept Check 15.1

Match the terms with the following descriptions of delirium:

- (a) memory, (b) cause, (c) counseling, (d) confused, (e) elderly, and (f) trauma.

1. Managed care and patient _____ have been successful in preventing delirium in older adults.
2. Treatment of delirium depends on the _____ of the episode and can include medications, psychosocial intervention, or both.

3. Delirium severely affects people's _____, making tasks such as recalling one's own name difficult.
4. The _____ population is at the greatest risk of experiencing delirium resulting from improper use of medications.
5. Various types of brain _____, such as head injury or infection, have been linked to delirium.
6. People who suffer from delirium appear to be _____ or out of touch with their surroundings.

Major and Mild Neurocognitive Disorders

Few things are more frightening than the possibility of one day not recognizing those you love, not being able to perform the most basic of tasks and, worse yet, being acutely aware of this failure of your mind. When family members show these signs, initially adult children often deny any difficulty, coming up with excuses ("I forget things, too") for their parents' failing abilities. **Major neurocognitive disorder** (previously labeled **dementia**) is a gradual deterioration of brain functioning that affects memory, judgment, language, and other advanced cognitive processes. **Mild neurocognitive disorder** is a new *DSM-5* disorder that was created to focus attention on the early stages of cognitive decline. Here the person has modest impairments in cognitive abilities but can, with some accommodations (for example, making extensive lists

of things to do or creating elaborate schedules), continue to function independently.

Causes of neurocognitive disorders include several medical conditions and the abuse of drugs or alcohol that produce negative changes in cognitive functioning. Some of these conditions—for instance, infection or depression—can cause neurocognitive impairment, although it is often reversible through treatment

of the primary condition. Some forms of the disorder, such as Alzheimer's disease, are at present irreversible. Although delirium and neurocognitive disorder can occur together, neurocognitive disorder has a gradual progression as opposed to delirium's acute onset; people with neurocognitive disorder are not disoriented or confused in the early stages, unlike people with delirium. Like delirium, however, neurocognitive disorder has many causes,

PAT SUMMITT: Grit and Determination

At the age of 57, Pat Summitt was a highly successful basketball coach and mother, but she was beginning to experience lapses in her memory.

Friends started asking, "Are you having trouble with your memory?" Finally I admitted, "Sometimes I draw blanks." I

grew uncertain, and then a little frightened. I began staying in bed until late in the morning, which was unlike me. I'd always been a bolter, the first person up and the most energetic one, too, and I'd always gone to work earlier than anyone on my staff. But I began to dread going into the office. (p. 11)

Despite having cognitive difficulties, not all of her memories were lost to her in this initial stage of the disease. She began her memoir with the things she remembered.

I remember a tiny saloon in the Tennessee hills where the bartender squirted bourbon shots from a squeeze bottle, straight into the customers' mouths. I remember teaching a clinic to other coaches and opening the floor for questions, and a guy raised his hand and asked if I had any advice when it came to "coaching women." I remember leveling him with a death ray stare and then relaxing and curling up the corner of my mouth and saying, "Don't worry about coaching 'women.' Just go home and coach 'basketball.'" (p. 6)

I remember the night my son was born. The doctor placed him on my chest and I said, "Hey, Tyler, I've been waitin' on you." (pp. 6–7)

Her memory for important experiences that occurred years ago remained intact. However, recent experiences and facts were more elusive. She then goes on to describe some of the things she no longer remembered.

Sometimes, when I first wake up, I don't remember where I am. For a moment I'm disoriented and uneasy, and I have to lie there until it comes to me.

Occasionally when I'm asked a question, I begin to answer it but then I forget the subject—it slips away like a thread through my fingers.

I struggle to remember directions. There are moments when I'm driving to someplace I should know, and I have to ask, "Do I go left or right here?"

I tend not to remember what hotel room I'm in. I don't remember what times my appointments are. (p. 7)

Many people who begin to have these cognitive difficulties retell these initial experiences as incredibly frightening. However, Pat Summitt was known for her tough determination both on the basketball court and now battling Alzheimer's disease. Her reaction to her diagnosis and her doctor's recommendations show an incredible level of courage and strength.

In my case, symptoms began to appear when I was only 57. In fact, the doctors believe early-onset Alzheimer's has a strong genetic predictor, and that it may have been progressing hidden in me for some years before I was diagnosed. I'd been walking around with a slow-ticking, slow-exploding bomb in my brain cells, and it only became apparent when it began to seriously interfere with my work. (p. 9)

The doctor told me that given my diagnosis, frankly, he felt I could no longer work at all. I should step down immediately, because in his opinion the dementia would progress rapidly. I needed to quit, and get myself out of the public eye as quickly as possible, or I would "embarrass" myself and ruin my legacy. As he spoke, I felt my fist clench. It was all I could do not to lunge across the desk and drop him with one punch. Who did he think he was? Even if I had an irreversible brain disease—even if I did—what right did he have to tell me how to cope with it? Quit? Quit? (pp. 17–18)

She goes on to write about her unusually practical and optimistic perspective on having Alzheimer's disease—a view of this degenerative disease that should serve as a role model for the millions of people impacted by this disorder.

Above all, I know that Alzheimer's has brought me to a point that I was going to arrive at someday anyway. With or without this diagnosis, I was going to experience diminishment. We all do. It's our fate. No, I can't size up a court of ten players anymore, see the clock out of one eye and the shifting schemes of opposing players with the other, and order up a countermove by hollering "Five!" or "Motion!" But I can suggest that people with mild to moderate stages of dementia have far more abilities than incapacities. I can suggest that just because certain circuits of memory or swiftness of synapses may fail, thought and awareness and consciousness do not. (p. 375)

including a variety of traumas to the brain such as stroke (which destroys blood vessels), the infectious diseases of syphilis and HIV, severe head injury, the introduction of certain toxic or poisonous substances, and diseases such as Parkinson's, Huntington's, and, the most common cause of dementia, Alzheimer's. Consider the personal account by Pat Summitt, the most successful NCAA basketball coach of all time. She coached the Tennessee Lady Vols basketball team from 1974 to 2012—winning a record setting 1,098 games—until her symptoms of neurocognitive disorder due to Alzheimer's disease prevented her from working with the team full-time. Unfortunately, Pat Summitt passed away in 2016 at the age of 64 as the result of complications due to Alzheimer's. Before she died she courageously wrote of her experiences with this disorder (Summitt, 2013).

After several evaluations, which included neurological evaluations, magnetic resonance imaging (MRI) showing some damage in several parts of her brain, and a spinal tap that showed the presence of beta amyloid protein, Pat Summitt's neurologist concluded that she had early onset neurocognitive disorder due to Alzheimer's disease. People at the same stage of decline as she will continue to deteriorate and eventually may die – as she did – from complications of their disorder.

Clinical Description and Statistics

Depending on the individual and the cause, the gradual progression of neurocognitive disorder may have somewhat different symptoms, although all aspects of cognitive functioning are eventually affected. In the initial stages, memory impairment is typically seen as an inability to register ongoing events. In other words, a person can remember how to talk and may remember events from many years ago but will have trouble remembering what happened in the past hour. For example, Pat Summitt had vivid recollections about her childhood but could not remember which direction to drive in familiar places.

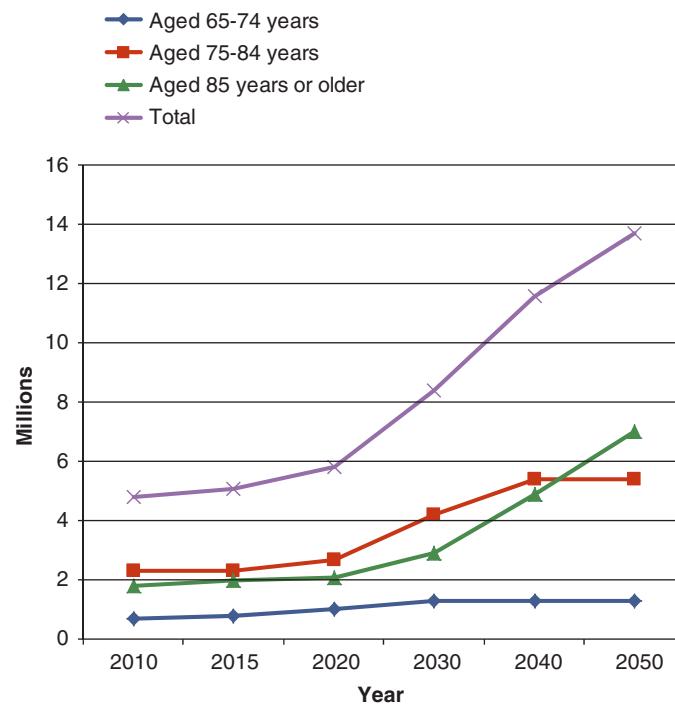

Pat Summitt couldn't find her way home because visuospatial skills are impaired among people with neurocognitive disorder. **Agnosia**, the inability to recognize and name objects, is one of the most familiar symptoms. **Facial agnosia**, the inability to recognize even familiar faces, can be extremely distressing to family members. A general deterioration of intellectual function results from impairment in memory, planning, and abstract reasoning.

Perhaps partly because people suffering from neurocognitive disorder are aware that they are deteriorating mentally, emotional changes often occur as well. Common side effects are delusions (irrational beliefs), depression, agitation, aggression, and apathy (Lovestone, 2012). It is difficult, however, to establish the cause-and-effect relationship. It is not known how much behavioral change is caused by progressive brain deterioration directly and how much is a result of the frustration and discouragement that inevitably accompany the loss of function and the isolation of “losing” loved ones. Cognitive functioning continues to deteriorate until the person requires almost total support to carry out day-to-day activities. Ultimately, death occurs as the result of inactivity, combined with the onset of other illnesses, such as pneumonia.

Globally, it is estimated that one new case of major neurocognitive disorder is identified every 7 seconds (Ferri et al., 2005).

Major neurocognitive disorder can develop at almost any age, although this disorder is more frequent in older adults. The methodology for estimating the number of those suffering from major neurocognitive disorder has resulted in sometimes diverging numbers (Launer, 2011). Current estimates in the United States suggest a prevalence of around 5 million people with major neurocognitive disorder (Alzheimer's Association, 2011), with rates of a little more than 5% in people older than 65 and 20% to 40% in those older than 85 (Richards & Sweet, 2009). The increasing number of people with just one form of neurocognitive disorder—due to Alzheimer's disease—is alarming. A dramatic rise in Alzheimer's disease is predicted through the year 2050 as larger numbers of people are expected to live beyond 85 years of age. ● Figure 15.1 illustrates how the prevalence of neurocognitive disorder due to Alzheimer's disease is projected to greatly increase in older adults, partly as a result of the increase of baby boomers who will become senior citizens (Hebert, Weuve, Scherr, & Evans, 2013). Among the eldest of adults, research on centenarians (people 100 years and older) indicates that up to 100% showed signs of neurocognitive disorder (Davey et al., 2013; Imhof et al., 2007). Neurocognitive disorder due to Alzheimer's disease rarely occurs in people under 45 years of age.

Estimates of the prevalence of the new *DSM-5* diagnosis—mild neurocognitive disorder—have been studied by the Einstein Aging Study at Yeshiva University (Katz et al., 2012). Researchers recruited 1,944 adults aged 70 or older and assessed them for mild neurocognitive disorder as well as mild amnestic neurocognitive

● FIGURE 15.1

With the increasing numbers of persons living longer, the rate of Alzheimer's disease is predicted to escalate dramatically through the year 2050. (From Hebert, L. E., Weuve, J., Scherr, P. A., & Evans, D. A. (2013). Alzheimer disease in the United States (2010–2050) estimated using the 2010 census. *Neurology*, 80(19), 1778–1783.)

disorder in this group. This latter disorder—in its more severe state—was previously a separate *DSM* disorder (*amnestic disorder*) but has been folded into the general neurocognitive disorder group. Almost 10% of those over 70 had mild neurocognitive disorder, and 11.6% met the criteria for mild amnestic neurocognitive disorder. Race also seemed to be a factor with black men and women at higher risk for mild neurocognitive disorder than white men and women (Katz et al., 2012).

A problem with confirming prevalence figures for neurocognitive disorder is that survival rates alter the outcomes. Because adults are generally living longer and are therefore more at risk of developing neurocognitive disorder, it is not surprising that the disorder is more prevalent. Incidence studies, which count the number of new cases in a year, may thus be the most reliable method for assessing the frequency of neurocognitive disorder, especially among the elderly. Research shows that the rate for new cases doubles with every 5 years of age after age 75. Many studies find greater increases of neurocognitive disorder among women (Carter, Resnick, Mallampalli, & Kalbarczyk, 2012). Neurocognitive disorder due to Alzheimer's disease may, as we discuss later, be more prevalent among women. Together, results suggest that neurocognitive disorder is relatively common among older adults, and the chances of developing it increase rapidly after the age of 75.

In addition to the human costs of neurocognitive disorder, the financial costs are staggering. Estimates of the costs of caring for people with neurocognitive disorder due to Alzheimer's disease are often quoted to be about \$100 billion per year in the United States. One estimate indicates that the total worldwide societal cost of major neurocognitive disorder is more than \$604 billion (Wimo et al., 2013), including informal care and direct medical costs. Also, many times, family members care for an afflicted person around the clock, which is an inestimable personal and financial commitment (Lovestone, 2012).

DSM-5 identifies classes of neurocognitive disorder based on etiology: (1) Alzheimer's disease, (2) vascular injury, (3) frontotemporal degeneration, (4) traumatic brain injury, (5) Lewy body disease, (6) Parkinson's disease, (7) HIV infection, (8) substance use, (9) Huntington's disease, (10) prion disease, and (11) another

medical condition. We emphasize neurocognitive disorder due to Alzheimer's disease because of its prevalence (almost half of those with neurocognitive disorder exhibit this type) and the relatively large amount of research conducted on its etiology and treatment.

Neurocognitive Disorder Due to Alzheimer's Disease

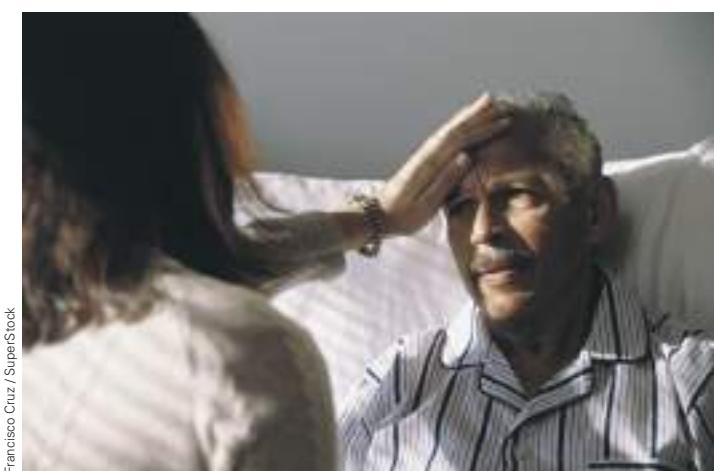

In 1907, the German psychiatrist Alois Alzheimer first described the disorder that bears his name. He wrote of a 51-year-old woman who had a “strange disease of the cerebral cortex” that manifested as progressive memory impairment and other behavioral and cognitive problems, including suspiciousness (Richards & Sweet, 2009). He called the disorder an “atypical form of senile dementia”; thereafter, it was referred to as **Alzheimer's disease**.

Description and Statistics

The *DSM-5* diagnostic criteria for **neurocognitive disorder due to Alzheimer's disease** include multiple cognitive deficits that develop gradually and steadily. Predominant are impairment of memory, orientation, judgment, and reasoning. The inability to integrate new information results in failure to learn new associations. Individuals with Alzheimer's disease forget important events and lose objects. Their interest in nonroutine activities narrows. They tend to lose interest in others and, as a result, become more socially isolated. As the disorder progresses, they can become agitated, confused, depressed, anxious, or even combative. Many of these difficulties become more pronounced late in the day—in a phenomenon referred to as “sundowner syndrome”—perhaps as a result of fatigue or a disturbance in the brain's biological clock (Ferrazzoli, Sica, & Sancesario, 2013; Lemay & Landreville, 2010).

People with neurocognitive disorder due to Alzheimer's disease also display one or more other cognitive disturbances, including aphasia (difficulty with language), apraxia (impaired motor functioning), agnosia (failure to recognize objects), or difficulty with activities such as planning, organizing, sequencing, or abstracting information. These cognitive impairments have a serious negative impact on social and occupational functioning, and they represent a significant decline from previous abilities.

Research using brain scans is being conducted on people with mild neurocognitive disorder to see whether changes in brain structure early in the development of Alzheimer's disease can be detected, which could lead to early diagnosis. In the past, a definitive diagnosis of Alzheimer's disease could be made only after an autopsy determined that certain characteristic types of damage were present in the brain. There is now growing evidence, however, that the use of sophisticated brain scans along with new chemical tracers may soon be able to help clinicians identify the presence of Alzheimer's disease before the significant declines in cognitive abilities (through a project called the Alzheimer's Disease Neuroimaging Initiative [ADNI]) or death (Douaud et al., 2013; Weiner et al., 2012). In addition, research on the presence of certain markers for Alzheimer's (e.g., beta amyloid—the substance in the amyloid plaques found in the brains of persons with this disease) in spinal fluid also appears to increase the accuracy of a diagnosis (Vanderstichele et al., 2012). Currently, to make a

Testing for Neurocognitive Disorder due to Alzheimer's Disease

Type*	Maximum Score†	Question
Orientation	5	Ask the patient, "What is the (year) (season) (date) (day) (month)?"
	5	Ask the patient, "Where are we—(state) (country) (town) (hospital) (floor)?"
Registration	3	Name three objects, using 1 second to say each. Then ask the patient all three after you have said them. (Give one point for each correct answer.) Then repeat them until the patient learns all three. (Count and record the number of trials.)
Attention and Calculation	5	Count backward from given number (like 100) by subtracting 7s. (Give one point for each correct answer; stop after five answers.) Alternatively, spell "world" backward.
Recall	3	Have the patient name the three objects learned previously. (Give one point for each correct answer.)
Language	9	Have the patient name a pencil and a watch. (1 point) Have the patient repeat the following: "No ifs, ands, or buts." (1 point) Have the patient follow a three-stage command: "Take a piece of paper in your right hand, fold it in half, and put it on the floor." (3 points) Have the patient read and obey the following: "Close your eyes." (1 point) Have the patient write a sentence. (1 point) Have the patient copy a design. (1 point)

Note: One part of the diagnosis of the neurocognitive disorder due to Alzheimer's disease uses a relatively simple test of the patient's mental state and abilities, like this one, called the Mini Mental State Inpatient Consultation Form. A low score on such a test does not necessarily indicate a medical diagnosis of the disorder.

*The examination also includes an assessment of the patient's level of consciousness: alert, drowsy, stupor, or coma.

diagnosis without direct examination of the brain, a simplified version of a mental status exam is used to assess language and memory problems (see Table 15.1).

In an interesting, somewhat controversial study—referred to as the “Nun Study”—the writings of a group of Catholic nuns collected over several decades appeared to indicate early in life which women were most likely to develop Alzheimer's disease later (Snowdon et al., 1996). Researchers observed that samples from the nuns' journals over the years differed in the number of ideas each contained, which the scientists called “idea density.” In other words, some sisters described events in their lives simply: “I was born in Eau Claire, Wis, on May 24, 1913 and was baptized in St. James Church.” Others were more elaborate in their prose: “The happiest day of my life so far was my First Communion Day which was in June nineteen hundred and twenty when I was but eight years of age, and four years later in the same month I was confirmed by Bishop D. D. McGavich” (Snowdon et al., 1996, pg., 530). When findings of autopsies on 14 of the nuns were correlated with idea density, the simple writing (low idea density) occurred among all 5 nuns with Alzheimer's disease (Snowdon et al., 1996). This is an elegant research study, because the daily lives of the nuns were similar, which ruled out many other possible causes. There is some concern, however, about overgeneralizing from this one study, and we must be cautious about depending too much on these observations, because only a small number of people were examined. Promising preliminary research on the early signs of neurocognitive disorder due to Alzheimer's disease has identified some small changes in neurocognitive functioning that

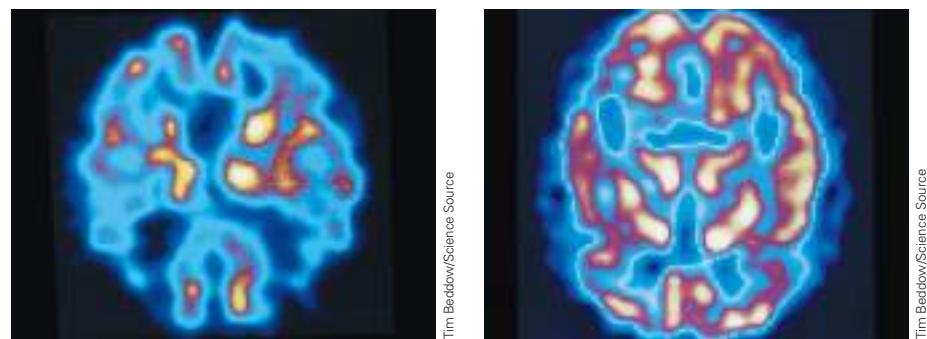

research continues to attempt to pin down and measure reliably. For example, by continuously measuring the cognitive functioning of a person, it may be possible to start detecting when some of this person's cognitive functioning may start to decline. Early detection before individuals meet clinical criteria is especially important because early intervention has been shown to have the biggest impact (Rentz et al., 2013).

Cognitive deterioration with Alzheimer's disease is slow during the early and later stages but more rapid during the middle stages (Ito et al., 2011; Richards & Sweet, 2009). The average survival time is estimated to be about 4 to 8 years, although many individuals live dependently for more than 20 years. In some forms, the disease can occur relatively early, during the 40s or 50s (sometimes referred to as *early onset*), but it usually appears during the 60s or 70s. Approximately 50% of the cases of neurocognitive disorder are found to be the result of Alzheimer's disease, which is believed to afflict more than 5.3 million Americans and millions more worldwide (Alzheimer's Association, 2015).

Some early research on prevalence suggested that Alzheimer's disease may occur more often in people who are poorly educated (Amieva et al., 2014; Fratiglioni et al., 1991). Greater impairment among uneducated people might indicate a much earlier onset, suggesting that Alzheimer's disease causes intellectual dysfunction that in turn hampers educational efforts. Or there could be something about intellectual achievement that prevents or delays the onset of symptoms of the disorder. Later research seems to confirm the latter explanation. It appears that educational level may predict a delay in the observation of symptoms (Amieva et al., 2014).

Unfortunately, people who attain a higher level of education also decline more rapidly once the symptoms become more severe (Scarmeas, Albert, Manly, & Stern, 2006), suggesting that education does not prevent Alzheimer's disease but just provides a buffer period of better functioning. Educational attainment may somehow create a mental "reserve," a learned set of skills that help someone cope longer with the cognitive deterioration that marks the beginning of neurocognitive deficits. Some people may adapt more successfully than others and thus escape detection longer. Brain deterioration may thus be comparable for both groups, but better-educated individuals may be able to function successfully on a day-to-day basis for a longer period. This tentative hypothesis may prove useful in designing treatment strategies, especially during the early stages of the disorder.

A biological version of this theory—the cognitive reserve hypothesis—suggests that the more synapses a person develops throughout life, the more neuronal death must take place before the signs of dementia are obvious (Farias et al., 2012). Mental activity that occurs with education presumably builds up this reserve of synapses and serves as an initial protective factor in the development of the disorder. It is likely that both skill development and the changes in the brain with education may contribute to how quickly the disorder progresses.

The PET scan of a brain afflicted with Alzheimer's disease (left) shows significant tissue deterioration in comparison with a normal brain (right).

Research suggests that Alzheimer's disease may be more prevalent among women (Alzheimer's Association, 2015; Craig & Murphy, 2009), even when women's higher survival rate is factored into the statistics. In other words, because women live longer than men on average, they are more likely to experience Alzheimer's and other diseases, but longevity alone does not account for the higher prevalence of the disorder among women. A tentative explanation involves the hormone estrogen. Women lose estrogen as they grow older, so perhaps estrogen is protective against the disease. A large and important study—the Women's Health Initiative Memory Study—looked at hormone use among women and its effect on Alzheimer's disease (Lobo, 2013; Shumaker et al., 2004).

Diagnostic Criteria for Major or Mild Neurocognitive Disorder due to Alzheimer's Disease

- A.** The criteria are met for major or mild neurocognitive disorder.
- B.** There is insidious onset and gradual progression of impairment in one or more cognitive domains (for major neurocognitive disorder, two domains must be impaired).
- C.** Criteria are met for either probable or possible Alzheimer's disease as follows:

For major neurocognitive disorder:

Probable Alzheimer's disease is diagnosed if either of the following is present; otherwise, possible Alzheimer's disease should be diagnosed.

- 1.** Evidence of a causative Alzheimer's disease genetic mutation from family history or genetic testing
- 2.** All three of the following are present:
 - a.** Clear evidence of decline in memory and learning and at least one other cognitive domain (based on detailed history or serial neuropsychological testing).
 - b.** Steadily progressive, gradual decline in cognition, without extended plateaus.
 - c.** No evidence of mixed etiology (i.e., absence of other neurodegenerative or cerebrovascular disease, or another neurological, mental, or systemic disease or condition likely contributing to cognitive decline).

For mild neurocognitive disorder:

Probable Alzheimer's disease is diagnosed if there is evidence of a causative Alzheimer's disease genetic mutation from either genetic testing or family history.

Possible Alzheimer's disease is diagnosed if there is no evidence of a causative Alzheimer's disease genetic mutation from either genetic testing or family history, and all three of the following are present:

- 1.** Clear evidence of decline in memory and learning.
 - 2.** Steadily progressive, gradual decline in cognition, without extended plateaus.
 - 3.** No evidence of mixed etiology (i.e., absence of other neurodegenerative or cerebrovascular disease, or another neurological or systemic disease or condition likely contributing to cognitive decline).
- D.** The disturbance is not better explained by cerebrovascular disease, another neurodegenerative disease, the effects of a substance, or another mental, neurological, or systemic disorder.

In its initial findings, the study followed women over age 65 using a type of combined estrogen plus progestin known as Prempro and, contrary to the belief that giving women estrogen would decrease their chance of developing neurocognitive disorder, they observed an *increased* risk for Alzheimer's disease (Coker et al., 2010; Maki & Henderson, 2012). More research is ongoing into the individual effects of these two types of hormones on dementia.

Finally, there appear to be questions about the prevalence of Alzheimer's disease according to cultural and/or racial identity. Early research seemed to suggest that certain populations (such as those with Japanese, Nigerian, certain Native American, and Amish backgrounds) were less likely to be affected (for example, see Pericak-Vance et al., 1996; Rosenberg et al., 1996). Similarly, prevalence rates of Alzheimer's disease in low- and middle-income countries have also been reportedly lower than higher-income countries (Sosa-Ortiz, Acosta-Castillo, & Prince, 2012). More recent work indicates, however, that some of these differences may be due to lower numbers in those who seek assistance (possibly due to stigma as well as high levels of social care from family members), as well as differences in education, and how the disorders were measured (Sosa-Ortiz et al., 2012; Wilson et al., 2010). For example, individuals in low- and middle-income countries did not meet *DSM* criteria for the disorder given that they did not have much social or occupational interference because their families were taking care of them (Sosa-Ortiz et al., 2012). Alzheimer's disease is found in roughly the same numbers across all ethnic groups, with one study finding a slightly lower rate among American Indians (Weiner, Hynan, Beekly, Koepsell, & Kukull, 2007). As you will see, findings like these help bring us closer to understanding the causes of this devastating disease.

Vascular Neurocognitive Disorder

Each year, 500,000 people die from strokes (any diseases or traumas to the brain that result in restriction or cessation of blood

flow). Although stroke is the third-leading cause of death in the United States, many people survive, but one potential long-term consequence can be severely debilitating. **Vascular neurocognitive disorder** is a progressive brain disorder that is a common cause of neurocognitive deficits. It is one of the more common causes of neurocognitive disorder (Erkinjuntti, 2012).

Description and Statistics

The word *vascular* refers to blood vessels. When the blood vessels in the brain are blocked or damaged and no longer carry oxygen and other nutrients to certain areas of brain tissue, damage results. Because multiple sites in the brain can be damaged, the profile of degeneration—the particular skills that are impaired—differs from person to person. *DSM-5* lists as criteria for vascular neurocognitive disorder cognitive disturbances such as declines in speed of information processing and executive functioning (e.g., complex decision-making) (Erkinjuntti, 2012). In contrast, those with Alzheimer's disease have memory problems as their initial cognitive disturbance.

Compared with research on neurocognitive disorder due to Alzheimer's type, there are fewer studies on vascular neurocognitive disorder, perhaps because of its lower incidence rates. The prevalence of vascular neurocognitive disorder is approximately 1.5% in people 70 to 75 years of age and increases to 15% for those over the age of 80 (Neugroschi, Kolevzon, Samuels, & Marin, 2005). The risk for men is slightly higher than among women, in contrast with the higher risk among women for Alzheimer's type dementia, and this has been reported in many developed and developing countries (Kalaria et al., 2008). The relatively high rate of cardiovascular disease among men in general may account for their increased risk of vascular neurocognitive disorder. The onset of vascular dementia is typically more sudden than the onset for the Alzheimer's type, probably because the disorder is the result of stroke, which inflicts brain damage

immediately. The outcome, however, is similar for people with both types: Ultimately, they will require formal nursing care until they succumb to an infectious disease such as pneumonia, to which they are susceptible because of weakening of the immune system.

Other Medical Conditions That Cause Neurocognitive Disorder

In addition to Alzheimer's disease and vascular damage, a number of other neurological and biochemical processes can lead to neurocognitive disorder. *DSM-5* identifies eight specific causes in addition to Alzheimer's disease and vascular damage: frontotemporal degeneration, traumatic brain injury, Lewy body disease, Parkinson's disease, HIV infection, substance use, Huntington's disease, and prion disease. Each of these is discussed here. In addition, a final category—neurocognitive disorder due to another medical condition—is provided for other causes. Other medical conditions that can lead to neurocognitive disorder include normal pressure hydrocephalus (excessive water in the cranium, resulting from brain shrinkage), hypothyroidism (an underactive thyroid gland), brain tumor, and vitamin B12 deficiency. There is increasing recognition of neurocognitive disorder among athletes who receive repeated blows to the head. In the past, this type of neurocognitive disorder was referred to as *dementia pugilistica* (which suggested that it was restricted to boxers or pugilists) but it is currently referred to as *chronic traumatic encephalopathy (CTE)*. CTE is caused by repetitive **head trauma** that can provoke distinctive neurodegeneration (Baugh et al., 2012). In their effect on cognitive ability, all of these disorders are comparable to the other forms of neurocognitive disorder we have discussed so far.

Descriptions and Statistics

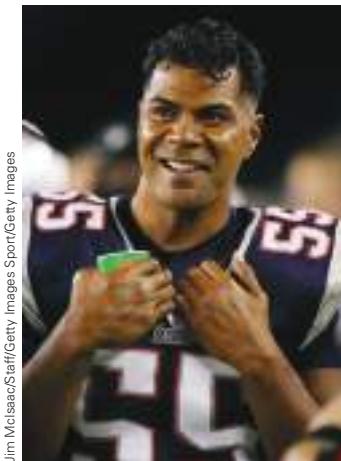

Frontotemporal neurocognitive disorder is an overarching term used to categorize a variety of brain disorders that damage the frontal or temporal regions of the brain—areas that affect personality, language, and behavior (Gustafson & Brun, 2012). *DSM-5* identifies two variants of frontotemporal neurocognitive disorder—through declines in appropriate behavior (e.g., socially inappropriate actions, apathy, making poor judgments) or language (e.g., problems with speech, finding the

right word, naming objects). One of the disorders in this category of neurocognitive disorders is **Pick's disease**, a rare neurological condition—occurring in about 5% of those people with neurocognitive impairment—that produces symptoms similar to that of Alzheimer's disease. The course of this disease is believed to last from 5 to 10 years, and appears to have a genetic component (Gustafson & Brun, 2012). Pick's disease usually occurs relatively early in life—during a person's 40s or 50s—and is therefore considered an example of early onset neurocognitive disorder.

Severe trauma to the head causes the brain to sustain lasting injuries (called **traumatic brain injury** or **TBI**) which can lead to neurocognitive disorder (Fleminger, 2012). **Neurocognitive disorder due to traumatic brain injury** includes symptoms that persist for at least a week following the trauma, including executive dysfunction (e.g., difficulty planning complex activities) and problems with learning and memory. Those that are at greatest risk for TBI are teens and young adults, especially accompa-

nied by alcohol abuse or lower socio-economic class (Fleminger, 2012). Traffic accidents, assaults, falls, and suicide attempts are common causes, as is being exposed to bomb blasts in combat.

The second most common type of neurocognitive disorders (after Alzheimer's disease) is **neurocognitive disorder due to Lewy body disease** (Aarsland, Ballard, Rongve, Broadstock, & Svenningsson, 2012; McKeith et al., 2005). Lewy bodies are microscopic deposits of a protein that damage brain cells over time. The signs of this disorder come on gradually and include impairment in alertness and attention, vivid visual hallucinations, and motor impairment as seen in Parkinson's disease. In fact, there is some overlap between this disorder and **neurocognitive disorder due to Parkinson's disease** (Mindham & Hughes, 2012).

Parkinson's disease is a degenerative brain disorder that affects about 100 to 300 people in every 100,000 people worldwide, though estimates vary widely due to challenges in diagnosing the disorder (Wirdefeldt, Adami, Cole, Trichopoulos, & Mandel, 2011). Movie and television star Michael J. Fox and former U.S. Attorney General Janet Reno both suffer from this progressive disorder. Motor problems are characteristic among people with Parkinson's disease, who tend to have stooped posture, slow body movements (called *bradykinesia*), tremors, and jerkiness in walking. The voice

Diagnostic Criteria for Major or Mild Frontotemporal Neurocognitive Disorder

- A.** The criteria are met for major or mild neurocognitive disorder.
- B.** The disturbance has insidious onset and gradual progression.
- C.** Either (1) or (2):
 - 1.** Behavioral variant:
 - a.** Three or more of the following behavioral symptoms:
 - i.** Behavioral disinhibition
 - ii.** Apathy or inertia
 - iii.** Loss of sympathy or empathy
 - iv.** Perseverative, stereotyped, or compulsive/ritualistic behavior
 - v.** Hyperorality and dietary changes
 - b.** Prominent decline in social cognition and/or executive abilities.
 - 2.** Language variant:
 - a.** Prominent decline in language ability, in the form of speech production, word finding, object naming, grammar, or word comprehension
- D.** Relative sparing of learning and memory and perceptual-motor function.
- E.** The disturbance is not better explained by cerebrovascular disease, another neurodegenerative disease, the effects of a substance, or another mental, neurological, or systemic disorder.

Probable frontotemporal neurocognitive disorder is diagnosed if either of the following is present; otherwise, possible frontotemporal neurocognitive disorder should be diagnosed:

- 1.** Evidence of a causative frontotemporal neurocognitive disorder genetic mutation, from either family history or genetic testing
- 2.** Evidence of disproportionate frontal and/or temporal lobe involvement from neuroimaging

Possible frontotemporal neurocognitive disorder is diagnosed if there is no evidence of a genetic mutation, and neuroimaging has not been performed.

 - 1.** Loss of consciousness
 - 2.** Posttraumatic amnesia
 - 3.** Disorientation and confusion
 - 4.** Neurological signs (e.g., neuroimaging demonstrating injury; a new onset of seizures; a marked worsening of a preexisting seizure disorder; visual field cuts; anosmia; hemiparesis)
- C.** The neurocognitive disorder presents immediately after the occurrence of the traumatic brain injury or immediately after recovery of consciousness and persists past the acute post-injury period.

is also affected; afflicted individuals speak in a soft monotone. The changes in motor movements are the result of damage to dopamine pathways. Because dopamine is involved in complex movement, a reduction in this neurotransmitter makes affected individuals increasingly unable to control their muscle movements, which leads to tremors and muscle weakness. In addition to degeneration of these pathways, Lewy bodies are also present in the brains of affected persons. The course of the disease varies widely, with some individuals functioning well with treatment. It is estimated that about 75% of people who survive more than 10 years with Parkinson's disease develop neurocognitive disorder; conservative estimates place the rate at 4 to 6 times that found in

the general population (Aarsland & Kurz, 2010; Svenningsson, Westman, Ballard, & Aarsland, 2012).

The **human immunodeficiency virus type 1 (HIV-1)**, which causes AIDS, can also cause neurocognitive disorder (called **neurocognitive disorder due to HIV infection**) (Maj, 2012). This impairment seems to be independent of the other infections that accompany HIV; in other words, the HIV infection itself seems to be responsible for the neurological impairment. The early symptoms of neurocognitive disorder resulting from HIV are cognitive slowness, impaired attention, and forgetfulness. Affected individuals also tend to be clumsy, to show repetitive movements such as tremors and leg weakness, and to become apathetic and socially withdrawn.

People with HIV seem particularly susceptible to impaired thinking in the later stages of HIV infection, although significant declines in cognitive abilities may occur earlier. Cognitive impairments were highly common among those infected with HIV, but with the introduction of new medications (highly active antiretroviral therapies, or HAARTs), less than 10% of patients now experience neurocognitive disorder (Maj, 2012). HIV-1 accounts for a relatively small percentage of people with neurocognitive disorder compared to Alzheimer's disease and vascular causes, but its presence can complicate an already-devastating set of medical conditions.

Like neurocognitive disorder from Parkinson's disease and several other causes, neurocognitive disorder resulting from HIV is sometimes referred to as *subcortical dementia*, because it affects primarily the inner areas of the brain, below the outer layer called the cortex (Clifford & Ances, 2013). The distinction between cortical (including neurocognitive disorder due to Alzheimer's disease) and subcortical dementia is important because of the different expressions of neurocognitive disorder in these two categories (see Table 15.2). **Aphasia**, which involves impaired language skills, occurs among people with neurocognitive disorder due to Alzheimer's disease but not among people with subcortical dementia. In contrast, people with subcortical dementia are more

likely to experience severe depression and anxiety than those with neurocognitive disorder due to Alzheimer's disease. In general, motor skills including speed and coordination are impaired early on among those with subcortical dementia. The differing patterns of impairment can be attributed to the different areas of the brain affected by the disorders causing the neurocognitive disorder.

Huntington's disease is a genetic disorder that initially affects motor movements, typically in the form of *chorea*, involuntary limb movements (Pringsheim et al., 2012). People with Huntington's disease can live for 20 years after the first signs of the disease appear, although skilled nursing care is often required during the final stages. Just as with Parkinson's disease, only a portion of people with Huntington's disease go on to display cognitive deficits—42.5% of new Huntington's disorder cases also present with *mild* cognitive impairment (Robbins & Cools, 2014).

- 1.** There is no evidence of mixed etiology (i.e., absence of other neurodegenerative or cerebrovascular disease or another neurological, mental, or systemic disease or condition likely contributing to cognitive decline).
- 2.** The Parkinson's disease clearly precedes the onset of neurocognitive disorder.

The AIDS virus may cause neurocognitive disorder in the later stages.

Estimates of how many individuals go on to develop neurocognitive disorders vary widely from 20% to 80%—although some researchers believe that all patients with Huntington's disease would eventually display neurocognitive impairments if they lived long enough (Marsh & Margolis, 2009). **Neurocognitive disorder due to Huntington's disease** also follows the subcortical pattern.

The search for the gene responsible for Huntington's disease reads like a detective story. For some time, researchers have known that the disease is inherited as an autosomal dominant disorder, meaning that approximately 50% of the offspring of an adult with Huntington's disease will develop the disease. Since 1979, behavioral scientist Nancy Wexler and a team of researchers have been studying the largest known extended family in the world afflicted by Huntington's disease in small villages in Venezuela. The villagers have cooperated with the research, partly because Wexler herself lost her mother, three uncles, and her maternal grandfather to Huntington's disease, and she, too, may develop the disorder (Wexler, 2012). Using genetic linkage analysis techniques (see Chapter 4), these researchers first mapped the deficit to an area on

chromosome 4 (Gusella et al., 1983) and then identified the elusive gene (Huntington's Disease Collaborative Research Group, 1993). Finding that one gene that causes a disease is unusual; research on other inherited mental disorders typically points to multiple gene (polygenic) influences.

Neurocognitive disorder due to prion disease is a rare progressive neurodegenerative disorder caused by “prions”—proteins that can reproduce themselves and cause damage to brain cells leading to neurocognitive decline (Collinge, 2012). Unlike other infectious agents such as bacteria or viruses, prions are thought by some to have no DNA or RNA that can be destroyed by chemicals or radiation. As a result, there is no known treatment for prion disease, and the course of this disorder is always fatal. On the positive side, prions are not contagious in humans and have only been contracted through cannibalism (causing kuru) or accidental inoculations (e.g., through blood transfusions from an infected person) (Collinge, 2012). One type of prion disease, **Creutzfeldt-Jakob disease**, is believed to affect only one in every million individuals (Heath et al., 2010; Sikorska, Knight, Ironside, & Liberski, 2012). An alarming development in the study of Creutzfeldt-Jakob disease is the finding of 10 cases of a new variant that may be linked to bovine spongiform encephalopathy, more commonly referred to as “mad cow disease” (Ebringer, 2015; Neugroschi et al., 2005).

This discovery led to a ban on exporting beef from the United Kingdom for a number of years because the disease might be transmitted from infected cattle to humans. Substance/Medication-Induced Neurocognitive Disorder

Prolonged drug use, especially combined with poor diet, can damage the brain and, in some circumstances, can lead to neurocognitive disorder. This impairment unfortunately lasts beyond the period involved in intoxication or withdrawal from these substances.

Description and Statistics

As many as 50% to 70% of chronic heavy alcohol users show cognitive impairment (Sico et al., 2014), and 7% of those with an

alcohol use disorder also meet criteria for a neurocognitive disorder (Neugroschi et al., 2005). The long-term abuse of a number of drugs can lead to symptoms of neurocognitive disorder, including alcohol, inhalants such as glue or gasoline (which some people inhale for the euphoric feeling they produce), and sedative, hypnotic, and anxiolytic drugs (see Chapter 11). These drugs pose a threat because they create physiological dependence, making it difficult for a user to stop ingesting them. The resulting brain damage can be permanent and can cause the same symptoms as seen in neurocognitive disorder due to Alzheimer's type. The DSM-5 criteria for **substance/medication-induced neurocognitive disorder** are essentially the same as many of the other forms of neurocognitive disorder; they include memory impairment and at least one of the following cognitive disturbances: aphasia (language disturbance), apraxia (inability to carry out motor activities despite intact motor function), agnosia (failure to recognize or identify objects despite intact sensory function), or a disturbance in executive functioning (such as planning, organizing, sequencing, and abstracting).

Causes of Neurocognitive Disorder

As our technology for studying the brain advances, so does our understanding of the many and varied causes of neurocognitive disorder. A complete description of what is known about the origins of this type of brain impairment is beyond the scope of this book, but we highlight some insights available for more common forms of this disorder.

Biological Influences

Cognitive abilities can be adversely compromised in many ways. As you have seen, neurocognitive disorder can be caused by a number of processes: Alzheimer's disease, Huntington's disease, Parkinson's disease, head trauma, substance abuse, and others. The most common cause of neurocognitive disorder, Alzheimer's disease, is also the most mysterious. Because of its prevalence and our relative ignorance about the factors responsible for it, Alzheimer's disease has held the attention of many researchers who are trying to find the cause and ultimately a treatment or cure for this devastating condition.

Findings from Alzheimer's research seem to appear almost daily. We should be cautious when interpreting the output of this fast-paced and competitive field; too often, as you have seen in other areas, findings are heralded prematurely as conclusive and important. Remember that "discoveries" of a single gene for bipolar disorder, schizophrenia, and alcoholism were later shown to be based on overly simplistic accounts. Similarly, findings from Alzheimer's research are sometimes too quickly sanctioned as accepted truths before they have been replicated, an essential validation process.

One lesson in scientific caution comes from research that demonstrates a negative correlation between cigarette smoking and Alzheimer's disease (Brenner et al., 1993). In other words, the study found that smokers are less likely than nonsmokers to develop Alzheimer's disease. Does this mean smoking has a protective effect, shielding a person against the development of this disease? On close examination, the finding may instead be the

result of the differential survival rates of those who smoke and those who do not. In general, nonsmokers tend to live longer and are thereby more likely to develop Alzheimer's disease, which appears later in life. Some even believe the relative inability of cells to repair themselves, a factor that may be more pronounced among people with Alzheimer's disease, may interact with cigarette smoking to shorten the lives of smokers who are at risk for Alzheimer's disease (Riggs, 1993). Put another way, smoking may exacerbate the degenerative process of Alzheimer's disease, causing people with the disease who also smoke to die earlier than nonsmokers who have Alzheimer's disease (Ashare, Karlawish, Wileyto, Pinto, & Lerman, 2012). These types of studies and the conclusions drawn from them should make us sensitive to the complicated nature of the disorders.

What do we know about Alzheimer's disease, the most common cause of neurocognitive disorder? After the death of the patient he described as having a "strange disease of the cerebral cortex," Alois Alzheimer performed an autopsy. He found that the brain contained large numbers of tangled, strandlike filaments within the brain cells (referred to as *neurofibrillary tangles*). This type of damage occurs in everyone with Alzheimer's disease. A second type of degeneration results from gummy protein deposits—called *amyloid plaques* (also referred to as *neuritic* or *senile plaques*)—that accumulate between the neurons in the brains of people with this disorder. Amyloid plaques are also found in older adults who do not have symptoms of neurocognitive disorder, but they have far fewer of them than do individuals with Alzheimer's disease (Richards & Sweet, 2009). Both forms of damage—neurofibrillary tangles and amyloid plaques—accumulate over the years and are believed to produce the characteristic cognitive disorders we have been describing (Weiner et al., 2012).

These two types of degeneration affect extremely small areas and can be detected only by a microscopic examination of the brain. As mentioned earlier, scientists are close, however, to

developing the neuroimaging technology and measures to assess amyloid proteins in spinal fluid that may soon detect the early development of these types of brain cell damage without having to rely on an autopsy (Weiner et al., 2012). In addition to having neurofibrillary tangles and amyloid plaques, over time the brains of many people with Alzheimer's disease atrophy (shrink) to a greater extent than would be expected through normal aging (Lovestone, 2012). Because brain shrinkage has many causes, however, only by observing the tangles and plaques can a diagnosis of Alzheimer's disease be properly made.

Rapid advances are being made toward uncovering the genetic bases of Alzheimer's disease (e.g., Seshadri et al., 2010). As with most other behavioral disorders we have examined, multiple genes seem to be involved in the development of Alzheimer's disease. Table 15.3 illustrates what we know so far. Genes on chromosomes 21, 19, 14, 12, and 1 have all been linked to certain forms of Alzheimer's disease (Neugroschi et al., 2005). The link to chromosome 21 was discovered first, and it resulted from the unfortunate observation that individuals with Down syndrome, who have three copies of chromosome 21 instead of the usual two, developed the disease at an unusually high rate (Report of the Advisory Panel on Alzheimer's Disease, 1995). More recent work has located relevant genes on other chromosomes. These discoveries indicate that there is more than one genetic cause of Alzheimer's disease. Some forms, including the one associated with chromosome 14, have an early onset. Pat Summitt was diagnosed with an early-onset form. In contrast, Alzheimer's disease associated with chromosome 19 seems to be a late-onset form of the disease that has an effect only after the age of about 60.

Some genes that are now identified are **deterministic**, meaning that if you have one of these genes you have a nearly 100% chance of developing Alzheimer's disease (Bettens, Sleegers, & Van Broeckhoven, 2010). Deterministic genes such as the precursor gene for small proteins called *amyloid beta peptides* (also referred to as beta-amyloid or A_b) and the *Presenilin 1* and *Presenilin 2* genes will inevitably lead to Alzheimer's disease, but, fortunately, these genes are also rare in the general population. For treatment purposes, this means that even if researchers can find a way to prevent these genes from leading to Alzheimer's disease, it will only help a relatively small number of people. On the other hand, some genes—including the *apolipoprotein E4* (*apo E4*) gene—are known as **susceptibility** genes. These genes only slightly increase the risk of developing Alzheimer's disease, but in contrast to the deterministic genes, these are more common in the general population.

(Lovestone, 2012). If future research can find ways to interfere with the *apo E4* gene, many people will be helped.

Although closing in on the genetic origins of Alzheimer's disease has not brought immediate treatment implications, researchers are nearer to understanding how the disease develops, which may result in medical interventions. Genetic research has advanced our knowledge of how the amyloid plaques develop in the brains of people with Alzheimer's disease and may hold a clue to its origins. In the core of the plaques is a solid waxy substance made up of a peptide called amyloid beta or Ab. Just as cholesterol buildup on the walls of blood vessels chokes the blood supply, deposits of Ab are believed by some researchers to cause the cell death associated with Alzheimer's disease (Lovestone, 2012). An important question, then, is "Why does this protein accumulate in the brain cells of some people but not of others?"

Two mechanisms that may account for amyloid protein buildup are being studied. The first involves *amyloid precursor protein* (APP), a large protein that is eventually broken down into the *amyloid protein* found in the amyloid plaques. Important work resulted in identifying the gene responsible for producing APP, on chromosome 21 (Lovestone, 2012). This finding may help integrate two observations about Alzheimer's disease: (1) APP produces the amyloid protein found in the amyloid plaques, and (2) Down syndrome, associated with an extra 21st chromosome, results in a higher incidence of the disease (see Chapter 14). The gene responsible for producing APP and, ultimately, amyloid protein, may be responsible for the relatively infrequent early-onset form of the disease, and its location could explain why people with Down syndrome—who have an extra 21st chromosome and therefore an extra APP gene—are more likely than the general population to develop Alzheimer's disease.

A second, more indirect way that amyloid protein may build up in brain cells is through *apolipoprotein E* (*apo E*), which normally helps transport cholesterol, including amyloid protein, through the bloodstream. There are at least three forms of this transporter protein: *apo E2*, *apo E3*, and *apo E4*. Individuals who have late-onset Alzheimer's disease, the most common form, are likely to carry the gene associated with *apo E4*, located on chromosome 19. Researchers have found that the majority of people with Alzheimer's disease who also have a family history of the disease will have at least one gene for *apo E4* (Lovestone, 2012). In contrast, approximately 64% of individuals with Alzheimer's disease who have no family history of the disease have at least one gene for *apo E4*, and only 31% of nonaffected individuals have the gene. Having two genes for *apo E4* (one on each member of the chromosome 19 pair) increases the risk for Alzheimer's disease: As many as 90% of people with two genes developed Alzheimer's disease (Reiman et al., 2007). In addition, having two *apo E4* genes seemed to decrease the mean age of onset from 84 years to 68 years. These results suggest that *apo E4* may be responsible for late-onset Alzheimer's disease and that a gene on chromosome 19 is responsible.

What is still not completely understood is how *apo E4* causes amyloid proteins to build up in the neurons of people who ultimately exhibit Alzheimer's disease and whether this process is responsible for the disease. One recent study examined the role of high blood pressure in creating amyloid proteins when interacting

with *apo E4* genotype in healthy adults. The study found that hypertension alone or *apo E4* alone did not increase amyloid deposits. However, healthy individuals with at least one *apo E4* gene and untreated high blood pressure had the greatest risk for amyloid proteins deposits. Also, the higher the blood-pressure, the more amyloid proteins deposits were found. On the other hand, those with high blood pressure under medical control had only slightly higher levels of amyloid deposits than people without it (Rodrigue et al., 2013).

Similarly, researchers are also examining potential gene-environment interactions in development of Alzheimer's disease. Several studies suggest a few areas of promise. One study found that having the *apo E4* genotype was more likely to produce cognitive decline in those persons living in stressful environments—suggesting a gene (*apo E4*)—environment (stress) interaction (Boardman, Barnes, Wilson, Evans, & de Leon, 2012). Another study found that among African Americans, having low levels of cholesterol seemed to reduce risk of Alzheimer's disease—but only among those who did not carry the *apo E4* gene (Evans et al., 2000). Finally, researchers found that physical exercise reduced the likelihood of developing the disease but, like the previous study, only among those without the *apo E4* gene (Podewils et al., 2005). This type of research holds the potential for better understanding the complex nature of Alzheimer's disease and may lead to important prevention strategies (such as lowering cholesterol levels and exercising regularly) (Pedersen, 2010).

For all disorders described in this book, we have identified the role of biological, psychological, or both types of stressors as partially responsible for the onset of the disorder. Does neurocognitive disorder due to Alzheimer's disease—which appears to be a strictly biological event—follow the same pattern? One of the leading candidates for an external contributor to this disorder is head trauma. As we have seen, it appears that repeated blows to the head can bring on neurocognitive disorder (chronic traumatic encephalopathy or CTE). Fighters who carry the *apo E4* gene may be at greater risk for developing neurocognitive disorder attributed to head trauma (Jordan et al., 1997). In addition to boxers, new research suggests links to the trauma experienced by NFL players and the

Nancy Wexler headed the team of scientists who found the gene for Huntington's disease.

development of CTE in these former athletes (Stamm et al., 2015). Head trauma may be one of the stressors that initiate the onset of neurocognitive disorder of varying types. Other such stressors include having diabetes, high blood pressure, or herpes simplex virus-1 (Richards & Sweet, 2009). As with each of the disorders discussed, psychological and biological stressors may interact with physiological processes to produce Alzheimer's disease.

We opened the section with a word of caution, which it is appropriate at this point to repeat. Some of the findings just reviewed are considered controversial, and many questions remain to be answered about neurocognitive disorder and one of its most common causes, Alzheimer's disease.

Psychological and Social Influences

Research has mostly focused on the biological conditions that produce neurocognitive disorder. Although few would claim that psychosocial influences directly cause the type of brain deterioration seen in people with neurocognitive disorder, they may help determine onset and course. For example, a person's lifestyle may involve contact with factors that can cause neurocognitive disorder. You saw, for instance, that substance abuse can lead to neurocognitive disorder and, as we discussed previously (see Chapter 11), whether a person abuses drugs is determined by a combination of biological and psychosocial factors. In the case of vascular neurocognitive disorder, a person's biological vulnerability to vascular disease will influence the chances of strokes that can lead to this form of disorder. Lifestyle issues such as diet, exercise, and stress influence cardiovascular disease and therefore help determine who experiences vascular neurocognitive disorder (see Chapter 9).

Cultural factors may also affect this process. For example, hypertension and strokes are more prevalent among African Americans and subgroups of Asian Americans than non-Hispanic whites (Howard et al., 2013; King, Mainous III, & Geesey, 2007). This may explain why vascular neurocognitive disorder is also more often observed in members of these groups. In an extreme example, exposure to prion disease can lead to neurocognitive disorder described previously as *kuru*. Prions can be passed on through a ritual form of cannibalism practiced in Papua New Guinea as a part of mourning (Collinge et al., 2006; Collinge et al., 2008). Neurocognitive disorder caused by head trauma and malnutrition are relatively prevalent in preindustrial rural societies (Del Parigi, Panza, Capurso, & Solfrizzi, 2006). Not getting enough of vitamins B₉ and B₁₂, in particular seems to lead to neurocognitive disorder, although the process is as yet unknown (Michelakos et al., 2013). These findings suggest that occupational safety (such as protecting workers from head injuries) and economic conditions influencing diet also affect the prevalence of certain forms of neurocognitive disorders. It is apparent that psychosocial factors help influence who does and who does not develop certain forms of neurocognitive disorder. Brain deterioration is a biological process but, as you have seen throughout this text, even biological processes are influenced by psychosocial factors.

Psychosocial factors themselves influence the course of neurocognitive disorder. Recall that educational attainment may affect the onset of dementia (Amieva et al., 2014). Having certain

skills may help some people cope better than others with the early stages of neurocognitive disorder. The early stages of confusion and memory loss may be better tolerated in cultures with lowered expectations of older adults. In certain cultures, including the Chinese, younger people are expected to take the demands of work and care from older adults after a certain age, and symptoms of dementia are viewed as a sign of normal aging (Sun, Ong, & Burnette, 2012; Hinton, Guo, Hillygus, & Levkoff, 2000). Neurocognitive disorder may go undetected for years in these societies (Sosa-Ortiz et al., 2012).

Much remains to be learned about the cause and course of most types of neurocognitive disorder. As you saw with Alzheimer's disease and Huntington's disease, certain genetic factors make some individuals vulnerable to progressive cognitive deterioration. In addition, brain trauma, some diseases, and exposure to certain drugs, such as alcohol, inhalants, and sedative, hypnotic, and anxiolytic drugs, can cause the characteristic decline in cognitive abilities. We also noted that psychosocial factors can help determine who is subject to these causes and how they cope with the condition. Looking at neurocognitive disorder from this integrative perspective should help you view treatment approaches in a more optimistic light. It may be possible to protect people from conditions that lead to neurocognitive disorder and to support them in dealing with the devastating consequences of having it. We next review attempts to help from both biological and psychosocial perspectives.

Treatment

For many of the disorders discussed in other chapters, treatment prospects are fairly good. Clinicians can combine various strategies to reduce suffering significantly. Even when treatment does not bring expected improvements, mental health professionals have usually been able to stop problems from progressing. This is not the case in the treatment of neurocognitive disorder.

One factor preventing major advances in the treatment of neurocognitive disorder is the nature of the damage caused by this disorder. The brain contains billions of neurons, many more than are used. Damage to some can be compensated for by others because of plasticity. There is a limit to where and how many neurons can be destroyed, however, before vital functioning is disrupted. Researchers are closing in on how to use the brain's natural process of regeneration to potentially reverse the damage caused in neurocognitive disorder (e.g., Wright, Kawas, & Harding, 2015). Currently, however, with extensive brain damage, no known treatment can restore lost abilities. The goals of treatment therefore become (1) trying to prevent certain conditions, such as substance abuse or strokes, that may bring on neurocognitive disorder; (2) trying to delay the onset of symptoms to provide better quality of life; and (3) attempting to help these individuals and their caregivers cope with the advancing deterioration. Most efforts in treating neurocognitive disorder have focused on the second and third goals, with biological treatments aimed at stopping the cerebral deterioration and psychosocial treatments directed at helping patients and caregivers cope.

A troubling statistic further clouds the tragic circumstances of neurocognitive disorder. In one study, more than 60% of caregivers

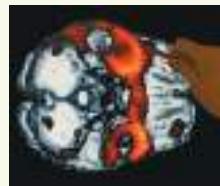

of people with neurocognitive disorder—usually relatives—have the symptoms characteristic of one or more anxiety disorders (55% of these caregivers had anxiety) and/or clinical depression (37% of the caregivers had depression) (Joling et al., 2015). Compared with the public, these caregivers use more psychotropic medications (designed to reduce symptoms of various psychological disorders) and report stress symptoms at 3 times the normal rate. Caring for people with neurocognitive disorder, especially in its later stages, is clearly a trying experience. In fact, there is some evidence to suggest that the stress associated with caring for a person with neurocognitive disorder may place the caregiver at greatly increased risk for developing neurocognitive disorder themselves (Norton et al., 2010). As a result, clinicians are becoming increasingly sensitive to the needs of these caregivers, and research is now exploring interventions that are easy to disseminate (such as over the internet) to assist them in caring for people with neurocognitive disorder. Preliminary results from such interventions are promising and have important implications for the caregivers of the “baby-boomer” generation (Blom, Bosmans, Cuijpers, Zarit, & Pot, 2013).

Biological Treatments

Neurocognitive disorder resulting from known infectious diseases, nutritional deficiencies, and depression can be treated if it is caught early. Unfortunately, however, no known treatment exists for the types of neurocognitive disorder that account for the vast majority of cases. Neurocognitive disorder caused by stroke, Parkinson’s disease, or Huntington’s disease is not currently treatable, because there is no effective treatment for the primary disorder. However, exciting research in several related areas has brought us closer to helping individuals with these forms of neurocognitive disorder. A substance that may help preserve and perhaps restore neurons—glial cell-derived neurotrophic factor—may someday be used to help reduce or reverse the progression of degenerative brain diseases (Lu, Nagappan, Guan, Nathan, & Wren, 2013). Researchers are also looking into the possible benefits of transplanting stem cells (fetal brain tissue) into the brains of people with such diseases. Initial results from these studies are still preliminary but appear promising (Pen & Jensen, 2016). Neurocognitive disorder brought on by strokes may now be more preventable by new drugs that help prevent much of the damage inflicted by the blood clots characteristic of stroke (Erkinjuntti, 2012). Most current attention is on a treatment for dementia of the Alzheimer’s type, because it affects so many people. Here, too, however, success has been modest at best.

Much work has been directed at developing drugs that will enhance the cognitive abilities of people with neurocognitive disorder due to Alzheimer’s type. Many seem to be effective

initially, but long-term improvements have not been observed in placebo-controlled studies (Richards & Sweet, 2009). Several drugs (called *cholinesterase inhibitors*) have had a modest impact on cognitive abilities in some patients and include donepezil (Aricept), rivastigmine (Exelon), and galantamine (Reminyl) (Trinh, Hoblyn, Mohanty, & Yaffe, 2003). *Tacrine hydrochloride* (Cognex), another in this family of drugs, is rarely used today because of the potential for liver damage (Rabins, 2006). These drugs prevent the breakdown of the neurotransmitter acetylcholine (which is deficient in people with Alzheimer’s disease), thus making more acetylcholine available to the brain. Research suggests that, when using these drugs, people’s cognitive abilities improve to the point where they were 6 months earlier (Kimchi & Lyketsos,

2015). But the gain is not permanent. Even people who respond positively do not stabilize but continue to experience the cognitive decline associated with Alzheimer’s disease. In addition, if they stop taking the drug—as almost three quarters of the patients do because of negative side effects such as liver damage and nausea—they lose even that 6-month gain (Kimchi & Lyketsos, 2015). Newer drugs are now being investigated for the treatment of Alzheimer’s disease. These include drugs that target the beta amyloid (plaques) in the brain, and it is hoped that these advances will finally provide a positive prognosis for this devastating disease (Lukiw, 2012; McClam, Marano, Rosenberg, & Lyketsos, 2015).

Several other medical approaches are being explored to slow the course of Alzheimer’s disease, but initial excitement generated by these approaches has waned with the findings from researchers. For example, most of you have heard of using *Ginkgo biloba* (maidenhair) to improve memory. Initial research suggested that this herbal remedy may produce modest improvements in the memory of people with Alzheimer’s disease, but other studies have not replicated this benefit (Vellas et al., 2012). Similarly, the effects of vitamin E have been evaluated. A few large studies have found that among individuals with moderately severe impairment, high doses of the vitamin (2,000 international units per day) delayed progression compared with a placebo (Dysken et al., 2014; Sano et al., 1997), but it did not prevent the development of the disease. Further research, in fact, indicates that taking high doses of vitamin E may actually increase mortality and therefore this intervention is no longer recommended (Richards & Sweet, 2009). Modest slowing of the progression of the disease also may be obtained by introducing exercise to patients (Paillard, Rolland, & de Souto Barreto, 2015). To date, however, no medical interventions are available that directly treat and therefore stop the progression of the conditions that cause the cerebral damage in Alzheimer’s disease.

Medical interventions for neurocognitive disorder also include the use of drugs to help with some associated symptoms. A variety of antidepressants—such as serotonin-specific reuptake inhibitors—are commonly recommended to alleviate the

depression and anxiety that too often accompany the cognitive decline. Antipsychotic medication is sometimes used for those who become unusually agitated (Richards & Sweet, 2009).

Other researchers are targeting vaccines that would potentially treat and prevent—rather than just delay—the symptoms of Alzheimer's disease. Much of the research is attempting to get the immune system to attack the process that overproduces the small proteins (Ab) that lead to cell death. Prior efforts had to be abandoned because of the severe negative side effects of the vaccine, which included serious brain inflammation. More recent research with humans and animals indicates that there may be several vaccines that could be effective in preventing the damage caused by Ab formation and therefore represent the first glimmer of hope for patients and their families (Davtyan et al., 2013).

This type of research currently begins with transgenic mice—mice in which the DNA has been altered. In the case of testing an Alzheimer's vaccine, the mice DNA is engineered to produce the same small proteins thought to be responsible for the neurocognitive disorder. Mice are good subjects because they age rapidly, with a 22-month-old mouse equivalent to a 65-year-old human (Davtyan et al., 2013; Morgan, 2007). This allows researchers to study how the brain reacts to the potential vaccine if it has already started the progression of Alzheimer's. If the results are promising in these transgenic mice, only then do researchers try small studies with humans. Researchers are optimistic that there may finally be intervention approaches that would reverse the current trend of increasing numbers of people with neurocognitive disorder. Next we describe psychosocial approaches that are used with medication to address the variety of problems that accompany memory difficulties.

Psychosocial Treatments

Psychosocial treatments are now receiving a great deal of attention for their ability to delay the onset of severe cognitive decline. These efforts focus on enhancing the lives of people with neurocognitive disorder, as well as those of their families.

People with neurocognitive disorder can be taught skills to compensate for their lost abilities. Some researchers have evaluated formal adaptations to help people in the early stages of neurocognitive disorder. Michelle Bourgeois (2007) created "memory wallets" to help people with Alzheimer's disease carry on conversations. On white index cards inserted into a plastic wallet are printed declarative statements such as, "My husband John and I have 3 children," or "I was born on January 6, 1921, in Pittsburgh." In one of her studies, Bourgeois (1992) found that adults with neurocognitive disorder due to Alzheimer's disease could, with minimal training, use this memory aid to improve their conversations with others. With advances in technology such as tablet computers that can be programmed to "speak" for the person, adaptations such as these help people communicate with others, help them remain aware of their surroundings, and can reduce

the frustration that comes with the awareness of their own decline (Fried-Oken et al., 2012).

Cognitive stimulation—encouraging people with neurocognitive disorder to practice learning and memory skills—seems to be an effective method for delaying the onset of the more severe cognitive effects of this disorder (Aguirre, Woods, Spector, & Orrell, 2013; Woods, Aguirre, Spector, & Orrell, 2012). These activities include word games, tests of memory of famous and familiar faces, and practice with numbers (for example, how much change back you would receive from a purchase). These types of skill-building exercises can maintain cognitive activity and improve the quality of life in those patients when compared with controls (Choi & Twamley, 2013).

What impact do the medical and nonmedical treatments have on those with Alzheimer's disease? Figure 15.2 illustrates how these interventions may delay the worst of the symptoms—essentially compressing the time when the person is most impaired (Becker, Mestre, Ziolko, & Lopez, 2007). The red line illustrates the typical course of the disease, which results in 3 to 5 years of severe impairment before death. However, with the interventions we highlighted (illustrated by the purple line), people are able to live more fully for a longer period, despite the still-inevitable impairment and death. Families find this extra time with their loved ones to be invaluable, and hopefully, with more advancements, we will see progress on improving mortality rates of this progressive disease.

Individuals with advanced neurocognitive disorder are not able to feed, bathe, or dress themselves. They cannot communicate with or recognize even familiar family members. They may wander away from home and become lost. Because they are no longer aware of social stigma, they may engage in public displays of sexual behavior, such as masturbation. They may be frequently agitated

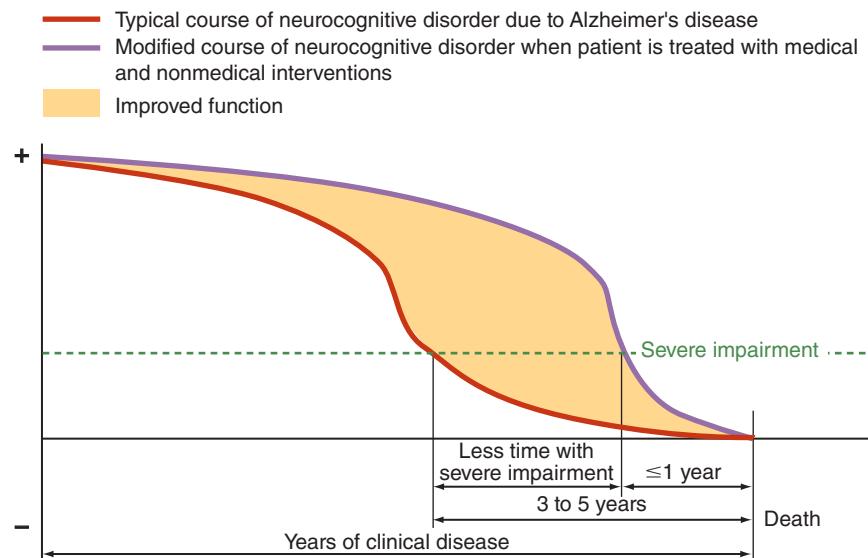

FIGURE 15.2

or even physically violent. To help both the person with dementia and the caregiver, researchers have explored interventions for dealing with these consequences of the disorder (Lovestone, 2012). For example, some research indicates that a combination of exercise for patients and instruction for caregivers on how to handle behavior problems can improve the overall health and the depression in people with Alzheimer's disease (Potter, Ellard, Rees, & Thorogood, 2011; Teri et al., 2003).

Of great concern is the tendency of people with neurocognitive disorder to wander. Sometimes they wind up in places or situations that may be dangerous (for example, stairwells or the street). Sometimes the person may be tied to a chair or bed, or sedated, to prevent roaming. Unfortunately, physical and medical restraint has its own risks, including additional medical complications; it also adds greatly to the loss of control and independence that already plague the person with neurocognitive disorder. Psychological treatment as an alternative to restraint sometimes involves providing cues for people to help them safely navigate around their home or other areas. New innovations in surveillance technology—creating a “smart home” that can monitor the location of the patient and warn caregivers—may provide more piece of mind for those who care for these patients. At the same time, ethical concerns are being raised about the use of this technology because of its ability to invade privacy (Bharucha et al., 2009; Chung, Demiris, & Thompson, 2016).

Someone with neurocognitive disorder can become agitated and sometimes verbally and physically aggressive. This behavior is understandably stressful for people trying to provide care. In these situations, medical intervention is often used, although many times with only modest results (Testad, Ballard, Brønnick, & Aarsland, 2010). Some research suggests that teaching communication skills in a manner similar to programs for persons with autism spectrum disorder (Durand, 2012) may help reduce aggressive behavior in persons with neurocognitive disorder (Livingston et al., 2014). In addition, caregivers are often given assertiveness training to help them deal with hostile behaviors (see Table 15.4). Some caregivers

may either passively accept all criticism inflicted by the person with neurocognitive disorder, which increases stress, or become angry and aggressive in return. This last response is of particular concern because of the potential for elder abuse. Withholding food or medication or inflicting physical abuse is most common among caregivers of elderly people who have cognitive deficits. Research has also shown that elder abuse occurs in nursing home and assisted living, with neglect and emotional abuse being the most common in these settings (Castle, Ferguson-Rome, & Teresi, 2015; Post, Page, Conner, & Prokhorov, 2010). It is important to teach caregivers how to handle stressful circumstances so that they do not escalate into abusive situations. Not a great deal of objective evidence supports the usefulness of assertiveness training for reducing caregiver stress, and more research is needed to guide future efforts.

In general, families of people with mild to moderate neurocognitive disorder can benefit from supportive counseling to help

them cope with the frustration, depression, guilt, and loss that take a heavy emotional toll. Clinicians must first recognize, however, that the ability to adapt to stressors differs among people. One study, for example, found cultural differences in the coping styles of caregivers. In one area of rural Alabama, white caregivers used acceptance and humor as coping strategies, and black caregivers used religion and denial (Kosberg, Kaufman, Burgio, Leeper, & Sun, 2007). Another large-scale study of 555 principal caregivers over a 3-year period identified a number of steps that can be taken to support caregivers through this difficult time (Aneshensel, Pearlin, Mullan, Zarit, & Whitlatch, 1995). Despite numerous studies aimed at supporting caregivers, however, the results to date remain weak and additional work is needed to determine how best to support these individuals (Schoenmakers, Buntinx, & DeLepeleire, 2010; Tremont et al., 2015).

Early on, caregivers need basic information on the causes and treatment of neurocognitive disorder, financial and legal issues, and locating help for the patient and the family. As the disorder progresses, and the affected person requires increasing amounts of assistance, caregivers will need help managing behavioral difficulties (wandering away or violent outbursts) and developing effective ways to communicate with the patient. Clinicians also assist the family with decisions about hospitalizations and, finally, help them adjust during bereavement. However, the best methods to help caregivers help others are still being explored (Peeters, Van Beek, Meerveld, Spreeuwenberg, & Francke, 2010; Zabalegui et al., 2014).

Overall, the outlook for slowing (but not stopping) the cognitive decline characteristic of neurocognitive disorder is optimistic. The best available medications provide some recovery of function, but they do not stop the progressive deterioration. Psychological interventions may help people cope more effectively with the loss of cognitive abilities, especially in the earlier stages of this disorder. In addition, emphasis is placed on helping caregivers—the other victims of neurocognitive disorder—as the person they care for continues to decline.

Prevention

Without treatment, we need to rely even more heavily on prevention strategies for neurocognitive disorder. You can imagine that it is difficult to study prevention efforts for neurocognitive disorder because of the need to follow individuals for long periods to see whether the efforts are effective. One major study conducted in Sweden—where socialized medicine provides complete medical histories of all residents—looked at many of the risk factors (those

factors that increase the chance of having neurocognitive disorder) and protective factors (those that decrease the risk) under study today (Fratiglioni & Qiu, 2009; Fratiglioni, Winblad, & von Strauss, 2007). They looked at the medical records of 1,810 participants who were older than 75 at the time and followed them for about 13 years. Through interviews and medical histories, they came to three major conclusions: control your blood pressure, do not smoke, and lead an active physical and social life! These recommendations came out as the major factors that individuals can change—because you cannot change your genetics, for example—that will decrease the chances of developing neurocognitive disorder (Rizzuto, Orsini, Qiu, Wang, & Fratiglioni, 2012). Additional prevention research is ongoing, and there may be other potentially fruitful research areas that can lead to the successful prevention of this devastating disorder.

DSM Controversies: Is Normal Aging a Mental Disorder?

Researchers and clinicians have, for some time, recognized that many older adults begin to show cognitive decline in areas such as memory that is more pronounced than expected for their age and begins to affect their daily functioning (Petersen et al., 1999). This interest in the distinction between the normal forgetting that occurs as we age and the onset of neurocognitive disorder is motivated by a desire to both understand the progression of the cognitive changes that accompany neurocognitive disorder and to attempt early intervention. In response to this concern, DSM-5 introduced a new psychiatric disorder—**mild neurocognitive disorder**—to categorize the condition and bring it to the attention of clinicians (Ganguli et al., 2011).

This proposed distinction is consistent with some of the breakthroughs in diagnoses involving improved brain scanning and identification of biomarkers that we covered earlier in this chapter (Weiner et al., 2012). Researchers are becoming more sophisticated in their ability to identify beginning signs of neurocognitive disorder,

which not only allows for early diagnosis but also can highlight for clinicians the need to track cognitive abilities over time. However, this new disorder raised concerns among some in the field (Rabins & Lyketsos, 2011).

First, the distinction between “major” and “mild” neurocognitive disorder is a difficult one to make. DSM-5 attempts to quantify the declines by tying the diagnosis to cognitive test performance in the range of 122 standard deviations below what would be expected for a person of that age (American Psychiatric Association, 2013). Below-average performance does not necessarily mean, however, that the person has declining cognitive function. That can be assessed only if performance was measured through cognitive assessment *before* the decline occurred. But, it has been argued, routine cognitive testing is not typically done on adults until after some concern is raised, making conclusions about changes in functioning problematic (Frances, 2010).

A second concern is one that is relevant for a number of other disorders as well. The addition of new disorders

(such as mild neurocognitive disorder as well as others such as premenstrual mood dysphoric disorder) and the broadening of the definitions of others have some concerned that eventually most people will meet the criteria for one or more psychiatric disorders. In the case of mild neurocognitive disorder, will we be labeling people—and perhaps prescribing drugs—to those who exhibit normal forgetting related to age? As a whole, the consequences of these changes across DSM-5 are not trivial (Frances, 2010). Pharmaceutical companies are incentivized to find more customers for psychiatric drugs and therefore expanding the number of people with a diagnosis could increase business. The legal system could be impacted with a greater number of people using “mental illness” as a mitigating factor in their defense. These issues are far from being resolved and it is important to note that DSM-5 is a work in progress that will hopefully evolve with our expanding scientific understanding of the nature and causes of all of the maladies impacting us.

Summary

Delirium

- ▶ Delirium is a temporary state of confusion and disorientation that can be caused by brain trauma, intoxication by drugs or poisons, surgery, and a variety of other stressful conditions, especially among older adults.

Major and Mild Neurocognitive Disorders

- ▶ Neurocognitive disorder is a progressive and degenerative condition marked by gradual deterioration of a range of cognitive abilities including memory, language, and planning, organizing, sequencing, and abstracting information.
- ▶ Mild neurocognitive disorder is a condition in which there are early signs of cognitive decline such that it begins to interfere with activities of daily living.

- ▶ Alzheimer’s disease is the leading cause of neurocognitive disorder, affecting approximately 4 million people in the United States; there is currently no known cause or cure.
- ▶ To date, there is no effective treatment for the irreversible neurocognitive disorder caused by Alzheimer’s disease, Lewy bodies, vascular disease, Parkinson’s disease, Huntington’s disease, and various less common conditions that produce progressive cognitive impairment. Treatment often focuses on helping patients cope with the continuing loss of cognitive skills and helping caregivers deal with the stress of caring for affected individuals.

Exploring Neurocognitive Disorders

- When the brain is damaged, the effects are irreversible, accumulating until learning, memory, or consciousness are obviously impaired.
- Neurocognitive disorders develop much later than intellectual disability and other learning disorders, which are believed to be present at birth.

Perspectives on Mental Health Law

We begin this chapter with a return to Arthur, whom we described in Chapter 13 as having psychotic symptoms. Revisiting the case from his family's perspective reveals the complexities of mental health law and the ethical aspects of working with people who have psychological disorders.

Arthur... A Family's Dilemma

As you remember, Arthur was brought to our clinic by family members because he was speaking and acting strangely. He talked incessantly about his “secret plan” to save all the starving children in the world. His family’s concern intensified when Arthur said he was planning to break into the German embassy and present his plan to the German ambassador. Alarmed by his increasingly inappropriate behavior and fearing he would be hurt, the family was astounded to learn they could not force him into a psychiatric hospital. Arthur could admit himself—which was not likely, given his belief that nothing was wrong with him—but they had no power to admit him involuntarily unless he was in danger of doing harm to himself or others. Even if they sincerely believed some harm might be forthcoming, this wasn’t sufficient reason to admit him involuntarily. The family coped with this emergency as best they could for several weeks until the worst of Arthur’s behaviors began to diminish.

Arthur suffered from what is known as brief psychotic disorder (see Chapter 13). Fortunately for him, this is one of the few psychotic disorders that is not chronic. What is important here is to see how the mental health system responded. Because Arthur had not hurt himself or someone else, he had to seek help on his own before the hospital would assist him, even though everyone involved realized that such action on his part was unlikely. This response by the mental health system added one more layer of helplessness to the family’s already desperate emotional state. Why wouldn’t the mental health facility admit Arthur, who was clearly out of touch with reality and in need of help? Why couldn’t his own family authorize the mental health facility to act? What

would have happened if Arthur had entered the German embassy and hurt or, worse, killed someone? Would he have gone to jail, or would he have finally received help from the mental health community? Would Arthur have been held responsible if he hurt other people while he was delusional? These are just a few of the many issues that surface when we try to balance the rights of people who have psychological disorders with the responsibilities of society to provide care.

Mental health professionals face such questions daily. They must both diagnose and treat people and consider individual and societal rights and responsibilities. As we describe how systems of ethics and legal concepts have developed, remember they change with time and with shifting societal and political perspectives on mental illness. How we treat people with psychological disorders is partly a function of how society views these people. For example, do people with mental illness need help and protection, or does society need protection from them? As public opinion about people with mental illness changes, so do the relevant laws and legal and ethical issues affect both research and practice. As you will see, the issues affecting research and practice are often complementary. For example, confidentiality is required to protect the identity of a participant in a research study and of a patient seeking help for a psychological disorder. Because people who receive mental health services often simultaneously participate in research studies, we must consider the concerns of both constituencies.

Civil Commitment

The legal system exercises significant influence over the mental health system, for better or for worse. Laws have been designed to protect people who display abnormal behavior and to protect society. Often, achieving this protection is a delicate balancing act, with the scales sometimes thought to be tipped in favor of the rights of individuals and at other times in favor of society. For example, each state has **civil commitment laws** that detail when a person can be legally declared to have a mental illness and be placed in a hospital for treatment (Nunley, Nunley, Cutleb, Dentingeh, & McFahland, 2013). When Arthur’s family tried to have him involuntarily committed to a mental health facility, hospital officials decided that because he was not in imminent danger of hurting himself or others he could not be committed against his

will. In this case, the laws protected Arthur from involuntary commitment, but they also put him and others at potential risk by not compelling him to get help. In a now-classic book, La Fond and Durham (1992) argue that two clear trends in mental health law are evident in the recent history of the United States. According to these authors, a “liberal era” from 1960 to 1980 was characterized by a commitment to individual rights and fairness. In contrast, 1980 to the present has been a “neoconservative era,” partly in reaction to the liberal reforms of the 1960s and 1970s that focused on majority concerns, including law and order. In the liberal era, the rights of people with mental illness dominated; in the neoconservative era, the rights of people with mental illness have been limited to provide greater protection to society.

Civil commitment laws in the United States date back to the late 19th century. Before this time, almost all people with severe mental illness were cared for by family members or the community or were left to care for themselves. An alarming trend accompanied the development of a large public hospital system devoted to treating such individuals: involuntary commitment of people for reasons unrelated to mental illness (Simon & Shuman, 2009). There were even instances in which women were committed to psychiatric hospitals by their husbands simply for holding differing personal or political views. In the 1800s, Mrs. E. P. W. Packard crusaded for better civil commitment laws after being involuntarily confined to a psychiatric hospital for 3 years because her husband felt her religious views were “dangerous to the spiritual interests of his children and the community” (Packard & Olsen, 1871; p. 11).

Criteria for Civil Commitment

Historically, states have permitted commitment when several conditions have been met: (1) The person has a “mental illness” and is in need of treatment, (2) the person is dangerous to himself or herself or others, or (3) the person is unable to care for himself, a situation considered a “grave disability.” How these conditions are interpreted has varied over the years and has always been controversial. Two types of authority permit the government to take actions that are against a citizen’s will: police power and *parens*

patriae (“state or country as the parent”) power. Under police power, the government takes responsibility for protecting the public health, safety, and welfare and can create laws and regulations to ensure this protection. Criminal offenders are held in custody if they are a threat to society. The state applies *parens patriae* power when citizens are not likely to act in their own best interest; for example, to assume custody of children who have no living parents. Similarly, it is used to commit individuals with severe mental illness to mental health facilities when it is believed that they might be harmed because they are unable to secure the basic necessities of life, such as food and shelter (grave disability), or because they do not recognize their need for treatment (Nunley et al., 2013). Under *parens patriae* power, the state acts as a surrogate parent, presumably in the best interests of a person who needs help.

A person in need of help can always voluntarily request admission to a mental health facility; after an evaluation by a mental health professional, a patient may be accepted for treatment. When an individual does not voluntarily seek help but others feel that treatment or protection is necessary, however, the formal process of civil commitment can be initiated. The specifics of this process differ from state to state, but it usually begins with a petition by a relative or mental health professional to a judge. The court may then request an examination to assess psychological status, ability for self-care, need for treatment, and potential for harm. The judge considers this information and decides whether commitment is appropriate. This process is similar to other legal proceedings, and the person under question has all the rights and protections provided by the law. In most states, the person can even request that a jury hear the evidence and make a determination. In all cases, the person must be notified that the civil commitment proceedings are taking place, must be present during the trial, must have representation by an attorney, and can examine the witnesses and request an independent evaluation. These safeguards are built into the civil commitment process to guarantee the rights of the person being examined and to ensure that no one is involuntarily committed to a psychiatric facility for other than legitimate reasons.

Another route to civil commitment is being adopted by some states: court-ordered assisted outpatient treatment (AOT) (Nunley et al., 2013). In this option, the person with severe

mental illness agrees to receive treatment as a condition for continuing to live in the community. These AOT laws provide a balance between the individual's right to live independently and the community's concerns about safety (Nunley et al., 2013).

In emergency situations, when there is clearly immediate danger, a short-term commitment can be made without the formal proceedings required of a civil commitment. Family members or sometimes police officers certify that the person presents a "clear and present danger" to herself or to others (Nunley et al., 2013). Arthur's family was unsuccessful in having him admitted on an emergency basis because it was not clear that anyone was in immediate danger, only that someone might be hurt. Again, deciding what is a "clear and present danger" sometimes requires a great deal of subjective judgment from the court and from mental health professionals.

Defining Mental Illness

The concept of mental illness figures prominently in civil commitment, and it is important to understand how it is defined. **Mental illness** is a legal concept, typically meaning severe emotional or thought disturbances that negatively affect an individual's health and safety. Each state has its own definition. For example, in New York, "Mental illness means an affliction with a mental disease or mental condition which is manifested by a disorder or disturbance in behavior, feeling, thinking, or judgment to such an extent that the person afflicted requires care, treatment and

rehabilitation" (*New York Mental Hygiene Law*, 1992). In contrast, in Connecticut, "Mentally ill person" means a person who has a mental or emotional condition that has substantial adverse effects on his or her ability to function and who requires care and treatment, and specifically excludes a person who is an alcohol-dependent person or a drug-dependent person" (Connecticut General Statutes Annotated, 1992). Many states exclude cognitive disability or substance-related disorders from the definition of mental illness.

Mental illness is *not* synonymous with psychological disorder; in other words, receiving a diagnosis according to the *Diagnostic and Statistical Manual (DSM-5)* does not necessarily mean that a person's condition fits the legal definition of mental illness. Although the *DSM* is quite specific about criteria that must be met for diagnosis, there is considerable ambiguity about what constitutes a "mental condition" or what are "adverse effects on his or her ability to function." This allows flexibility in making decisions individually, but it also maintains the possibility of subjective impression and bias as influences on these decisions.

Dangerousness

Assessing whether someone is a danger to self or others is a critical determinant of the civil commitment process. **Dangerousness** is a particularly controversial concept to describe people with mental illness: according to popular opinion, people who are mentally ill are more dangerous than those who are not (Kobau, Dilorio, Chapman, & Delvecchio, 2010; Schomerus et al., 2012). Although this conclusion is questionable, it is still widespread, partly because of sensational media reports. Such views are important to the process of civil commitment if they bias a determination of dangerousness and unfairly link it with severe mental illness.

The results of research on dangerousness and mental illness are often mixed, but evidence points to a moderately increased rate of violence among people with mental illness (Elbogen & Johnson, 2009; Elbogen, Dennis, & Johnson, in press). Closer examination of this kind of research reveals that although having a mental illness generally does increase the likelihood of future violence, specific factors such as a high anger predisposition, recent stressors (e.g., victimization) and substance use are likely responsible for the increased risk of violence (Elbogen et al., in press). It is also the presence of these risk factors that may predict the reoccurrence of perpetrated violent crimes by individual with mental illness.

Unfortunately, the widely held misperception that people with mental illness are more dangerous may differentially affect ethnic minorities (Vinkers, de Vries, van Baars, & Mulder, 2010). Black males are often perceived as dangerous, even when they don't exhibit any violent behavior, which may partly explain why Black individuals are overrepresented among those who are involuntarily committed to state psychiatric institutions (Lindsey, Joe, Muroff, & Ford, 2010).

How do you determine whether a person is dangerous to others? How accurate are mental health professionals at predicting who will and who will not later be violent? The answers bear directly on the process of civil commitment, as well as on protection for society. If we can't accurately predict dangerousness, how can we justify involuntary commitment?

The government can exert *parens patriae* to protect people from hurting themselves.

Research using functional imaging technologies reveals that our ability to “feel the pain” of other people—feeling empathetic to others in distress—involves activation of the prefrontal cortex (Escobar et al., 2014; Hillis, 2014; Robertson et al., 2007), and damage to this area prevents people from using empathy to make moral decisions (Damasio, 2007; Decety & Skelly, 2013). This important research is now being used in court proceedings to help decide guilt or innocence (Mobbs, Lau, Jones, & Frith, 2009). Will it be argued that defendants who have psychopathy (see Chapter 12), for example, should be judged not responsible for their behavior because their inability to empathize with others has its origin in the brain? This “brain blame” will become more prominent in coming years because our definitions of insanity have not kept up with our understanding of the combined contributions of the environment and biology to mental illness and criminal behavior (Greely & Simpson, 2012).

Numerous risk assessment tools are routinely used to determine if someone is likely to be dangerous to society—including the Psychopathy Checklist-Revised (PCL-R) (Hare & Vertommen, 2003; Neumann, Johansson, & Hare, 2013), described in Chapter 12, that is used to identify persons with psychopathy. Evidence from numerous studies suggest that these tools are best at identifying persons at low risk of being violent but only marginally successful at accurately detecting who will be violent at a later point (Fazel, Singh, Doll, & Grann, 2012). Mental health professionals can identify groups of people who are at greater risk than the general population for being violent—such as having a previous history of both violence and drug or alcohol dependence—and can so advise the court. What clinicians cannot yet do is predict with certainty whether a particular person will or will not become violent.

Procedural Changes Affecting Civil Commitment

Clearly, there are significant problems with the process of civil commitment. In particular, deciding whether a person has a mental illness or is dangerous requires considerable subjective judgment and, because of varying legal language, this determination can differ from state to state. These problems have resulted in a number of significant legal developments. We look next at how changes in civil commitment procedures have resulted in significant economic and social consequences, including an impact on one of our more important social problems: homelessness.

The Supreme Court and Civil Commitment

In 1957, the parents of Kenneth Donaldson had him committed to the Florida State Hospital for treatment of paranoid schizophrenia. Donaldson was not considered dangerous, yet, despite repeated offers of placement in a halfway house or with a friend, Dr. O’Connor, the superintendent of the hospital, refused to release him for almost 15 years, during which Donaldson received virtually no treatment (Donaldson, 1976). Donaldson successfully sued Dr. O’Connor for damages,

winning \$48,500. In deciding the case, the Supreme Court found that “a State cannot constitutionally confine . . . a non-dangerous individual who is capable of surviving safely in freedom by himself or with the help of willing and responsible family and friends” (*O’Connor v. Donaldson*, 1975).

Here, and in a subsequent decision known as *Addington v. Texas* (1979), the Supreme Court said that more than just a promise of improving quality of life is required to commit someone involuntarily. If nondangerous people with mental illness can survive in the community with the help of others, they should not be detained against their will. Needing treatment or having a grave disability was not sufficient to commit someone involuntarily with a mental illness. The effect of this decision substantially limited the government’s ability to commit individuals unless they were dangerous (Nunley et al., 2013).

Criminalization

Because of the tightened restrictions on involuntary commitment that prevailed in the 1960s and 1970s, many people who would normally have been committed to mental health facilities for treatment were instead being handled by the criminal justice system. In other words, people with severe mental illness were now living in the community, but many were not receiving the mental health services they needed and would eventually run afoul of the legal system because of their behavior. This “criminalization” of the mentally ill was of great concern because the criminal justice system was not prepared to care for these individuals (Chaimowitz, 2012; Lamb, 2009; Lamb & Weinberger, 2009). Family members were increasingly frustrated that they couldn’t obtain treatment for their loved ones, who were instead languishing in jail without help.

Deinstitutionalization and Homelessness

In addition to criminalization, two other trends emerged at this time, starting in the 1980s: an increase in the number of people who were homeless and **deinstitutionalization**, the movement of people with severe mental illness out of institutions. Remember that homelessness is not exclusively a problem of the mentally ill. Approximately 2 million to 3 million people will experience a night of homelessness in the United States each year, and estimates place the numbers of homeless people at more than 400,000

Larry Hogue was involuntarily committed to a psychiatric hospital because, homeless and under the influence of drugs (left), he terrorized residents of a New York City neighborhood for years. Once off drugs (right), Hogue was able to control himself.

on any given night (Substance Abuse and Mental Health Services Administration, 2011). The estimates of psychological disorders among those who are homeless vary, in part because of the difficulty in tracking these individuals. Best estimates suggest that diagnoses of severe mental illness (for example, schizophrenia and bipolar disorder) among homeless persons is about 30% (Substance Abuse and Mental Health Services Administration, 2011). For reasons not yet fully understood, ethnicity may also play a part in who among people with mental illness becomes homeless. In a large study in San Diego County, for example, Latinos and Asian Americans with mental illness were less likely to become homeless, but African Americans were more likely to be homeless (Folsom et al., 2005).

Information on the characteristics of people who are homeless is important because it provides us with clues about why people become homeless, and it dispels the notion that all homeless people have mental health problems. For a time, homelessness was blamed on strict civil commitment criteria and deinstitutionalization (Colp, 2009; Nooe & Patterson, 2010); that is, policies to severely limit who can be involuntarily committed, the limits placed on the hospital stays of people with severe mental illness, and the concurrent closing of large psychiatric hospitals were held responsible for the substantial increase in homelessness during the 1980s. Although a sizable percentage of homeless people have mental illness, the rise in homelessness is also the result of such economic factors as increased unemployment and a shortage of low-income housing (Nooe & Patterson, 2010). Yet the perception that civil commitment restrictions and deinstitutionalization caused homelessness resulted in movements to change commitment procedures.

Reforms in civil commitment that made it more difficult to commit someone involuntarily occurred at the same time the policy of deinstitutionalization was closing large psychiatric hospitals (Nunley et al., 2013). Deinstitutionalization had two goals: (1) to close the large state mental hospitals and (2) to create a network of community mental health centers where the released individuals could be treated. Although the first goal appears to have been substantially accomplished, with about a 75% decrease in the number of hospitalized patients (Kiesler & Sibulkin, 1987), the essential goal of providing alternative community care appears not to have been attained. Instead, there was **transinstitutionalization**, or the movement of people with severe mental illness from large psychiatric hospitals to nursing homes or other group residences, including jails and prisons, many of which provide only marginal services (Lamb & Weinberger, 2009; Primeau, Bowers, Harrison, & XuXu, 2013). Because of the deterioration in care for many people who had previously been served by the mental hospital system, deinstitutionalization is largely considered a failure. Although many praise the ideal of providing community care for people with severe mental illness, the support needed to provide this type of care has been severely deficient.

Reactions to Strict Commitment Procedures

Arthur's psychotic reaction and his family's travails in trying to get help occurred during the mid-1970s, a time characterized by greater concern for individual freedom than for society's rights and by the belief that people with mental illness were not properly

served by being forced into treatment. Others, however, especially relatives of afflicted people, felt that by not coercing some individuals into treatment, the system was sanctioning their mental decline and placing them at grave risk of harm. The culmination of a number of factors—such as the lack of success with deinstitutionalization, the rise in homelessness, and the criminalization of people with severe mental illness—gave rise to a backlash against their perceived causes, including the strict civil commitment laws. The case of Joyce Brown captures this clash of concerns between individual freedoms for people with mental illness and society's responsibility to treat them.

Joyce Brown...

Homeless but Not Helpless

During a 1988 winter emergency in New York City, Mayor Ed Koch ordered that all homeless people who appeared to be mentally ill should be involuntarily committed to a mental health facility for their protection. He used the legal principle of *parens patriae* to justify this action, citing the need to protect these individuals from the cold and from themselves. One of the people who was taken off the streets, 40-year-old Joyce Brown, was picked up against her will and admitted to Bellevue Hospital, where she received a diagnosis of paranoid schizophrenia. She had been homeless for some time, swearing at people as they walked by; at one point, she adopted the name Billie Boggs after a New York television personality with whom she fantasized a relationship. Supported by the New York Civil Liberties Union, Brown contested her commitment and was released after 3 months (Tushnet, 2008).

This case is important because it illustrates the conflicting interests over civil commitment. Brown's family had for some time been concerned about her well-being and had tried unsuccessfully to have her involuntarily committed. Although she had never hurt anyone or tried to commit suicide, they felt that living on the streets of New York City was too hazardous, and they feared for her welfare. City officials expressed concern for Brown and others like her, especially during the dangerously cold winter, although some suspected that this was an excuse to remove people with disturbing behavior from the streets of affluent sections (Kasindorf, 1988). Brown chose not to seek treatment and resisted efforts to place her in alternative settings. At times, she could be quite articulate in making a case for her freedom of choice. Only weeks after she was released from the hospital, she was again living on the streets. Brown was involuntarily committed to a mental health facility again in early 1994 and was released at her insistence a short time later. This continued a pattern that lasted for years (Failer, 2002).

Rulings such as *O'Connor v. Donaldson* and *Addington v. Texas* had argued that mental illness and dangerousness should be criteria for involuntary commitment. Because of cases like Brown's and concerns about homelessness and criminalization, however, a movement emerged calling for a return to broader civil procedures that would permit commitment not only of those who

showed dangerousness to self or others, but also of individuals in need of treatment and those with grave disability—and not dangerous—an opinion that continues to be shared by many today (Gordon, 2015). Groups including the National Alliance on Mental Illness, a coalition of family members of people with mental illness, argued for legal reform to make involuntary commitment easier—an emotional response to the failure to protect and treat people with mental illness. Several states in the late 1970s and early 1980s changed their civil commitment laws in an attempt to address these concerns. For example, the state of Washington revised its laws in 1979 to allow commitment of people who were judged to be in need of treatment, which produced a 91% increase in the number of involuntary commitments in the first year it was in effect (Durham & La Fond, 1985). There was essentially no change in the size of the hospital population at this time, only in the status under which patients were committed (La Fond & Durham, 1992). Whereas people were previously detained because of violence, they were now admitted under *parens patriae* powers; also, whereas most admissions had been voluntary, they were now involuntary. Hospitals began to fill up because of longer stays and repeated admissions and they accepted only involuntary admissions; therefore, the result of easing the procedure for involuntarily committing people with mental illness was only to change the authority under which they were admitted.

The special case of sex offenders has attracted public attention in recent years, and the issue of how to treat repeat offenders is at the heart of the concerns over civil commitment. In the years between 1930 and 1960, some states passed “sexual psychopath laws” that provided hospitalization instead of incarceration, but for an indefinite period (Saleh, Malin, Grudzinskas Jr., & Vitacco, 2010). Sex offenders (rapists and pedophiles) could be civilly committed until they demonstrated that treatment was effective. However, because treatment is often unsuccessful when attempted with uncooperative clients (see Chapter 10) and because public opinion moved from a priority to treat to a priority to punish, these laws were repealed

or went unused. Recent efforts have focused on incarcerating sex offenders for their crimes and, if they are judged still dangerous at the end of their sentences, civilly committing them. Such “sexual predator” laws were first enacted in 1990, and the Kansas version was upheld as constitutional by the U.S. Supreme Court (*Kansas v. Hendricks*, 1997). Confinement of this type was viewed by the court as acceptable because it was seen as treatment, even though the justices conceded that such treatment is often ineffective (Zonana & Buchanan, 2009). Some are greatly concerned that these types of laws give the government too much latitude in using civil commitment (as opposed to incarceration) just to keep certain individuals away from others in society (La Fond, 2005). However, those who are incarcerated and released from prison face many legal restrictions (e.g., housing) that may have negative effects by limiting rehabilitation and reintegration into society (Bonnar-Kidd, 2010).

An Overview of Civil Commitment

What should the criteria be for involuntarily committing someone with severe mental illness to a mental health facility? Should imminent danger to self or others be the only justification, or should society act as a parent and coerce people who appear to be in distress and in need of asylum or safety? How do we address the concerns of families like Arthur’s who see their loved ones overcome by psychological problems? And what of our need not to be verbally harassed by people like Joyce Brown? When do these rights take precedence over the rights of an individual to be free from unwanted incarceration? It is tempting to conclude that the legal system has failed to address these issues and reacts only to the political whims of the times.

A significant number of the homeless are individuals with mental disorders, many of whom live with their children in shelters or on the streets.

From another point of view, however, the periodic change in laws is a sign of a healthy system that responds to the limitations of previous decisions. The reactions by the Supreme Court in the 1970s to the coercive and arbitrary nature of civil commitment were as understandable as more recent attempts to make it easier to commit people in obvious need of help. As the consequences of these changes become apparent, the system responds to correct injustices. Although improvements may seem excruciatingly slow and may not always correctly address the issues in need of reform, the fact that laws can be changed should make us optimistic that the needs of individuals and of society can ultimately be addressed through the courts.

Concept Check 16.1

Check your understanding of civil commitment by filling in the blanks.

Several conditions must be met before the state is permitted to commit a person involuntarily: The person has a(n) (1) _____ and is in need of treatment, the person is considered (2) _____ to herself or others, and the person is unable to care for himself or herself, also known as (3) _____.

Mental illness is a(n) (4) _____ concept, typically meaning severe emotional or thought disturbances that negatively affect an individual's health and safety, although this definition differs from state to state. When the laws about civil commitment emerged, (5) _____ (movement of disabled individuals out of mental institutions) and (6) _____ (movement of disabled individuals to a less restrictive facility) also occurred.

Criminal Commitment

What would have happened if Arthur had been arrested for trespassing on embassy grounds or, worse yet, if he had hurt or killed someone in his effort to present his plan for saving starving children? Would he have been held responsible for his actions, given his obvious disturbed mental state? How would a jury have responded to him when he seemed fine just several days later? If he was not responsible for his behavior then, why does he seem so normal now?

These questions are of enormous importance as we debate whether people should be held responsible for their criminal behavior despite the possible presence of mental illness. Cases such as that of Andrea Yates, who was first convicted and sentenced to life in prison for drowning her five children in a bathtub in 2001 but later found not guilty by reason of insanity (NGRI), causes some to wonder whether the laws have gone too far. **Criminal commitment** is the process by which people are held because (1) they have been accused of committing a crime and are detained in a mental health facility until they can be assessed as fit or unfit to participate in legal proceedings against them, or (2) they have been found not guilty of a crime by reason of insanity.

The Insanity Defense

The purpose of our criminal justice system is to protect our lives, our liberty, and our pursuit of happiness, but not all people are punished for criminal behavior. The law recognizes that, under certain circumstances, people are not responsible for their behavior and it would be unfair and perhaps ineffective to punish them. Current views originate from a case recorded more than 150 years ago in England. Daniel M'Naghten today might receive the diagnosis of paranoid schizophrenia. He held the delusion that the English Tory party was persecuting him, and he set out to kill the British prime minister. He mistook the man's secretary for the prime minister and killed the secretary instead. In what has become known as the M'Naghten rule, the English court decreed that people are not responsible for their criminal behavior if they do not know what they are doing or if they don't know that what they are doing is wrong. This ruling was, in essence, the beginning of the *insanity defense* (see summary in Table 16.1). For more than 100 years, this rule was used to determine culpability when a person's mental state was in question.

In the intervening years, other standards have been introduced to modify the M'Naghten rule because many critics felt that simply relying on an accused person's knowledge of right or wrong was too limiting and a broader definition was needed (Simon & Shuman, 2009). Mental illness alters not only a person's cognitive abilities but also that person's emotional functioning, and mental health professionals believed the entire range of functioning should be taken into account when a person's responsibility was determined. One influential decision, known as the Durham rule, was initiated in 1954 by Judge David Bazelon of the Federal Circuit Court of Appeals for the District of Columbia and based on the case *Durham v. United States* (1954). The Durham rule broadened the criteria for responsibility from knowledge of right or wrong to state that the "accused is not criminally responsible if his unlawful act was the product of mental disease or mental defect" (see Table 16.1). This decision was initially hailed by mental health professionals because it allowed them to present to a judge or jury a complete picture of the person with mental illness. Unfortunately, it was soon apparent that mental health professionals did not have the expertise to assess reliably whether a person's mental illness caused the criminal behavior in question and therefore that decisions were being based on unscientific opinions (Gunn & Wheat, 2012). Although the Durham rule is no longer used, it caused a reexamination of the criteria used in the insanity defense.

An influential study of the question surrounding the definition of culpability was conducted around the same time as the Durham decision by a group of attorneys, judges, and law scholars who belonged to the American Law Institute (ALI). Their challenge was to develop criteria for determining whether a person's mental competence makes him answerable for criminal behavior. The ALI first reaffirmed the importance of distinguishing the behavior of people with mental illness from that of people without mental disorders. Its members pointed out that the threat of punishment was unlikely to deter someone who had severe mental illness; the group's position was that these individuals should instead be treated until they improve and should then be released. (This recommendation is discussed further when we examine recent developments and criticisms of the insanity defense.) The ALI concluded that people

are not responsible for their criminal behavior if, because of their mental illness, they cannot recognize the inappropriateness of their behavior or control it (American Law Institute, 1962). The criteria shown in Table 16.1, known as the ALI test, stipulate that a person must either be unable to distinguish right from wrong—as set forth in the M'Naghten rule—or be incapable of self-control to be shielded from legal consequences.

The ALI also included provisions for the concept of **diminished capacity** (see Table 16.1), which holds that people's ability to understand the nature of their behavior and therefore their criminal intent can be diminished by their mental illness. The theory of criminal intent—otherwise called *mens rea*, or having a “guilty mind”—is important legally because to convict someone of a crime, there must be proof of the physical act (*actus rea*) and the mental state (*mens rea*) of the person committing the act (Gunn & Wheat, 2012). For example, if a woman accidentally hits someone who steps in front of her car and the person subsequently dies, the woman would not be held criminally responsible; although a person was killed, there was no criminal intent—the driver didn't deliberately hit the person and attempt murder. The diminished capacity concept proposes that a person with mental illness who commits a criminal offense may not, because of the illness, have criminal intent and therefore cannot be held responsible.

Reactions to the Insanity Defense

Judicial rulings through the 1960s and 1970s regarding criminal responsibility parallel the course of civil commitment. An effort was made to focus on the needs of people with mental illness who

also broke the law, providing mental health treatment instead of punishment. The successful use of concepts such as *insanity* or *diminished capacity* in criminal cases alarmed large segments of the population, however. For instance, in 1979 a man successfully pleaded NGRI after being arrested for writing bad checks. His case was based on the testimony of an expert witness who said he suffered from pathological gambling disorder and he therefore could not distinguish right from wrong (*State v. Campanaro*, 1980). Other successful defenses were based on disorders in the *DSM*, such as posttraumatic stress disorder and kleptomania (Novak, 2010), and on disorders not covered in the *DSM*, including battered wife syndrome (Cookson, 2009).

Without question, the case that prompted the strongest outrage against the insanity defense and the most calls for its abolition is that of John W. Hinckley, Jr. (Zapf, Zottoli, & Pirelli, 2009). On March 31,

Alex Wong/Staff/Getty Images News/ Getty Images

James Brady, President Ronald Reagan's press secretary, was wounded in 1981 by a gunman attempting to assassinate the president. In 1994, Brady and his wife, Sarah, celebrated the passage of the Brady Act, which imposed stricter controls on the possession of handguns.

1981, as President Ronald Reagan walked out of the Washington Hilton Hotel, Hinckley fired several shots, hitting and seriously wounding the president, a Secret Service agent, a police officer, and James Brady, the president's press secretary. In an instant, Secret Service agents tackled and disarmed Hinckley. Hinckley was obsessed with actress Jodie Foster; he claimed he tried to kill the president to impress her. Hinckley was judged by a jury to be NGRI, using the ALI standard. The verdict sent shock waves throughout the country and legal community (Zapf et al., 2009). One of the many consequences of this event was that James Brady and his wife, Sarah, became advocates for stricter gun control laws and saw the ultimate passage of the Brady Act in 1994.

Although the insanity defense had already been criticized in the United States, about 75% of the states substantially changed their insanity defense rules after Hinckley's verdict, making it more difficult to use this defense (Simon & Shuman, 2014). As you have seen before, such impulses often are based more on emotion than on fact. Highly publicized cases, such as those of Hinckley, Charles Manson, Jeffrey Dahmer, and Ted Kaczynski, have led many people to associate mental illness with violence, thereby creating an unfavorable public perception of the insanity defense. One telephone survey study found that 91% of people who responded agreed with the statement, "judges and juries have a hard time telling whether the defendants are really sane or insane" (Hans, 1986). Almost 90% agreed the "insanity plea is a loophole that allows too many guilty people to go free." In a similar study, 90% of people agreed "the insanity plea is used too much. Too many people escape responsibilities for crimes by pleading insanity" (Pasewark & Seidenzahl, 1979). Is there hard evidence that the insanity defense is used too often?

A study of the public's impression of the insanity defense compared it with the actual use of the defense and its outcomes (Silver, Cirincione, & Steadman, 1994). As Table 16.2 shows, the public's perception that this defense is used in 37% of all felony cases is a gross overestimate; the actual figure is less than 1%. The public also overestimates how often the defense is successful, as well as how often people judged NGRI are set free. People tend to underestimate the length of hospitalization of those who are acquitted. This last issue is important: In contrast to public perceptions, the length of time a person is confined to a hospital after being judged NGRI may exceed the time the person would have spent in jail had that person been convicted of the crime (Simon & Shuman, 2014). Hinckley, for example, was a patient in St. Elizabeth's Hospital for more than 30 years and only recently in 2016 was he released. Other research shows that individuals with mental illness who are found guilty of *nonviolent* crimes can be committed more than 8 times as long as those people without mental illness placed in prison (Perlin, 2000). In contrast to public perception, people with mental illness apparently do not often "beat the rap" as a result of being judged NGRI.

Despite sound evidence that it is not used excessively and does not result in widespread early release of dangerous individuals, major changes were made in the criteria for the insanity defense after the Hinckley verdict. Both the American Psychiatric Association (1983) and the American Bar Association (1984) recommended modifications, moving back toward M'Naghten-like definitions. Shortly afterward, Congress passed the

Insanity Defense Reform Act of 1984, which incorporated these suggestions and made successful use of the insanity defense more difficult.

Another attempt at reforming the insanity plea has been to replace the NGRI verdict with a verdict of guilty but mentally ill (GBMI) (Kimonis, 2015; Torry & Billick, 2010). Although there are several versions of the GBMI verdict, the shared premise is that the consequences for a person ruled GBMI are different from those for a person who is NGRI. People found to be NGRI are not sent to prison but are evaluated at a psychiatric facility until such time as they are judged ready for release. A person determined to be no longer mentally ill must be released. If Arthur had committed a crime and was found NGRI, because his brief psychotic disorder was quickly resolved, he would probably have been released immediately. In contrast, one version of the GBMI verdict in theory allows the system both to treat and to punish the individual. The person found guilty is given a prison term just as if there were no question of mental illness. Whether the person is incarcerated in prison or in a mental health facility is decided by legal authorities. If the person recovers from mental illness before the sentence has passed, that person can be confined in prison for the maximum length of the term. If Arthur were found GBMI under this system, he could serve a full prison sentence, even though his mental illness was resolved. This version of GBMI has been adopted by a number of states (Simon & Shuman, 2014).

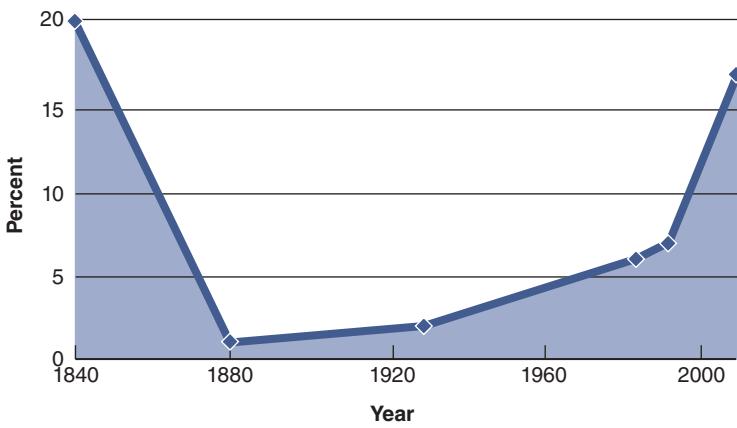

The second version of GBMI is even harsher for the mentally ill offender. Convicted individuals are imprisoned, and prison authorities may provide mental health services if they are available. The verdict itself is simply a declaration by the jury that the person was mentally ill at the time the crime was committed and does not result in differential treatment for the perpetrator. Idaho, Montana, and Utah have abandoned the insanity defense

of verdicts available (NGRI versus GBMI) depends on the laws of the particular state where the crimes were committed. Overall, some estimate that there are more than 3 times the number of people with severe mental illness in jails than in hospitals, pointing to the consequences of these changes in mental health laws (Torrey, Eslinger, Lamb, & Pavle, 2010). ● Figure 16.1 illustrates how people with severe mental illness are increasingly being placed in prisons rather than in special mental health facilities. The percentage of placements in prisons is approaching rates comparable to that of those more than 150 years ago, before adequate services were available.

altogether and have adopted this version of GBMI (“The Evolving Insanity Defense,” 2006).

As noted, the GBMI verdict was a reaction to the perceived loophole provided by the insanity defense. It has been used in several states for more than 15 years, and its effects have been investigated by researchers. Two studies have shown that people who receive the GBMI verdict are more likely to be imprisoned and to receive longer sentences than people pleading NGRI (Callahan, McGreevy, Cirincione, & Steadman, 1992; Keilitz, 1987). Research also indicates that individuals receiving GBMI verdicts are no more likely to receive treatment than other prisoners who have mental illness (Keilitz, 1987; Smith & Hall, 1982). Currently, the type

Therapeutic Jurisprudence

There is a built-in tension between the judicial system and the mental health system. The legal system is, by design, adversarial. In other words, it was created with prosecutors and defendants, winners and losers. In contrast, the mental health system is set up to find solutions to important psychological problems without placing blame on any parties. The goal is for both sides to “win.” Fortunately, there is an increasing recognition in the legal system that a strict adversarial approach to dealing with people with mental health problems may be harmful to everyone. As a result of this change in thinking, when individuals with psychological disorders break the law, they may now find themselves in one of a variety of “problem-solving courts” (Ahern & Coleman-Eufinger, 2013; Goodale, Callahan, & Steadman, 2013). These courts are designed to address the unique needs of people with specific problems. For example, today in many states you can find drug treatment courts, domestic violence courts, and mental health courts, among others. Interestingly, models of problem-solving courts have their roots in the legal systems of tribal societies in the United States, Canada, Australia, and New Zealand (King & Wexler, 2010).

These problem-solving courts are based on the concept of therapeutic jurisprudence—in essence, using what we know about behavior change to help people in trouble with the law. In drug treatment court, for example, a judge might be assigned to all criminal cases involving drug-addicted defendants. The judge would have the leeway to delay sentencing under the condition that the accused obtained and held a job for 6 months, received drug treatment during that time, and remained drug free. Similarly, a defendant in a mental health court might be helped by referrals to existing programs in the community and involvement of family members. Rather than simply trying to decide between prison and freedom, the court can serve as an instrument of social change. This evolving concept may provide effective alternatives in the criminal justice system for people with severe mental illness.

Society has long recognized the need to identify criminals who may not be in control of their behavior and who may not benefit from simple incarceration. The challenge is in trying to do what may be impossible: determining whether the person knew what she was doing, knew right from wrong, and could control her behavior. Mental health professionals cannot assess mental health retrospectively. An additional dilemma is the desire, on the one hand, to provide care to people with mental illness and, on the other, to treat them as responsible individuals. Finally, we must resolve the simultaneous and conflicting interests of wanting to assist people with mental illness and wanting to be protected from them. The recent trend of using problem-solving courts may be one way to address these concerns. We must reach a national consensus about the basic value of people with mental illness to decide how they should be dealt with legally. We hope the recent trend of favoring law and order over the rights of people with mental illness can be moderated to provide attention to both concerns.

Competence to Stand Trial

Before people can be tried for a criminal offense, they must be able to understand the charges against them and to assist with their

own defense, criteria outlined by the Supreme Court in *Dusky v. United States* (1960). Thus, in addition to interpreting a person's state of mind during the criminal act, experts must also anticipate the person's state of mind during the subsequent legal proceedings. A person could be ruled NGRI because of his mental illness at the time of the criminal act yet still be competent to stand trial, a situation that would have occurred in Arthur's case had he committed a crime.

A person determined to be incompetent to stand trial typically loses the authority to make decisions and faces commitment. Because a trial requires a determination of **competence**, most people with obvious and severe impairments who commit crimes are never tried. Some observers estimate that for every person who receives a verdict of NGRI, 45 others are committed to a mental health facility with a diagnosis of severe mental illness (Butler, 2006). The length of stay is the time it takes the committed person to regain competence. Because this period can be drawn out, the courts have ruled it cannot be indefinite and that, after a reasonable amount of time, the person must be found competent, set free, or committed under civil law (*Jackson v. Indiana*, 1972). Laws are often not precise in their language, and the phrase "reasonable amount of time" is open to a great deal of interpretation.

A final issue relates to the legal concept of burden of proof, the weight of evidence needed to win a case. In decisions of competence to stand trial, an important ruling placed responsibility on the defendant to provide the burden of proof—in this case, that she is incompetent to stand trial (*Medina v. California*, 1992). Again, public concern that dangerous individuals with mental illness are routinely acquitted and let loose on society after committing multiple violent offenses flies in the face of the facts. More realistically, a person with mental illness commits a nonviolent crime and receives treatment through legal actions, such as the competence proceedings.

Duty to Warn

Do mental health professionals have any responsibility for the actions of the people they serve? This is especially important when we consider the dangerous behavior exhibited by a minority of people with severe mental illness. What are the responsibilities of professionals who suspect that someone with whom they are working may hurt or even kill another person? Must they contact the appropriate authority or the person who may be harmed, or are they forbidden to discuss information disclosed during therapy sessions?

These issues were the subject of a tragic case known as *Tarasoff v. Regents of the University of California* (1974, 1976). In 1969, Prosenjit Poddar, a graduate student at the University of California, Berkeley, killed a fellow student, Tatiana Tarasoff, who had previously rejected his romantic advances. At the time of the murder, he was being seen by two therapists at the University Health Center and had received a diagnosis of paranoid schizophrenia. At his last session, Poddar hinted that he was going to kill Tarasoff. His therapist believed this threat was serious and contacted the campus police, who investigated the allegation and received assurances from Poddar

that he would leave Tarasoff alone. Weeks later, after repeated attempts to contact her, Poddar shot and stabbed Tarasoff until she died.

After learning of the therapists' role in the case, Tarasoff's family sued the university, the therapists, and the university police, saying they should have warned Tarasoff that she was in danger. The court agreed, and the Tarasoff case has been used ever since as a standard for therapists concerning their **duty to warn** a client's potential victims. Related cases have further defined the role of the therapist in warning others (Johnson, Persad, & Sisti, 2014; Mason, Worsley, & Coyle, 2010). Courts have generally ruled that the threats must be specific. In *Thompson v. County of Alameda* (1980), the California Supreme Court ruled that a therapist does not have a duty to warn when a person makes nonspecific threats against nonspecific people. It is difficult for therapists to know their exact responsibilities for protecting third parties from their clients. Good clinical practice dictates that any time they are in doubt they should consult with colleagues. A second opinion can be just as helpful to a therapist as to a client.

Mental Health Professionals as Expert Witnesses

Judges and juries often have to rely on **expert witnesses**, individuals who have specialized knowledge, to assist them in making decisions (Mullen, 2010). We have alluded to several instances in which mental health professionals serve in such a capacity, providing information about a person's dangerousness or ability to understand and participate in the defense. The public perceives expert witnesses ambivalently. On one hand, they see the value of persuasive expert testimony in educating a jury; on the other, they see expert witnesses as "hired guns" whose opinions suit the side that pays their bills (Simon & Shuman, 2009). How reliable are the judgments of mental health professionals who act as expert witnesses?

To take one example, in deciding whether someone should be civilly committed, the assessor must determine the person's potential for future violence. Research suggests that mental health professionals can make reliable predictions of dangerousness over the short term, for 2 to 20 days after the evaluation (Scott et al., 2008). They have not, however, been able to make reliable predictions of violence after longer periods (Fazel et al., 2012). It seems that the assessment tools that professionals use to assess danger may impact accuracy. Assessment tools that were designed to assess danger of violence in specific groups of patients (e.g., juvenile offenders) were more accurate than general assessment tools (Singh, Grann, & Fazel, 2011). A second area in which mental health professionals are often asked to provide consultation is in assigning a diagnosis. In Chapter 3, we discussed the development of systems to ensure the reliability of diagnoses. Recent revisions of diagnostic criteria, most notably *DSM-IV-TR* and *DSM-5*, have addressed this issue directly, thus helping clinicians make diagnoses that are generally reliable. Remember, however, that the legal definition of mental illness is not matched by a comparable disorder in *DSM-5*. Therefore, statements about whether someone has a

"mental illness" reflect determinations made by the court, not by mental health professionals.

Mental health professionals appear to have expertise in identifying *malingering* and in assessing competence. Remember that to malinger is to fake or grossly exaggerate symptoms, usually to be absolved from blame. For example, a person might claim to have been actively hallucinating at the time of the crime and therefore not responsible. Research indicates that the Minnesota Multiphasic Personality Inventory test is mostly accurate in revealing malingering in people claiming to have serious mental illness. The examiners look for true symptoms, but ones people with mental illness rarely report. Malingeringers, in their rush to fake their illness, will often overreport these problems, perhaps to convince others they are mentally ill (Sellbom, Toomey, Wygant, Kucharski, & Duncan, 2010; Tarescavage, Wygant, Gervais, & Ben-Porath, 2013). Mental health professionals also appear capable of providing reliable information about a person's competence, or ability to understand and assist with a defense (Shulman, Cohen, Kirsh, Hull, & Champine, 2007). Overall, mental health professionals can provide judges and juries with reliable and useful information in certain areas (Scott et al., 2008).

The research described here does not indicate how accurate expert testimony is under everyday conditions. In other words, under the right circumstances experts can make accurate determinations of the short-term risks that a person will commit an act of violence, is faking certain symptoms, or is competent to stand trial and of what diagnosis should be made. Still, other factors conspire to influence expert testimony. Personal and professional opinions that exceed the competence of the expert witness can influence what information is or is not presented, as well as how it is relayed to the court (Drogin, Commons, Gutheil, Meyer, & Norris, 2012). For instance, if the expert witness believes generally that people should not be involuntarily committed to mental health facilities, this opinion will likely influence how the witness presents clinical information in civil commitment court proceedings.

Concept Check 16.2

Check your understanding of criminal commitment by identifying the following concepts: (a) competence to stand trial, (b) diminished capacity, (c) American Law Institute rule, (d) Durham rule, (e) M'Naghten rule, (f) malingering, (g) expert witness, and (h) duty to warn.

1. The defendant does not go to trial because she is unable to understand the proceedings and assist in the defense. _____
2. The person could not distinguish between right and wrong at the time of the crime. _____
3. The person is not responsible for the crime if he is not able to appreciate the wrongfulness of behavior caused by mental disease or defect. _____
4. One of my clients threatened his mother's life during his session today. Now I must decide whether I have a(n) _____. _____
5. A mental disorder could lessen a person's ability to understand criminal behavior and to form criminal intent. _____
6. Dr. Z testified in court that the defendant was faking and exaggerating symptoms to evade responsibility. Dr. Z is acting as a(n) _____, and the defendant is _____. _____
7. The person is not criminally responsible if the crime was the result of "mental disease or mental defect." _____

Patients' Rights and Clinical Practice Guidelines

Until about 40 years ago, people in mental health facilities were accorded few rights. What treatment they received and whether they could make phone calls, send and receive mail, or have visitors were typically decided by hospital personnel who rarely consulted with the patient. Abuses of this authority, however, led to legal action and subsequent rulings by the courts concerning the rights of people in these facilities.

The Right to Treatment

One of the most fundamental rights of people in mental health facilities is the right to treatment (Bloch & Green, 2012). For too many and for too long, conditions were poor and treatment was lacking in numerous large mental health facilities. Starting in the early 1970s, a series of class-action lawsuits (filed on behalf of many individuals) helped establish the rights of people with mental illness and mental retardation. A landmark case, *Wyatt v.*

Stickney (1972), grew out of a lawsuit filed by the employees of large institutions in Alabama who were fired because of funding difficulties. The case also established, for the first time, the minimum standards that facilities had to meet in relation to the people who were hospitalized. Among the standards set by *Wyatt v. Stickney* were minimum staff-patient ratios and physical requirements, such as a certain number of showers and toilets for a given number of residents. The case also mandated that facilities make positive efforts to attain treatment goals for their patients.

Wyatt v. Stickney went further and expanded on a concept called the “least restrictive alternative,” indicating that, wherever possible, people should be provided with care and treatment in the least confining and limiting environment possible. For example, the court noted the following for those with mental retardation:

Residents shall have a right to the least restrictive conditions necessary to achieve the purpose of habilitation. To this end the institution shall make every attempt to move residents from (1) more to less structured living; (2) large to smaller facilities; (3) large to smaller living units; (4) group to individual residences; (5) segregated from the community to integrated into the community; (6) dependent living to independent living. (*Wyatt v. Stickney*, 1972)

Despite this movement to secure treatment for people in mental health facilities, a gap was left as to what constituted proper treatment. The case of *Youngberg v. Romeo* (1982) reaffirmed the need to treat people in nonrestrictive settings but essentially left to professionals the decision about the type of treatment to be provided. This concerned patient advocates because, historically, leaving treatment to professional judgment has not always resulted in the intended end for the people in need of help. In 1986, Congress provided a number of safeguards by passage of the Protection and Advocacy for Mentally Ill Individuals Act (Woodside & Legg, 1990), which established a series of protection and advocacy agencies in each state to investigate allegations of abuse and neglect and to act as legal advocates. This layer of protection has resulted in a balance between professional concerns and needs and rights of patients in mental health facilities.

The Right to Refuse Treatment

One of the most controversial issues in mental health today is the right of people, especially those with severe mental illness, to refuse treatment (Bloch & Green, 2012; Simon & Shuman, 2014). In recent times, the argument has centered on the use of antipsychotic medications. On one side of the issue are the mental health professionals who believe that, under certain circumstances, people with severe mental illness are not capable of making a decision in their own best interest and that the clinician is therefore responsible for providing treatment, despite the protestations of the affected people. On the other side, patients and their advocates argue that all people have a fundamental right to make decisions about their own treatment, even if doing so is not in their own best medical interests.

Although this controversy is not yet resolved, one court case has responded to a related question: Can people be “forced” to become competent to stand trial? This is an interesting dilemma: If

people facing criminal charges are delusional or have such frequent severe hallucinations that they cannot fully participate in the legal proceedings, can they be forced against their will to take medication to reduce these symptoms, thereby making them competent to stand trial? A Supreme Court ruling, *Riggins v. Nevada* (1992), stated that, because of the potential for negative side effects (such as the involuntary motor movements associated with tardive dyskinesia), people cannot be forced to take antipsychotic medication. Other rulings, however, make allowances for involuntary medication following a *Harper* hearing (“*Washington v. Harper*,” 1990)—a due process hearing that allows mental health professionals to argue for the merits of medication use and the patient to provide a counterargument. This process was used to involuntarily medicate Jared Loughner—the man who eventually pleaded guilty to 19 charges of murder and attempted murder for a 2011 attack in Tucson, Arizona, in which U.S. Representative Gabrielle Giffords was severely injured and six other people were killed.

The Rights of Research Participants

Throughout this text we have described research conducted worldwide with people who have psychological disorders. We also touched briefly in Chapter 4 on the issue of the rights of these individuals. In general, people who participate in psychological research have the following rights (American Psychological Association, 2010a, 2010b):

1. The right to be informed about the purpose of the research study
2. The right to privacy
3. The right to be treated with respect and dignity
4. The right to be protected from physical and mental harm
5. The right to choose to participate or to refuse to participate without prejudice or reprisals
6. The right to anonymity in the reporting of results
7. The right to the safeguarding of their records

These rights are particularly important for people with psychological disorders who may not be able to understand them fully (Bloch & Green, 2012). One of the most important concepts in research is that those who participate must be fully informed about the risks and benefits of the study. Simple consent is not sufficient; it must be *informed consent*, or formal agreement by the subject to participate after being fully apprised of all important aspects of the study, including any possibility of harm. An important case underlines the significance of informed consent and the sometimes-gray areas that exist in applied research.

Greg Aller... Concerned About Rights

In 1988, 23-year-old Greg Aller signed a consent form agreeing to participate in a treatment study at the University of California at Los Angeles (UCLA) Neuropsychiatric Institute (Willwerth, 1993). Since the previous year, Greg had experienced vivid and frightening

(Continued next page)

hallucinations and delusions about space aliens. His parents had contacted UCLA for assistance. They learned that the university was initiating a new study to evaluate people in the early stages of schizophrenia and to assess the effects of the withdrawal of medication. If Greg participated, he could receive extremely expensive drug therapy and counseling free. After taking the drug Prolixin for 3 months as part of the study, he improved dramatically; the hallucinations and delusions were gone. He was now able to enroll in college, and he made the dean's list.

Although overjoyed with the results, Greg's parents were concerned about the second phase of the study, which involved taking him off the medication. They were reassured by the researchers that this was an important and normal part of treatment for people with schizophrenia and that the potential for negative side effects of taking the drug for too long was great. They were also told the researchers would put Greg back on the medication if he grew considerably worse without it.

Toward the end of 1989, Greg was slowly taken off the drug, and he soon started having delusions about former President Ronald Reagan and space aliens. Although his deterioration was obvious to his parents, Greg did not indicate to the researchers that he needed the medication or tell them of his now-continuous hallucinations and delusions. Greg continued to deteriorate, at one point threatening to kill his parents. After several more months, Greg's parents persuaded him to ask for more medication. Although better than he was earlier, Greg has still not returned to the much-improved state he achieved following his first round of medication. •

This case highlights the conflicts that can arise when researchers attempt to study important questions in psychopathology. Administrators at the National Institutes of Health reported that the UCLA researchers did not give Greg and his family all the information about the risks of treatment and the possibility of other approaches (Aller & Aller, 1997).

Critics claim that informed consent in this and similar situations are too often not fully met and that information is often altered to ensure participation. The UCLA researchers note, however, that what they did was no different from what would have happened outside the research study: They attempted to remove Greg from potentially dangerous antipsychotic medication. The controversy emerging from this case should be an

added warning to researchers about their responsibilities to people who participate in their studies and their obligation to design added safeguards to protect the welfare of their study subjects. Some are now exploring methods to assess formally whether participants with mental illness fully understand the risks and benefits associated with these studies (e.g., Harmell, Palmer, & Jeste, 2012; Palmer, Savla, Roesch, & Jeste, 2013).

Evidence-Based Practice and Clinical Practice Guidelines

Health-care delivery systems around the world have become extremely interested in determining whether treatments commonly used for both physical and psychological disorders are effective. This concern stems partly from the greatly increased expense of health care and from the fact that much of the cost is picked up by governments around the world. As a result, governments and health-care policy makers are increasingly promoting evidence-based practice (EBP): health-care practices supported by research findings demonstrating that they are effective. EBP is one of those ideas that comes along occasionally and takes the world by storm. Although some tenets of EBP have been around for decades, it is only in the past 15 years that EBP has been formally identified as a systematic method of delivering clinical care (Institute of Medicine, 2001; Sackett, Strauss, Richardson, Rosenberg, & Haynes, 2000). In the United States, the President's New Freedom Commission on Mental Health (2003, p. 21) made the principal recommendation of its final report to advance EBPs and "expand the workforce providing evidence-based mental health services and supports." The American Psychological Association Presidential Task Force in 2006 adopted as policy a report describing EBP in psychology and encouraging wide adoption of the notion of basing principles of psychological practice on evidence (APA, 2006).

As described throughout this book, evidence has accumulated on the effectiveness of psychological treatments for specific disorders both in research clinics and in clinics that serve the public directly (Barlow, Bullis, Comer, & Ametaj, 2013; IOM, 2015). When this evidence is put in the form of recommendations on how to treat a particular problem, these recommendations are called clinical practice guidelines (Hollon et al., 2014; IOM, 2011). In 1989, legislation established a new branch of the federal government called the Agency for Health Care Policy and Research. In 1999, this agency was reauthorized by Congress and renamed the Agency for Healthcare Research and Quality. The purpose of this agency is to establish uniformity in the delivery of effective health and mental health care and to communicate to practitioners, policy makers, and patients alike throughout the country the latest developments in treating certain disorders effectively. The agency is also responsible for research into improving systems for the delivery of health and mental health services. Now with the passage in 2010 of legislation to provide a form of national health insurance in the United States (the Patient Protection and Affordable Care Act or "Obamacare"), making health care more efficient and effective is more important than ever.

The government hopes not only to reduce costs by eliminating unnecessary or ineffective treatments but also to facilitate the utilization of effective interventions based on the latest research

evidence (IOM, 2015). In recent years, governments have allocated billions of dollars to facilitate dissemination and implementation of evidence-based psychological treatments in various health-care systems such as the Veterans Health Administration in the United States and the National Health Service in the United Kingdom (McHugh & Barlow, 2010, 2012). Treating people effectively—alleviating their pain and distress—is the most important way to reduce health-care costs because these individuals will no longer request one treatment after another in an unending search for relief. To this end, as part of the ACA, Congress enabled the Patient-Centered Outcomes Research Institute to facilitate research on which treatments for what conditions are most effective, and to disseminate this information widely (Dickersin, 2010).

Anticipating the importance of this trend and the necessity that clinical practice guidelines be sound and valid, a task force of the American Psychological Association composed a template, or set, of principles for constructing and evaluating guidelines for clinical interventions for both psychological disorders and psychosocial aspects of physical disorders. These principles were published in 1995 and revised in 2002 with relatively few changes (American Psychological Association, 2002a).

The task force decided that clinical practice guidelines for specific disorders should be constructed on the basis of two simultaneous considerations, or axes: the clinical efficacy axis and the clinical utility axis. The **clinical efficacy axis** is a thorough

consideration of the scientific evidence to determine whether the intervention in question is effective. This evidence would answer the question: Is the treatment effective when compared with an alternative treatment or with no treatment in a controlled clinical research context? In Chapter 4, we reviewed the various research strategies used to determine whether an intervention is effective.

As you will remember, for many reasons, a treatment might seem effective when it is not. For instance, if patients improve on their own while being treated simply because of the passage of time or the natural healing process, the treatment had little to do with the improvement. It is possible that nonspecific effects of the treatment—perhaps just meeting with a caring health professional—are enough to make someone feel better without any contribution from the particular treatment technique. To determine clinical efficacy, experiments called clinical trials must establish whether the intervention in question is better than no therapy, better than a nonspecific therapy, or better than an alternative therapy. (The latter finding provides the highest level of evidence for a treatment's effectiveness.) Clinicians might also rely on information collected from various clinics where a large number of practitioners are treating the disorder in question. If these clinicians collect systematic data on the outcomes of their patients, they can ascertain how many are “cured,” how many improve somewhat without recovering, and how many fail to respond to the intervention. Such data are referred to as *quantified clinical observations* or *clinical replication*.

In some cases, randomized controlled trials will exist. More often, data will be in the form of quantified clinical observations (clinical replication series) or other strategies, such as health economic calculations.

series. Finally, a *clinical consensus* of leading experts is also a valuable source of information, although not as valuable as data from quantified clinical observations or randomized controlled trials (in which individuals are assigned randomly to a treatment or a control condition to evaluate the efficacy of the treatment).

The **clinical utility axis** is concerned with the effectiveness of the intervention in the practice setting in which it is to be applied, regardless of research evidence on its efficacy; in other words, will an intervention with proven efficacy in a research setting also be effective in the various clinical settings where the interventions are most often applied? Also, is application of the intervention in the settings where it is needed feasible and cost-effective? This axis is concerned with external validity, the extent to which an internally valid intervention is effective in different settings or under different circumstances from those where it was tested, and how easily it can be disseminated and implemented in those settings.

The first major issue to consider on the clinical utility axis is feasibility. Will patients accept the intervention and comply with its requirements, and is it relatively easy to administer? As noted in Chapter 7, electroconvulsive therapy is an effective treatment for severe depression in many cases, but it is extremely frightening to patients, many of whom refuse it. The treatment also requires sophisticated procedures and close supervision by medical personnel, usually in a hospital setting. Therefore, it is not particularly feasible and is used only as a last resort.

A second issue on the clinical utility axis is generalizability, which refers to the extent to which an intervention is effective with patients of differing backgrounds (ethnicity, age, or sex), as well as in different settings (inpatient, outpatient, or community) or with different therapists. Again, an intervention could be effective in a research setting with one group of patients but generalize poorly across different ethnic groups. In summary, a treatment can be highly effective as determined by the clinical efficacy axis, but unless the treatment is widely generalizable, feasible, and cost-effective, it is unlikely to be disseminated or implemented. For a summary of these two axes, see Table 16.3.

In reading the disorder chapters (Chapters 5–15 of this book), you will have noted a number of effective treatments, both psychosocial and medical. In the future, we will see a great deal of additional research to establish both the clinical efficacy and the clinical utility of various interventions for psychological disorders, and the development of ever more sophisticated clinical practice guidelines (Barlow et al., 2013; IOM, 2015). In 2010, the American Psychological Association decided to develop its own set of clinical practice guidelines on providing the best evidence-based psychological care for people with psychological disorders (Hollon et. al., 2014).

In Chapter 1, we reviewed various activities that make up the role of scientist-practitioners in the mental health professions, who take a scientific approach to their clinical work to provide the most effective assessment procedures and interventions. Changes

in the delivery of mental health services are likely to be accompanied by considerable disruption, because this is a major system that affects millions of people. But the change will also bring opportunities. Scientist-practitioners will contribute to the process of guidelines development in several ways. For example, as attempts are made to assess the clinical utility or external validity of interventions, the collected experience of thousands of mental health professionals will be immensely valuable. Most information relevant to clinical utility or external validity will be collected by these clinicians in the course of their practice. Thus, they will truly fulfill the scientist-practitioner role to the benefit of patients being treated for mental health issues.

Conclusions

Therapy and scientific progress do not occur in a vacuum. People who study and treat abnormal behavior are responsible not only for mastering the wealth of information we have only touched on in this book but also for understanding and appreciating their role in society and in the world. Every facet of life—from the biological to the social, political, and legal—interacts with every other facet; if we are to help people, we must appreciate this complexity.

We hope we have given you a good sense of the challenges faced by workers in the field of mental health and have spurred some of you to join us in this rewarding work.

Concept Check 16.3

Identify the following situation using one of these terms: (a) informed consent, (b) refuse treatment, (c) clinical utility, (d) clinical efficacy, and (e) reduce costs.

1. Recently, clinical practice guidelines were established on two axes. The _____ axis is a consideration of the scientific evidence to determine whether the intervention in question is effective.
2. The _____ axis is concerned with an intervention's effectiveness in the clinical setting where it will be applied, not in the research setting.
3. The clinical researcher knows the potential for harm of the participants is slight but is nevertheless careful to tell them about it and asks them whether they agree to give their _____.
4. Clinical practice guidelines are designed to safeguard clients and _____.
5. The Supreme Court ruling in *Riggins v. Nevada* helped support a patient's right to _____.

Summary

Perspectives on Mental Health Law

- ▶ Societal views of people with mental illness change with time, often as responses to perceived problems with and as intended improvements of relevant laws. According to researchers, a “liberal era” between 1960 and 1980 in the United States was characterized by a commitment to individual rights and fairness; the “neoconservative era” that followed focuses on majority concerns and on law and order.

Civil Commitment

- ▶ Civil commitment laws determine the conditions under which a person may be certified legally to have a mental illness and therefore to be placed in a hospital, sometimes in conflict with the person’s own wishes.
- ▶ Historically, states have permitted commitment when several conditions have been met: (1) the person has a mental illness and is in need of treatment, (2) the person is dangerous to himself or to others, or (3) the person is unable to care for himself.
- ▶ *Mental illness* as used in legal system language is not synonymous with *psychological disorder*; each state has its own definition of mental illness, usually meant to include people with severe disturbances that negatively affect their health and safety.
- ▶ Having a mental illness does not seem to increase the likelihood of dangerousness, that is, that a person will commit violent acts in the future, although having symptoms of hallucinations and delusions does seem to indicate more risk for behaving violently.
- ▶ The combination of the lack of success with deinstitutionalization, which has resulted instead in transinstitutionalization; the rise in homelessness; and the criminalization of people with severe mental illness led to a backlash against the perceived causes of these factors, including the strict civil commitment laws.

Criminal Commitment

- ▶ Criminal commitment is the process by which people are held for one of two reasons: (1) They have been accused of committing a crime and are detained in a mental health facility until they can be determined fit or unfit to participate in legal proceedings against them, or (2) they have been found not guilty of a crime by reason of insanity.
- ▶ The insanity defense is defined by a number of legal rulings: The M’Naghten rule states that people are not responsible for criminal behavior if they do not know what they are doing, or if they do

know and they don’t know it is wrong. The Durham rule broadened the criteria for responsibility from knowledge of right or wrong to the presence of a “mental disease or defect.” The American Law Institute criteria concluded that people were not responsible for their criminal behavior if, because of their mental illness, they lacked either the cognitive ability to recognize the inappropriateness of their behavior or the ability to control their behavior.

- ▶ The concept of diminished capacity holds that people’s ability to understand the nature of their behavior and therefore their criminal intent could be lessened by their mental illness.
- ▶ A determination of competence must be made before an individual can be tried for a criminal offense: To stand trial, people must be competent—able to understand the charges against them and to assist with their own defense.
- ▶ Duty to warn is a standard that sets forth the responsibility of the therapist to warn potential victims that a client may attempt to hurt or kill them.
- ▶ Individuals who have specialized knowledge and who assist judges and juries in making decisions, especially about such issues as competence and malingering, are called expert witnesses.

Patients’ Rights and Clinical Practice Guidelines

- ▶ One of the more fundamental rights of patients in mental health facilities is their right to treatment; that is, they have a legal right to some sort of ongoing effort to both define and strive toward treatment goals. By contrast, a great deal of controversy exists over whether all patients are capable of making a decision to refuse treatment. This is an especially difficult dilemma in the case of antipsychotic medications that may improve patients’ symptoms but bring with them severe negative side effects.
- ▶ Subjects who participate in any research study must be fully informed of the risks and benefits and formally give their informed consent to indicate they have been fully informed.
- ▶ Clinical practice guidelines can play a major role in providing information about types of interventions that are likely to be effective for a specific disorder, thereby setting the stage for evidence-based practice. Critical to such a determination are measures of clinical efficacy (internal validity) and clinical utility (external validity); in other words, the former is a measure of whether a treatment works, and the latter is a measure of whether the treatment is effective in a variety of settings and can be implemented in those settings.

Glossary

Note: Many familiar words have specialized meanings and usage in psychology. A number of these, used in the text, are defined here.

abnormal behavior A psychological dysfunction within an individual that is associated with distress or impairment in functioning and a response that is not typical or culturally expected.

actigraph Small electronic device that is worn on the wrist like a watch and records body movements. This device can be used to record sleep-wake cycles.

action potentials Short periods of electrical activity at the membrane of a neuron, responsible for the transmission of signals within the neuron.

acute pain Pain that typically follows an injury and disappears once the injury heals or is effectively treated.

acute stress disorder Severe reaction immediately following a terrifying event, often including amnesia about the event, emotional numbing, and **derealization**. If symptoms persist beyond one month, victims are diagnosed with **posttraumatic stress disorder**.

adjustment disorders Clinically significant emotional and behavioral symptoms in response to one or more specific stressors.

adoption studies In genetics research, the study of first-degree relatives reared in different families and environments. If they share common characteristics, such as a disorder, this finding suggests that those characteristics have a genetic component.

affect Conscious, subjective aspect of an **emotion** that accompanies an action at a given time.

agnosia Inability to recognize and name objects; may be a symptom of **major neurocognitive disorder** or other brain disorders.

agonist Chemical substance that effectively increases the activity of a **neurotransmitter** by imitating its effects.

agonist substitution Replacement of a drug on which a person is dependent with one that has a similar chemical makeup, an **agonist**. Used as a treatment for **substance dependence**.

agoraphobia Anxiety disorder characterized by anxiety about being in places or situations from which escape might be difficult in the event of panic symptoms or other unpleasant physical symptoms (e.g., incontinence).

AIDS-related complex (ARC) Group of minor health problems such as weight loss, fever, and night sweats that appears after HIV infection but before development of full-blown AIDS.

alcohol By-product of the fermentation of yeasts, sugar, and water; the most commonly used and abused **depressant** substance.

alcohol dehydrogenase (ADH) Enzyme that helps humans metabolize **alcohol**. Different levels of its subtypes may account for different susceptibilities to disorders such as **fetal alcohol syndrome**.

alcohol-related disorders Cognitive, biological, behavioral, and social problems associated with **alcohol** use and abuse.

alogia Deficiency in the amount or content of speech, a disturbance often seen in people with **schizophrenia**.

alters Shorthand term for alter egos, the different personalities or identities in **dissociative identity disorder**.

Alzheimer's disease "Strange disease of the cerebral cortex" that causes an "atypical form of senile dementia," discovered in 1906 by German psychiatrist Alois Alzheimer.

amniocentesis Prenatal medical procedure that allows the detection of abnormalities (for example, **Down syndrome**) in the developing fetus. It involves removal and analysis of amniotic fluid from the mother.

amphetamine Stimulant medication used to treat hypersomnia by keeping the person awake during the day, and to treat **narcolepsy**, including sudden onset episodes, by suppressing **rapid eye movement sleep**.

analog model Approach to research that employs subjects who are similar to clinical clients, allowing replication of a clinical problem under controlled conditions.

anhedonia Inability to experience pleasure, associated with some **mood** and schizophrenic disorders.

animal phobia Unreasonable, enduring **fear** of animals or insects that usually develops early in life.

anorexia nervosa Eating disorder characterized by recurrent food refusal, leading to dangerously low body weight.

antagonist In **neuroscience**, a chemical substance that decreases or blocks the effects of a **neurotransmitter**.

antagonist drugs Medications that block or counteract the effects of psychoactive drugs.

antigens Foreign materials that enter the body, including bacteria and parasites.

antisocial personality disorder Cluster B (dramatic, emotional, or erratic) **personality disorder** involving a pervasive pattern of disregard for and violation of the rights of others.

anxiety Mood state characterized by marked negative affect and bodily symptoms of tension in which a person apprehensively anticipates future danger or misfortune. Anxiety may involve feelings, behaviors, and physiological responses.

aphasia Impairment or loss of language skills resulting from brain damage caused by **stroke**, **Alzheimer's disease**, or other illness or trauma.

apnea See **sleep apnea**.

association studies Research strategies for comparing **genetic markers** in groups of people with and without a particular disorder.

associative splitting Separation among basic functions of human personality (for example, cognition, **emotion**, and perception) seen by some as the defining characteristic of **schizophrenia**.

attachment disorders Developmentally inappropriate behaviors in which a child is unable or unwilling to form normal attachment relationships with caregiving adults.

attention deficit/hyperactivity disorder (ADHD) Developmental disorder featuring maladaptive levels of inattention, excessive activity, and impulsiveness.

attenuated psychosis syndrome Disorder involving the onset of psychotic symptoms such as hallucinations and delusions, which puts a person at high risk for schizophrenia; designated for further study by **DSM-5**.

autism spectrum disorder (autism)

Neurodevelopmental disorder characterized by significant impairment in social interactions and communication and restricted patterns of behavior, interest, and activity.

autoimmune disease Condition in which the body's **immune system** attacks healthy tissue rather than **antigens**.

avoidant personality disorder Cluster C (anxious or fearful) **personality disorder** featuring a pervasive pattern of social inhibition, feelings of inadequacy, and hypersensitivity to criticism.

avolition *Apathy*, or the inability to initiate or persist in important activities.

barbiturates Sedative (and addictive) drugs including Amytal, Seconal, and Nembutal that are used as sleep aids.

bariatric surgery Surgical approach to extreme **obesity**, usually accomplished by stapling the stomach to create a small stomach pouch or bypassing the stomach through gastric bypass surgery.

baseline Measured rate of a behavior before introduction of an intervention that allows comparison and assessment of the effects of the intervention.

behavior therapy Array of therapy methods based on the principles of behavioral and **cognitive science**, as well as principles of learning as applied to clinical problems. It considers specific behaviors rather than inferred conflicts as legitimate targets for change.

- behavioral assessment** Measuring, observing, and systematically evaluating (rather than inferring) the client's thoughts, feelings, and behavior in the actual problem situation or context.
- behavioral inhibition system (BIS)** Brain circuit in the limbic system that responds to threat signals by inhibiting activity and causing anxiety.
- behavioral medicine** Interdisciplinary approach applying behavioral science to the prevention, diagnosis, and treatment of medical problems.
- behavioral model** Explanation of human behavior, including dysfunction, based on principles of learning and adaptation derived from experimental psychology.
- behaviorism** Explanation of human behavior, including dysfunction, based on principles of learning and adaptation derived from experimental psychology.
- benzodiazepines** Antianxiety drugs including Valium, Xanax, Dalmane, and Halcion also used to treat insomnia. Effective against anxiety (and, at high potency, panic disorder), they show some side effects, such as some cognitive and motor impairment, and may result in substance dependence. Relapse rates are extremely high when the drug is discontinued.
- binge** Relatively brief episode of uncontrolled, excessive consumption, usually of food or alcohol.
- binge-eating disorder (BED)** Pattern of eating involving distress-inducing binges not followed by purging behaviors; being considered as a new DSM diagnostic category.
- biofeedback** Use of physiological monitoring equipment to make individuals aware of their own bodily functions, such as blood pressure or brain waves, that they cannot normally access, with the purpose of controlling these functions.
- bipolar I disorder** Alternation of major depressive episodes with full manic episodes.
- bipolar II disorder** Alternation of major depressive episodes with hypomanic episodes (not full manic episodes).
- blood-injection-injury phobia** Unreasonable fear and avoidance of exposure to blood, injury, or the possibility of an injection. Victims experience fainting and a drop in blood pressure.
- body dysmorphic disorder (BDD)** Disorder featuring a disruptive preoccupation with some imagined defect in appearance ("imagined ugliness"). Now classified among obsessive-compulsive and related disorders; previously grouped with DSM-IV somatoform disorders.
- borderline personality disorder** Cluster B (dramatic, emotional, or erratic) personality disorder involving a pervasive pattern of instability of interpersonal relationships, self-image, affects, and control over impulses.
- brain circuits Neurotransmitter** currents or neural pathways in the brain.
- breathing-related sleep disorders** Sleep disruption leading to excessive sleepiness or insomnia, caused by a breathing problem such as interrupted (**sleep apnea**) or labored (hypoventilation) breathing.
- brief psychotic disorder** Psychotic disturbance involving **delusions**, **hallucinations**, or **disorganized speech** or behavior but lasting less than 1 month; often occurs in reaction to a stressor.
- bulimia nervosa** Eating disorder involving recurrent episodes of uncontrolled excessive (**binge**) eating followed by compensatory actions to remove the food (for example, deliberate vomiting, laxative abuse, and excessive exercise).
- caffeine use disorders** Cognitive, biological, behavioral, and social problems associated with the use and abuse of caffeine.
- cancer** Category of often-fatal medical conditions involving abnormal cell growth and malignancy.
- cannabis** See **marijuana**.
- cannabis use disorders** A problematic pattern of cannabis use leading to clinically significant impairment or distress.
- cardiovascular disease** Afflictions in the mechanisms, including the heart, blood vessels, and their controllers, responsible for transporting blood to the body's tissues and organs. Psychological factors may play important roles in such diseases and their treatments.
- case study method** Research procedure in which a single person or small group is studied in detail. The method does not allow conclusions about cause-and-effect relationships, and findings can be generalized only with great caution (contrast with **single-case experimental design**).
- castration anxiety** In **psychoanalysis**, the fear in young boys that they will be mutilated genetically because of their lust for their mothers.
- catalepsy** Motor movement disturbance seen in people with some psychoses and **mood disorders** in which body postures are waxy and can be "sculpted" to remain fixed for long periods.
- catatonia** Disorder of movement involving immobility or excited agitation. Sometimes accompanies psychotic disorders or mood disorders.
- catatonic immobility** Disturbance of motor behavior in which the person remains motionless, sometimes in an awkward posture, for extended periods.
- catharsis** Rapid or sudden release of emotional tension thought to be an important factor in psychoanalytic therapy.
- childhood disintegrative disorder Pervasive developmental disorder** involving severe regression in language, adaptive behavior, and motor skills after a 2- to 4-year period of normal development.
- childhood-onset speech fluency disorder (stuttering)** Repetitions of words or parts of words, as well as prolongations of speech sounds.
- chorionic villus sampling (CVS)** A genetic test conducted during early pregnancy that samples cells found in the placenta (chorionic villi) and assesses possible genetic or chromosomal problems in the fetus.
- chronic fatigue syndrome (CFS)** Incapacitating exhaustion following only minimal exertion, accompanied by fever, headaches, muscle and joint pain, depression, and anxiety.
- chronic pain** Enduring pain that does not decrease over time; may occur in muscles, joints, and the lower back, and may be caused by enlarged blood vessels or degenerating or cancerous tissue. Other significant factors are social and psychological.
- circadian rhythm sleep disorders** Sleep disturbances resulting in sleepiness or insomnia, caused by the body's inability to synchronize its sleep patterns with the current pattern of day and night.
- circumplex model of emotions** A model describing different emotions as points in a 2-dimensional space of valence and arousal.
- civil commitment laws** Legal proceedings that determine a person is mentally disordered and may be hospitalized, even involuntarily.
- classical categorical approach Classification** method founded on the assumption of clear-cut differences among disorders, each with a different known cause.
- classical conditioning** Fundamental learning process first described by Ivan Pavlov. An event that automatically elicits a response is paired with another stimulus event that does not (a neutral stimulus). After repeated pairings, the neutral stimulus becomes a conditioned stimulus that by itself can elicit the desired response.
- classification** Assignment of objects or people to categories on the basis of shared characteristics.
- clinical assessment** Systematic evaluation and measurement of psychological, biological, and social factors in a person presenting with a possible **psychological disorder**.
- clinical description** Details of the combination of behaviors, thoughts, and feelings of an individual that make up a particular disorder.
- clinical efficacy axis** One of a proposed set of guidelines for evaluating clinical interventions on the evidence of their effectiveness (compare with **clinical utility axis**).
- clinical significance** Degree to which research findings have useful and meaningful applications to real problems.
- clinical utility axis** One of a proposed set of guidelines for evaluating clinical interventions by whether they can be applied effectively and cost effectively in real clinical settings (compare with **clinical efficacy axis**).
- cocaine** Derivative of coca leaves used medically as a local anesthetic and narcotic; often a substance of abuse.

cognitive science Field of study that examines how humans and other animals acquire, process, store, and retrieve information.	major cause of death in Western culture, with social and psychological factors involved.
cognitive therapy Treatment approach that involves identifying and altering negative thinking styles related to psychological disorders such as depression and anxiety and replacing them with more positive beliefs and attitudes and, ultimately, more adaptive behavior and coping styles.	correlation Degree to which two variables are associated. In a positive correlation , the two variables increase or decrease together. In a negative correlation , one variable decreases as the other increases.
cohort Participants in each age group of a study with a cross-sectional design .	correlation coefficient Computed statistic reflecting the strength and direction of any association between two variables. It can range from -1.00 through 0.00 (indicating no association) to +1.00, with the absolute value indicating the strength and the sign reflecting the direction.
cohort effect Observation that people of different age groups differ in their values and experiences.	course Pattern of development and change of a disorder over time.
collective unconscious Accumulated wisdom of a culture collected and remembered across generations, a psychodynamic concept introduced by Carl Jung.	covert sensitization Cognitive-behavioral intervention to reduce unwanted behaviors by having clients imagine the extremely aversive consequences of the behaviors and establish negative rather than positive associations with them.
comorbidity Presence of two or more disorders in an individual at the same time.	Creutzfeldt-Jakob disease Extremely rare type of prion disease that may result from a number of sources, including the consumption of beef from cattle with "mad cow disease."
comparative treatment research Outcome research that contrasts two or more treatment methods to determine which is most effective.	criminal commitment Legal procedure by which a person found not guilty of a crime by reason of insanity must be confined in a psychiatric hospital.
competence Ability of legal defendants to participate in their own defense and understand the charges and the roles of the trial participants.	cross-generational effect Limit on the generalizability of longitudinal research because the group under study may differ from others in culture and experience.
complicated grief Grief characterized by debilitating feelings of loss and emotions so painful that a person has trouble resuming a normal life; designated for further study as a disorder by <i>DSM-5</i> .	cross-sectional design Methodology to examine a characteristic by comparing individuals of different ages (contrast with longitudinal design).
compulsions Repetitive, ritualistic, time-consuming behaviors or mental acts a person feels driven to perform to suppress obsessions.	cultural-familial intellectual disability Mild intellectual disability that may be caused largely by environmental influences.
confound Any factor occurring in a study that makes the results uninterpretable because its effects cannot be separated from those of the variables being studied.	cyclothymic disorder Chronic (at least 2 years) mood disorder characterized by alternating mood elevation and depression levels that are not as severe as manic or major depressive episodes .
confounding variable Variable in a research study that was not part of the intended design and that may contribute to changes in the dependent variable .	dangerousness Tendency to violence that, contrary to popular opinion, is not more likely among mental patients.
control group Group of individuals in a study who are similar to the experimental subjects in every way but are not exposed to the treatment received by the experimental group. Their presence allows for a comparison of the differential effects of the treatment.	defense mechanisms Common patterns of behavior, often adaptive coping styles when they occur in moderation, observed in response to particular situations. In psychoanalysis , these are thought to be unconscious processes originating in the ego.
controlled drinking An extremely controversial treatment approach to alcohol dependence, in which severe abusers are taught to drink in moderation.	deinstitutionalization Systematic removal of people with severe mental illness or intellectual disability from institutions like psychiatric hospitals.
conversion disorder (functional neurological symptom disorder) Physical malfunctioning, such as blindness or paralysis, suggesting neurological impairment but with no organic pathology to account for it.	delayed ejaculation Disorder in which a man achieves orgasm only with great difficulty.
copy number variants Genes that are deleted as a result of mutations; these deletions may play a role in the development of ADHD and other disorders.	delirium Rapid-onset reduced clarity of consciousness and cognition, with confusion, disorientation, and deficits in memory and language.
coronary heart disease (CHD) Blockage of the arteries supplying blood to the heart muscle; a	delusion Psychotic symptom involving disorder of thought content and presence of strong beliefs that are misrepresentations of reality.
	delusional disorder Psychotic disorder featuring a persistent belief contrary to reality (delusion) but no other symptoms of schizophrenia .
	dementia Obsolete term for major neurocognitive disorder .
	dementia of the Alzheimer's type Obsolete term for major neurocognitive disorder due to Alzheimer's disease .
	dementia praecox Latin term meaning "premature loss of mind," an early label for what is now called schizophrenia , emphasizing the disorder's frequent appearance during adolescence. Called <i>démence précoce</i> in France.
	dependent personality disorder Cluster C (anxious or fearful) personality disorder characterized by a person's pervasive and excessive need to be taken care of, a condition that leads to submissive and clinging behavior and fears of separation.
	dependent variable In an experimental study, the phenomenon that is measured and expected to be influenced (compare with independent variable).
	depersonalization/derealization disorder Dissociative disorder in which feelings of depersonalization are so severe they dominate the client's life and prevent normal functioning.
	depressants Psychoactive substances that result in behavioral sedation, including alcohol and the sedative, hypnotic, and anxiolytic drugs.
	depressive cognitive triad Thinking errors in depressed people negatively focused in three areas: themselves, their immediate world, and their future.
	derealization Situation in which the individual loses a sense of the reality of the external world.
	deterministic In genetics, genes that lead to nearly a 100% chance of developing the associated disorder. These are rare in the population.
	diagnosis Process of determining whether a presenting problem meets the established criteria for a specific psychological disorder .
	dialectical behavioral therapy (DBT) Promising treatment for borderline personality disorder that involves exposing the client to stressors in a controlled situation, as well as helping the client regulate emotions and cope with stressors that might trigger suicidal behavior.
	diathesis-stress model Hypothesis that both an inherited tendency (a vulnerability) and specific stressful conditions are required to produce a disorder.
	dimensional approach Method of categorizing characteristics on a continuum rather than on a binary, either-or, or all-or-none basis.
	diminished capacity Evidence of an abnormal mental condition in people that causes criminal charges against them requiring intent or

knowledge to be reduced to lesser offenses requiring only reckless or criminal neglect.	(chromosome 21) and involving characteristic physical appearance. Sometimes known as trisomy 21.
directionality Possibility that when two variables, A and B, are correlated variable A causes variable B or variable B causes variable A.	
disinhibited social engagement disorder	dream analysis Psychoanalytic therapy method in which dream contents are examined as symbolic of id impulses and intrapsychic conflicts .
Condition in which a child shows no inhibitions whatsoever in approaching adults.	duty to warn Mental health professional's responsibility to break confidentiality and notify the potential victim whom a client has specifically threatened.
disorder of arousal Category of sleep disorder during NREM sleep that includes sleepwalking and sleep terrors .	dyssomnias Problems in getting to sleep or in obtaining sufficient quality sleep.
disorganized speech Style of talking often seen in people with schizophrenia , involving incoherence and a lack of typical logic patterns.	dysthymia See Persistent depressive disorder .
disruptive mood dysregulation disorder	effect size Statistical measure that shows the amount of difference among the members of a group in a clinical study.
Condition in which a child has chronic negative moods such as anger and irritability without any accompanying mania.	ego In psychoanalysis , the psychical entity responsible for finding realistic and practical ways to satisfy id drives.
dissociative amnesia Dissociative disorder featuring the inability to recall personal information, usually of a stressful or traumatic nature.	ego psychology Derived from psychoanalysis , this theory emphasizes the role of the ego in development and attributes psychological disorders to failure of the ego to manage impulses and internal conflicts. Also known as <i>self-psychology</i> .
dissociative disorder Disorder in which individuals feel detached from themselves or their surroundings and reality, experience, and identity may disintegrate.	electroconvulsive therapy (ECT) Biological treatment for severe, chronic depression involving the application of electrical impulses through the brain to produce seizures. The reasons for its effectiveness are unknown.
dissociative fugue Type of dissociative amnesia featuring sudden, unexpected travel away from home, along with an inability to recall the past, sometimes with assumption of a new identity.	electroencephalogram (EEG) Measure of electrical activity patterns in the brain, taken through electrodes placed on the scalp.
dissociative identity disorder (DID) Formerly known as multiple personality disorder; a disorder in which as many as 100 personalities or fragments of personalities coexist within one body and mind.	emotion Pattern of action elicited by an external event and a feeling state, accompanied by a characteristic physiological response.
dissociative trance disorder Altered state of consciousness in which people firmly believe they are possessed by spirits; considered a disorder only where there is distress and dysfunction.	endogenous opioids Substances occurring naturally throughout the body that function like neurotransmitters to shut down pain sensation even in the presence of marked tissue damage. These may contribute to psychological problems such as eating disorders. Also known as <i>endorphins</i> or <i>enkephalins</i> .
dopamine Neurotransmitter whose generalized function is to activate other neurotransmitters and to aid in exploratory and pleasure-seeking behaviors (thus balancing serotonin). A relative excess of dopamine is implicated in schizophrenia (although contradictory evidence suggests the connection is not simple), and its deficit is involved in Parkinson's disease .	endophenotypes Genetic mechanisms that contribute to the underlying problems causing the symptoms and difficulties experienced by people with psychological disorders .
double bind communication According to an obsolete, unsupported theory, the practice of transmitting conflicting messages that was thought to cause schizophrenia .	epidemiology Psychopathology research method examining the prevalence, distribution, and consequences of disorders in populations.
double depression Severe mood disorder typified by major depressive episodes superimposed over a background of persistent dysthymic mood . Also called "Persistent depressive disorder with intermittent major depressive episodes."	epigenetics The study of factors other than inherited DNA sequence, such as new learning or stress, that alter the phenotypic expression of genes.
double-blind control Procedure in outcome studies that prevents bias by ensuring that neither the subjects nor the providers of the experimental treatment know who is receiving treatment and who is receiving placebo.	equifinality Developmental psychopathology principle that a behavior or disorder may have several causes.
Down syndrome Type of intellectual disability caused by a chromosomal aberration	erectile disorder Recurring inability in some men to attain or maintain adequate penile erection until completion of sexual activity.
	essential hypertension High blood pressure with no verifiable physical cause, which makes up the overwhelming majority of high blood pressure cases.
	etiology Cause or source of a disorder.
	excitatory Causing excitation. Activating.
	excoriation (skin picking disorder) Recurrent, difficult-to-control picking of one's skin leading to significant impairment or distress.
	exhibitionistic disorder Sexual gratification attained by exposing genitals to unsuspecting strangers.
	exorcism Religious ritual that attributes disordered behavior to possession by demons and seeks to treat the individual by driving the demons from the body.
	experiment Research method that can establish causation by manipulating the variables in question and controlling for alternative explanations of any observed effects.
	expert witness Person who because of special training and experience is allowed to offer opinion testimony in legal trials.
	expressed emotion (EE) Hostility, criticism, and overinvolvement demonstrated by some families toward a family member with a psychological disorder . This can often contribute to the person's relapse .
	external validity Extent to which research findings generalize, or apply, to people and settings not involved in the study.
	extinction Learning process in which a response maintained by reinforcement in operant conditioning or pairing in classical conditioning decreases when that reinforcement or pairing is removed; also the procedure of removing that reinforcement or pairing.
	facial agnosia Type of agnosia characterized by a person's inability to recognize even familiar faces.
	factitious disorder Nonexistent physical or psychological disorder deliberately faked for no apparent gain except possibly sympathy and attention.
	false negative Assessment error in which no pathology is noted (that is, test results are negative) when one is actually present.
	false positive Assessment error in which pathology is reported (that is, test results are positive) when none is actually present.
	familial aggregation The extent to which a disorder is found among a patient's relatives.
	family studies Genetic studies that examine patterns of traits and behaviors among relatives.
	fear Emotion of an immediate alarm reaction to present danger or life-threatening emergencies.
	female orgasmic disorder Recurring delay or absence of orgasm in some women following a normal sexual excitement phase, relative to their prior experience and current stimulation. Also known as inhibited orgasm (female).
	female sexual interest/arousal disorder Recurrent inability in some women to attain or maintain adequate lubrication and sexual excitement swelling responses until completion of sexual activity.

fetal alcohol syndrome (FAS) Pattern of problems including learning difficulties, behavior deficits, and characteristic physical flaws, resulting from heavy drinking by the victim's mother when she was pregnant with the victim.	general adaptation syndrome (GAS) Sequence of reactions to sustained stress described by Hans Selye. These stages are alarm, resistance, and exhaustion, which may lead to death.	homosexual behavior Sexual activity with members of the same gender.
fetishistic disorder Long-term, recurring, intense sexually arousing urges, fantasies, or behavior that involve the use of nonliving, unusual objects and that cause distress or impairment in life functioning.	generalizability Extent to which research results apply to a range of individuals not included in the study.	hormone Chemical messenger produced by the endocrine glands.
fight-flight system (FFS) Brain circuit in animals that when stimulated causes an immediate alarm and escape response resembling human panic .	generalized amnesia Loss of memory of all personal information, including identity.	human genome project Ongoing scientific attempt to develop a comprehensive map of all human genes .
flat affect Apparently emotionless demeanor (including toneless speech and vacant gaze) when a reaction would be expected.	generalized anxiety disorder (GAD) Anxiety disorder characterized by intense, uncontrollable, unfocused, chronic, and continuous worry that is distressing and unproductive, accompanied by physical symptoms of tenseness, irritability, and restlessness.	human immunodeficiency virus type 1 (HIV-I) Disease that causes AIDS.
flight or fight response Biological reaction to alarming stressors that musters the body's resources (for example, blood flow and respiration) to resist or flee a threat.	genes Long deoxyribonucleic acid (DNA) molecules, the basic physical units of heredity that appear as locations on chromosomes. A single gene is a subunit of DNA that determines inherited traits in living things.	Huntington's disease Genetic disorder marked by involuntary limb movements and progressing to major neurocognitive disorder .
fragile X syndrome Pattern of abnormality caused by a defect in the X chromosome resulting in intellectual disability , learning problems, and unusual physical characteristics.	genetic linkage analysis Study that seeks to match the inheritance pattern of a disorder to that of a genetic marker . This helps researchers establish the location of the gene responsible for the disorder.	hypersomnolence disorder Sleep dysfunction involving an excessive amount of sleep that disrupts normal routines.
free association Psychoanalytic therapy technique intended to explore threatening material repressed into the unconscious . The patient is instructed to say whatever comes to mind without censoring.	genetic marker Inherited characteristic for which the chromosomal location of the responsible gene is known.	hypertension Major risk factor for stroke and heart and kidney disease that is intimately related to psychological factors. Also known as <i>high blood pressure</i> .
frontotemporal neurocognitive disorder Condition that damages the frontal or temporal regions of the brain; behavior or language is negatively affected.	genito-pelvic pain/penetration disorder Sexual dysfunction in which a woman experiences pain or difficulty with penetration during intercourse; may include vaginismus .	hypomanic episode Less severe and less disruptive version of a manic episode that is one of the criteria for several mood disorders .
frotteuristic disorder Paraphilic disorder in which the person gains sexual gratification by rubbing against unwilling victims in crowds from which they cannot escape.	genotype Specific genetic makeup of an individual.	hypothesis Educated guess or statement to be tested by research.
gambling disorder Persistent and recurrent problematic gambling behavior leading to clinically significant impairment or distress	glutamate Amino acid neurotransmitter that excites many different neurons , leading to action.	id In psychoanalysis , the unconscious psychological entity present at birth representing basic sexual and aggressive drives.
gamma-aminobutyric acid (GABA) Neurotransmitter that reduces activity across the synapse and thus inhibits a range of behaviors and emotions , especially generalized anxiety .	hallucinations Psychotic symptoms of perceptual disturbance in which things are seen, heard, or otherwise sensed although they are not actually present.	idiographic strategy Close and detailed investigation of an individual emphasizing what makes that person unique (compare with nomothetic strategy).
gender dysphoria Psychological dissatisfaction with biological gender, a disturbance in the sense of identity as a male or female. The primary goal is not sexual arousal but rather to live the life of the opposite gender.	hallucinogen Any psychoactive substance such as LSD or marijuana that can produce delusions , hallucinations , paranoia , and altered sensory perception.	illness anxiety disorder Somatic symptom disorder (previously known as somatiform disorder) involving severe anxiety over belief in having a disease process without any evident physical cause.
gender nonconformity A phenomenon in which pre-pubescent children do not identify with their biological sex, but instead identify strongly with the gender of the opposite sex and display varying degrees of behavior more characteristic of the opposite sex.	hallucinogen use disorders Cognitive, biological, behavioral, and social problems associated with the use and abuse of hallucinogenic substances.	immune system Body's means of identifying and eliminating any foreign materials (for example, bacteria, parasites, and even transplanted organs) that enter.
gene-environment correlation model Hypothesis that people with a genetic predisposition for a disorder may also have a genetic tendency to create environmental risk factors that promote the disorder.	head trauma Injury to the head and, therefore, to the brain, typically caused by accidents; can lead to cognitive impairments, including memory loss.	implicit memory Condition of memory in which a person cannot recall past events despite acting in response to them (contrast with explicit memory).
	health psychology Subfield of behavioral medicine that studies psychological factors important in health promotion and maintenance.	impulse-control disorders Disorders in which a person acts on an irresistible, but potentially harmful, impulse.
	hebephrenia Silly and immature emotionality; a characteristic of some types of schizophrenia .	inappropriate affect Emotional displays that are improper for the situation.
	heterosexual behavior Sexual activity with members of the opposite gender.	incest Deviant sexual attraction (pedophilia) directed toward a family member; often the attraction of a father toward a daughter who is maturing physically.
	histrionic personality disorder Cluster B (dramatic, emotional, or erratic) personality disorder involving a pervasive pattern of excessive emotionality and attention seeking.	incidence Number of new cases of a disorder appearing during a specific period (compare with prevalence).
		independent variable Phenomenon manipulated by the experimenter in a study and expected to influence the dependent variable .
		informed consent Ethical requirement whereby research subjects agree to participate in a study only after they receive full disclosure about the nature of the study and their own role in it.
		inhibitory Causing inhibition. Suppressing.

insomnia disorder Condition in which insufficient sleep interferes with normal functioning.		be overcome with accommodations such as extensive lists or elaborate schedules.
integrated grief Grief that evolves from acute grief into a condition in which the individual accepts the finality of a death and adjusts to the loss.	mixed features Condition in which the individual experiences both elation and depression or anxiety at the same time. Also known as <i>dysphoric manic episode</i> or <i>mixed manic episode</i> .	
intellectual disability (ID) A diagnosis received when one achieves a significantly below-average score on a test of intelligence and by limitations in the ability to function in areas of daily life.	modeling (also known as <i>observational learning</i>) Learning through observation and imitation of the behavior of other individuals and consequences of that behavior.	
intelligence quotient (IQ) Score on an intelligence test estimating a person's deviation from average test performance.	mood Enduring period of emotionality.	
intermittent explosive disorder Episodes during which a person acts on aggressive impulses that result in serious assaults or destruction of property.	mood disorders Group of disorders involving severe and enduring disturbances in emotionality ranging from elation to severe depression.	
internal validity Extent to which the results of a study can be attributed to the independent variable after confounding alternative explanations have been ruled out.	mood-stabilizing drug A medication used in the treatment of mood disorders , particularly bipolar disorder, that is effective in preventing and treating pathological shifts in mood.	
interpersonal psychotherapy (IPT) Brief treatment approach that emphasizes resolution of interpersonal problems and stressors, such as role disputes, in marital conflict or forming relationships in marriage or a new job. It has demonstrated effectiveness for such problems as depression.	moral therapy Psychosocial approach in the 19th century that involved treating patients as normally as possible in normal environments.	
intrapsychic conflicts In psychoanalysis, the struggles among the id , ego , and superego .	multidimensional integrative approach Approach to the study of psychopathology that holds psychological disorders as always being the products of multiple interacting causal factors.	
introspection Early, nonscientific approach to the study of psychology involving systematic attempts to report thoughts and feelings that specific stimuli evoked.	multiple baseline Single-case experimental design in which measures are taken on two or more behaviors or on a single behavior in two or more situations. A particular intervention is introduced for each at different times. If behavior change is coincident with each introduction, this is strong evidence the intervention caused the change.	
inverse agonist Chemical substance that produces effects opposite those of a particular neurotransmitter .	narcissistic personality disorder Cluster B (dramatic, emotional, or erratic) personality disorder involving a pervasive pattern of grandiosity in fantasy or behavior, need for admiration, and lack of empathy.	
joint attention Attention shared by two persons toward an object after one person has indicated interest in the object to the other person; this social interaction is limited or absent in people with autism spectrum disorder .	narcolepsy Sleep disorder involving sudden and irresistible sleep attacks.	
kleptomania Recurrent failure to resist urges to steal things not needed for personal use or their monetary value.	natural environment phobia Fear of situations or events in nature, especially heights, storms, and water.	
labeling Applying a name to a phenomenon or a pattern of behavior. The label may acquire negative connotations or be applied erroneously to the person rather than that person's behaviors.	naturalistic teaching strategies Instructional techniques that are used with children having neurodevelopmental disorders and that move away from traditional desk instruction toward more natural social interactions.	
language disorder Getting one's meaning or message across to others (expressive language disorder), or understanding the message coming from others (receptive language disorder)	negative correlation Association between two variables in which one increases as the other decreases.	
learned helplessness Martin Seligman's theory that people become anxious and depressed when they make an attribution that they have no control over the stress in their lives (whether or not they do in reality).	negative symptoms Less outgoing symptoms, such as flat affect and poverty of speech, displayed by some people with schizophrenia .	
learned helplessness theory of depression The theory according to which depression is the result of perceived or real absence of control over the outcome of an undesirable situation.	neurocognitive disorder due to Alzheimer's type Condition resulting from a disease that develops most often in people 50 and older, characterized by multiple cognitive defects that develop gradually and steadily.	
	neurocognitive disorder due to HIV infection Less common type of neurocognitive disorder that affects people who have HIV; may lead to impaired thinking in advanced stages.	

neurocognitive disorder due to Huntington's disease Neurological disorder that follows a subcortical pattern and is notable for causing involuntary limb movements.

neurocognitive disorder due to Lewy body disease Neurological impairment that affects people with Lewy body disease, in which protein deposits damage brain cells and gradually cause motor impairments and loss of alertness.

neurocognitive disorder due to Parkinson's disease Disorder characterized by progressive decline in motor movements; results from damage to dopamine pathways.

neurocognitive disorder due to prion disease Rare progressive neurodegenerative disorder caused by prions, proteins that can reproduce themselves and cause damage to brain cells.

neurocognitive disorder due to traumatic brain injury Condition resulting from jarring of the brain caused by a blow to the head or other impact; symptoms persist for at least a week after the initial trauma.

neurodevelopmental disorders Neurologically based disorders that are revealed in a clinically significant way during a child's developing years.

neurohormones Hormones that affect the brain and are increasingly the focus of study in **psychopathology**.

neuroimaging Sophisticated computer-aided procedures that allow noninvasive examination of nervous system structure and function.

neuron Individual nerve cell; responsible for transmitting information.

neuropsychological testing Assessment of brain and nervous system functioning by testing an individual's performance on behavioral tasks.

neuroscience Study of the nervous system and its role in behavior, thoughts, and **emotions**.

neurosis Obsolete psychodynamic term for **psychological disorder** thought to result from **unconscious** conflicts and the **anxiety** they cause. Plural is *neuroses*.

neurotransmitters Chemicals that cross the **synaptic cleft** between nerve cells to transmit impulses from one **neuron** to the next. Their relative excess or deficiency is involved in several **psychological disorders**.

nicotine Toxic and addictive substance found in tobacco leaves.

nicotine patch Patch placed on the skin that delivers **nicotine** to smokers without the carcinogens in cigarette smoke. Somewhat more successful than nicotine gum because it requires less effort by the wearer and delivers the drug more consistently; should be coupled with counseling to stop smoking and avoid **relapse**.

nicotine use disorders See **tobacco-related disorders**.

night eating syndrome Consuming a third or more of daily food intake after the evening meal and getting out of bed at least once during the night to have a high-calorie snack. In

the morning, however, individuals with night eating syndrome are not hungry and do not usually eat breakfast. These individuals do not **binge** during their night eating and seldom purge.

nightmares Frightening and anxiety-provoking dreams occurring during **rapid eye movement sleep**. The individual recalls the bad dreams and recovers alertness and orientation quickly.

nomenclature In a naming system or **nosology**, the actual labels or names that are applied. In **psychopathology**, these include **mood disorders** and eating disorders.

nomothetic strategy Identification and examination of large groups of people with the same disorder to note similarities and develop general laws (compare with **idiographic strategy**).

norepinephrine (also **noradrenaline**)

Neurotransmitter active in the **central** and **peripheral nervous systems**, controlling heart rate, blood pressure, and respiration, among other functions. Because of its role in the body's alarm reaction, it may also contribute generally and indirectly to **panic attacks** and other disorders.

nosology Classification and naming system for medical and psychological phenomena.

obesity Excess of body fat resulting in a body mass index (BMI, a ratio of weight to height) of 30 or more.

object relations Modern development in psychodynamic theory involving the study of how children incorporate the memories and values of people who are close and important to them.

obsessions Recurrent intrusive thoughts or impulses the client seeks to suppress or neutralize while recognizing they are not imposed by outside forces.

obsessive-compulsive disorder (OCD) Disorder involving unwanted, persistent, intrusive thoughts and impulses, as well as repetitive actions intended to suppress them.

obsessive-compulsive personality disorder

Cluster C (anxious or fearful) **personality disorder** featuring a pervasive pattern of preoccupation with orderliness, perfectionism, and mental and interpersonal control at the expense of flexibility, openness, and efficiency.

opiates Addictive psychoactive substances such as heroin, **opium**, and **morphine** that cause temporary euphoria and analgesia (pain reduction).

opioid use disorders Cognitive, biological, behavioral, and social problems associated with the use and abuse of **opiates** and their synthetic variants.

orgasmic reconditioning Learning procedure to help clients strengthen appropriate patterns of sexual arousal by pairing appropriate stimuli with the pleasurable sensations of masturbation.

other drugs of abuse Other substances that are abused but do not fit easily into one of the common categories including inhalants, anabolic steroids, and other over-the-counter and prescription medications.

panic Sudden, overwhelming fright or terror.

panic attack Abrupt experience of intense fear or discomfort accompanied by a number of physical symptoms, such as dizziness or heart palpitations.

panic control treatment (PCT) Cognitive-behavioral treatment for **panic attacks**, involving gradual exposure to feared somatic sensations and modification of perceptions and attitudes about them.

panic disorder Recurrent unexpected panic attacks accompanied by concern about future attacks and/or a lifestyle change to avoid future attacks.

paranoia People's irrational beliefs that they are especially important (**delusions of grandeur**) or that other people are seeking to do them harm.

paranoid personality disorder Cluster A (odd or eccentric) **personality disorder** involving pervasive distrust and suspiciousness of others such that their motives are interpreted as malevolent.

paraphilic disorders Sexual disorders and deviations in which sexual arousal occurs almost exclusively in the context of inappropriate objects or individuals.

parasomnias Abnormal behaviors such as **nightmares** or **sleepwalking** that occur during sleep.

Parkinson's disease Degenerative brain disorder principally affecting motor performance (for example, tremors and stooped posture) associated with reduction in **dopamine**.

Major neurocognitive disorder may be a result as well.

patient uniformity myth Tendency to consider all members of a category as more similar than they are, ignoring their individual differences.

pedophilia Paraphilia involving strong sexual attraction toward children.

persistent depressive disorder (dysthymia)

Mood disorder involving persistently depressed **mood**, with low self-esteem, **withdrawal**, pessimism, or despair, present for at least 2 years, with no absence of symptoms for more than 2 months.

personality disorders Enduring maladaptive patterns for relating to the environment and self, exhibited in a range of contexts that cause significant functional impairment or subjective distress.

personality inventories Self-report questionnaires that assess personal traits by asking respondents to identify descriptions that apply to them.

person-centered therapy Therapy method in which the client, rather than the counselor, primarily directs the course of discussion, seeking self-discovery and self-responsibility.

pervasive developmental disorder not otherwise specified Wide-ranging, significant, and long-lasting dysfunctions that appear before the age of 18.	prodromal stage Second of E. Morton Jellinek's four stages identified in the progression of alcoholism, featuring heavy drinking but with few outward signs of a problem.	psychological or emotional events such as anxiety, stress, and sexual arousal.
phenotype Observable characteristics or behaviors of an individual.	prognosis Predicted future development of a disorder over time.	psychosexual stages of development In psychoanalysis, the sequence of phases a person passes through during development. Each stage is named for the location on the body where id gratification is maximal at that time.
phenylketonuria (PKU) Recessive disorder involving the inability to break down a food chemical whose buildup causes intellectual disability, seizures, and behavior problems. PKU can be detected by infant screening and prevented by a specialized diet.	projective tests Psychoanalytically based measures that present ambiguous stimuli to clients on the assumption that their responses will reveal their unconscious conflicts. Such tests are inferential and lack high reliability and validity.	psychosocial treatment Treatment practices that focus on social and cultural factors (such as family experience), as well as psychological influences. These approaches include cognitive, behavioral, and interpersonal methods.
phobia Psychological disorder characterized by marked and persistent fear of an object or situation.	prosody Vocal characteristics such as tone and stress; people with autism spectrum disorder often have trouble recognizing and interpreting these vocal cues.	psychotic behavior Severe psychological disorder category characterized by hallucinations and loss of contact with reality.
Pick's disease Rare condition that results in early onset neurocognitive disorder.	prototypical approach System for categorizing disorders using both essential, defining characteristics and a range of variation on other characteristics.	psychotic disorder associated with another medical condition Condition that is characterized by hallucinations or delusions and that is the direct result of another physiological disorder, such as stroke or brain tumor.
placebo control group In an outcome experiment, a control group that does not receive the experimental manipulation but is given a similar procedure with an identical expectation of change, allowing the researcher to assess any placebo effect.	psychoactive substances Substances, such as drugs, that alter mood or behavior.	psychotic symptoms Delusions and hallucinations that may appear during depressive or manic episodes.
placebo effect Behavior change resulting from the person's expectation of change rather than from the experimental manipulation itself.	psychoanalysis Psychoanalytic assessment and therapy, which emphasizes exploration of, and insight into, unconscious processes and conflicts, pioneered by Sigmund Freud.	purging techniques In the eating disorder bulimia nervosa, the self-induced vomiting or laxative abuse used to compensate for excessive food ingestion.
polysomnographic (PSG) evaluation Assessment of sleep disorders in which a client sleeping in the lab is monitored for heart, muscle, respiration, brain wave, and other functions.	psychoanalyst Therapist who practices psychoanalysis after earning either an M.D. or a Ph.D. degree and receiving additional specialized postdoctoral training.	pyromania An impulse-control disorder that involves having an irresistible urge to set fires.
polysubstance use Use of multiple mind- and behavior-altering substances, such as drugs.	psychoanalytic model Complex and comprehensive theory originally advanced by Sigmund Freud that seeks to account for the development and structure of personality, as well as the origin of abnormal behavior, based primarily on inferred inner entities and forces.	randomization Method for placing individuals into research groups that assures each an equal chance of being assigned to any group, thus eliminating any systematic differences across groups.
positive correlation Association between two variables in which one increases as the other increases.	psychodynamic psychotherapy Contemporary version of psychoanalysis that still emphasizes unconscious processes and conflicts but is briefer and more focused on specific problems.	rapid eye movement (REM) sleep Periodic intervals of sleep during which the eyes move rapidly from side to side, and dreams occur, but the body is inactive.
posttraumatic stress disorder (PTSD) Enduring, distressing emotional disorder that follows exposure to severe helplessness or a fear-inducing threat. The victim reexperiences the trauma, avoids stimuli associated with it, and develops a numbing of responsiveness and an increased vigilance and arousal.	psychological autopsy Postmortem psychological profile of a suicide victim constructed from interviews with people who knew the person before death.	reactive attachment disorder Attachment disorder in which a child with disturbed behavior neither seeks out a caregiver nor responds to offers of help from one; fearfulness and sadness are often evident.
premature ejaculation Recurring ejaculation before the person wishes it, with minimal sexual stimulation.	psychological disorder Psychological dysfunction associated with distress or impairment in functioning that is not a typical or culturally expected response.	rebound insomnia In a person with insomnia, the worsened sleep problems that can occur when medications are used to treat insomnia and then withdrawn.
premenstrual dysphoric disorder Clinically significant emotional problems that can occur during the premenstrual phase of the reproductive cycle of a woman.	psychoncology Study of psychological factors involved in the course and treatment of cancer.	recurrent Repeatedly occurring.
prepared learning An ability that has been adaptive for evolution, allowing certain associations to be learned more readily than others.	psychoneuroimmunology (PNI) Study of psychological influences on the neurological responding involved in the body's immune response.	reinforcement In operant conditioning, consequences for behavior that strengthen it or increase its frequency. Positive reinforcement involves the contingent delivery of a desired consequence. Negative reinforcement is the contingent escape from an aversive consequence. Unwanted behaviors may result from their reinforcement or the failure to reinforce desired behaviors.
presenting problem Original complaint reported by the client to the therapist. The actual treated problem may sometimes be a modification derived from the presenting problem.	psychopathology Scientific study of psychological disorders.	relapse prevention Extending therapeutic progress by teaching the client how to cope with future troubling situations.
prevalence Number of people displaying a disorder in the total population at any given time (compare with incidence).	psychopathy Non-DSM-5 category similar to antisocial personality disorder but with less emphasis on overt behavior. Indicators include superficial charm, lack of remorse, and other personality characteristics.	relaxation response Active components of meditation methods, including repetitive thoughts of a sound to reduce distracting thoughts and closing the mind to other intruding thoughts, that decrease the flow of stress hormones
primary insomnia Difficulty in initiating, maintaining, or gaining from sleep; not related to other medical or psychological problems.	psychophysiological assessment Measurement of changes in the nervous system reflecting	
proband In genetics research, the individual displaying the trait or characteristic being studied.		

- and neurotransmitters** and cause a feeling of calm.
- reliability** Degree to which a measurement is consistent, for example, over time or among different raters.
- repeated measurement** When responses are measured on more than two occasions (not just before and after intervention) to assess trends.
- research design** Plan of experimentation used to test a **hypothesis**.
- retrospective information** Literally “the view back”; data collected by examining records or recollections of the past. It is limited by the accuracy, **validity**, and thoroughness of the sources.
- Rett disorder** Progressive neurodevelopmental disorder featuring constant hand-wringing, **intellectual disability**, and impaired motor skills.
- reuptake** Action by which a **neurotransmitter** is quickly drawn back into the discharging **neuron** after being released into a **synaptic cleft**.
- rheumatoid arthritis** Painful, degenerative disease in which the **immune system** essentially attacks itself, resulting in stiffness, swelling, and even destruction of the joints. **Cognitive-behavioral treatments** can help relieve pain and stiffness.
- schizoaffective disorder** Psychotic disorder featuring symptoms of both **schizophrenia** and major **mood disorder**.
- schizoid personality disorder** Cluster A (odd or eccentric) **personality disorder** featuring a pervasive pattern of detachment from social relationships and a restricted range of expression of **emotions**.
- schizophrenia** Devastating psychotic disorder that may involve characteristic disturbances in thinking (**delusions**), perception (**hallucinations**), speech, **emotions**, and behavior.
- schizophreniform disorder** Psychotic disorder involving the symptoms of **schizophrenia** but lasting less than 6 months.
- schizophrenogenic mother** According to an obsolete, unsupported theory, a cold, dominating, and rejecting parent who was thought to cause **schizophrenia** in her offspring.
- schizotypal personality disorder** Cluster A (odd or eccentric) **personality disorder** involving a pervasive pattern of interpersonal deficits featuring acute discomfort with, and reduced capacity for, close relationships, as well as cognitive or perceptual distortions and eccentricities of behavior.
- scientist-practitioners** Mental health professionals who are expected to apply scientific methods to their work. They must keep current in the latest research on **diagnosis** and treatment, they must evaluate their own methods for effectiveness, and they may generate their own research to discover new knowledge of disorders and their treatment.
- seasonal affective disorder (SAD) Mood disorder** involving a cycling of episodes corresponding to the seasons of the year, typically with depression occurring during the winter.
- self-actualizing** Process emphasized in humanistic psychology in which people strive to achieve their highest potential against difficult life experiences.
- self-efficacy** Perception of having the ability to cope with **stress** or challenges.
- self-monitoring** Action by which clients observe and record their own behaviors as either an assessment of a problem and its change or a treatment procedure that makes them more aware of their responses. Also called self-observation.
- self-psychology** See **ego psychology**.
- separation anxiety disorder** Excessive, enduring fear in some individuals that harm will come to them or their loved ones when they are apart.
- sequential design** Combination of the **cross-sectional** and **longitudinal designs** involving repeated study of different **cohorts** over time.
- serotonin** **Neurotransmitter** involved in processing of information and coordination of movement, as well as inhibition and restraint. It also assists in the regulation of eating, sexual, and aggressive behaviors, all of which may be involved in different **psychological disorders**. Its interaction with **dopamine** is implicated in **schizophrenia**.
- sex reassignment surgery** Surgical procedures to alter a person's physical anatomy to conform to that person's psychological gender identity.
- sexual dysfunction** Sexual disorder in which the client finds it difficult to function adequately while having sex.
- sexual masochism** **Paraphilia** in which sexual arousal is associated with experiencing pain or humiliation.
- sexual sadism** **Paraphilia** in which sexual arousal is associated with inflicting pain or humiliation.
- shaping** In **operant conditioning**, the development of a new response by reinforcing successively more similar versions of that response. Both desirable and undesirable behaviors may be learned in this manner.
- shared psychotic disorder (folie à deux)** Psychotic disturbance in which individuals develop a **delusion** similar to that of a person with whom they share a close relationship.
- single-case experimental design** Research tactic in which an **independent variable** is manipulated for a single individual, allowing cause-and-effect conclusions but with limited **generalizability** (contrast with **case study method**).
- situational phobia** Anxiety involving enclosed places (for example, claustrophobia) or public transportation (for example, **fear of flying**).
- sleep apnea** Disorder involving brief periods when breathing ceases during sleep.
- sleep efficiency (SE)** Percentage of time actually spent sleeping of the total time spent in bed.
- sleep terrors** Episodes of apparent awakening from sleep, accompanied by signs of **panic**, followed by disorientation and amnesia for the incident. These occur during **nonrapid eye movement sleep** and so do not involve frightening dreams.
- sleepwalking** **Parasomnia** that involves leaving the bed during **nonrapid eye movement sleep**. See also **somnambulism**.
- social anxiety disorder (also called social phobia)** Extreme, enduring, irrational **fear** and avoidance of social or performance situations.
- somatic symptom disorder** (previously known as **somatization disorder**) Disorder involving extreme and long-lasting focus on multiple physical symptoms for which no medical cause is evident.
- somnambulism** Repeated **sleepwalking** that occurs during **nonrapid eye movement sleep** and so is not the acting out of a dream. The person is difficult to waken and does not recall the experience.
- specific learning disorder** Neurodevelopmental disorder characterized by academic performance that is substantially below what would be expected given the person's age, intelligence quotient (IQ) score, and education.
- specific phobia** Unreasonable **fear** of a specific object or situation that markedly interferes with daily life functioning.
- standardization** Process of establishing specific norms and requirements for a measurement technique to ensure it is used consistently across measurement occasions. This includes instructions for administering the measure, evaluating its findings, and comparing these to data for large numbers of people.
- statistical significance** Probability that obtaining the observed research findings merely by chance is small.
- stimulants** Psychoactive substances that elevate mood, activity, and alertness, including **amphetamines**, caffeine, **cocaine**, and **nicotine**.
- stress** Body's physiological response to a stressor, which is any event or change that requires adaptation.
- stroke/cerebral vascular accident (CVA)** Temporary blockage of blood vessels supplying the brain, or a rupture of vessels in the brain, resulting in temporary or permanent loss of brain functioning.
- substance abuse** Pattern of psychoactive substance use leading to significant distress or impairment in social and occupational roles and in hazardous situations.
- substance dependence** Maladaptive pattern of substance use characterized by the need for increased amounts to achieve the desired effect, negative physical effects when the substance is withdrawn, unsuccessful efforts to control its use, and substantial effort expended to seek it or recover from its effects. Also known as *addiction*.

substance use The ingestion of psychoactive substances in moderate amounts that does not significantly interfere with social, educational, or occupational functioning.	token economy Social learning behavior modification system in which individuals earn items they can exchange for desired rewards by displaying appropriate behaviors.	unconditional positive regard Acceptance by the counselor of the client's feelings and actions without judgment or condemnation.
substance/medication-induced neurocognitive disorder Brain damage caused by prolonged use of drugs, often in combination with a poor diet.	tolerance Need for increased amounts of a substance to achieve the desired effect, and a diminished effect with continued use of the same amount.	unconscious Part of the psychic makeup that is outside the awareness of the person.
substance-induced psychotic disorder Psychosis caused by the ingestion of medications, psychoactive drugs, or toxins.	Tourette's disorder Developmental disorder featuring multiple dysfunctional motor and vocal tics.	vaginismus Recurring involuntary muscle spasms in the outer third of the vagina that interfere with sexual intercourse.
substance-related and addictive disorders Range of problems associated with the use and abuse of drugs such as alcohol , cocaine , heroin, and other substances people use to alter the way they think, feel, and behave. These are extremely costly in human and financial terms.	transference Psychoanalytic concept suggesting that clients may seek to relate to the therapist as they do to important authority figures, particularly their parents.	validity Degree to which a technique measures what it purports to measure.
suicidal attempts Efforts made to kill oneself.	transinstitutionalization Movement of people with severe mental illness from large psychiatric hospitals to smaller group residences.	variability Degree of change in a phenomenon over time.
suicidal ideation Serious thoughts about committing suicide.	transvestic disorder Paraphilia in which individuals, usually males, are sexually aroused or receive gratification by wearing clothing of the opposite sex.	vascular neurocognitive disorder Progressive brain disorder involving loss of cognitive functioning, caused by blockage of blood flow to the brain, that appears concurrently with other neurological signs and symptoms.
suicidal plans The formulation of a specific method of killing oneself.	traumatic brain injury (TBI) Brain damage caused by a blow to the head or other trauma that injures the brain and results in diminished neurocognitive capacity.	voyeuristic disorder Paraphilic disorder in which sexual arousal is derived from observing unsuspecting individuals undressing or naked.
superego In psychoanalysis , the psychical entity representing the internalized moral principles of parents and society.	trend Direction of change of a behavior or behaviors (for example, increasing or decreasing).	vulnerability Susceptibility or tendency to develop a disorder.
susceptibility In genetics, genes that only slightly increase the risk of developing the disorder, but in contrast to the deterministic genes, these are more common in the general population.	trichotillomania People's urge to pull out their own hair from anywhere on the body, including the scalp, eyebrows, and arm.	Wernicke-Korsakoff syndrome Organic brain syndrome resulting from prolonged heavy alcohol use, involving confusion, unintelligible speech, and loss of motor coordination. It may be caused by a deficiency of thiamine, a vitamin metabolized poorly by heavy drinkers.
synaptic cleft Space between nerve cells where chemical transmitters act to move impulses from one neuron to the next.	twin studies In genetics research, the comparison of twins with unrelated or less closely related individuals. If twins, particularly monozygotic twins who share identical genotypes , share common characteristics such as a disorder, even if they were reared in different environments, this is strong evidence of genetic involvement in those characteristics.	withdrawal Severely negative physiological reaction to removal of a psychoactive substance , which can be alleviated by the same or a similar substance.
systematic desensitization Behavioral therapy technique to diminish excessive fears , involving gradual exposure to the feared stimulus paired with a positive coping experience, usually relaxation.	type A behavior pattern Cluster of behaviors including excessive competitiveness, time-pressed impatience, accelerated speech, and anger, originally thought to promote high risk for heart disease.	withdrawal delirium (delirium tremens/DTs) Frightening hallucinations and body tremors that result when a heavy drinker withdraws from alcohol .
taxonomy System of naming and classification (for example, of specimens) in science.	type B behavior pattern Cluster of behaviors including a relaxed attitude, indifference to time pressure, and less forceful ambition; originally thought to promote low risk for heart disease.	withdrawal design Removing a treatment to note whether it has been effective. In single-case experimental designs , a behavior is measured (baseline), an independent variable is introduced (intervention), and then the intervention is withdrawn. Because the behavior continues to be measured throughout (repeated measurement), any effects of the intervention can be noted. Also called <i>reversal design</i> .
terminal button The end of an axon (of a neuron) where neurotransmitters are stored before release.		
testability Ability of a hypothesis , for example, to be subjected to scientific scrutiny and to be accepted or rejected, a necessary condition for the hypothesis to be useful.		
tobacco-related disorders Cognitive, biological, behavioral, and social problems associated with the use and abuse of nicotine .

DSM-5 DISORDERS FOR FURTHER STUDY

The DSM-5 Task Force judged that these disorders do not currently have sufficient supporting data for inclusion in *DSM-5* and therefore require further study. In fact, only a few of these proposed disorders will ultimately meet criteria, and others will be excluded from further consideration. Many of the more interesting disorders are discussed in one or more appropriate chapters.

Attenuated Psychosis Syndrome

Key features include delusions, hallucinations, or disorganized speech that distresses and disables the individual; the symptoms are like psychosis but not extreme enough to be considered a full psychotic disorder.

Depressive Episodes with Short-Duration Hypomania

Key features of this disorder are depressive episodes and episodes resembling hypomanic episodes but having a shorter duration (at least 2 days but below the 4-day minimum for hypomanic episodes).

Persistent Complex Bereavement Disorder

Key feature is intense grief for a year or more after the death of someone close to the bereaved individual.

Caffeine Use Disorder

Key features of this disorder are constant caffeine use and an inability to control use.

Internet Gaming Disorder

Key features of this disorder are the fixation on Internet games and continually playing them, at the expense of school, work, and/or social interactions.

Neurobehavioral Disorder Associated with Prenatal Alcohol Exposure

The key feature is diminished behavioral, cognitive, or adaptive functioning due to prenatal alcohol exposure.

Suicidal Behavior Disorder

Key feature is a suicide attempt within the past 2 years that is not related to confusion or delirium.

Nonsuicidal Self-Injury

Key feature is repeated, yet nonserious, self-inflicted bodily damage. The individual engages in these acts due to interpersonal problems, negative feelings, or uncontrollable and/or intense thoughts about the act of injuring themselves.
